PREFACE TO THE THIRD EDITION

It has been the dominant object of this Manual to furnish medical students—including interested practitioners—an outline of the current conceptions of the actions of drugs, especially from the point of view of their practical importance in medicine. Even with this restriction, the data of pharmacology comprise so many details, that it appeared advisable to make a definite distinction in the text, presenting in ordinary type a fairly concise and connected story of the facts and explanations that deserve study for their direct bearing on medical practice, or for a sound understanding of the subject; and relegating to smaller type the data of less frequent use, or of less immediate importance, which would only be consulted as special occasions arise. This arrangement is facilitated by the paragraph headings. The authors' references and bibliography are also designed to guide the inquirer to further information, rather than for the assignment of credit; although in matters of importance the discoverer is usually cited. Through these devices, the Manual was designed to serve as a reference-book as well as text. The author believes that the thoughtful student may be benefitted by the feeling that he is in position to confirm and form an independent judgment of the citations; that the practitioner may be helped toward additional information which he may need; and that the investigator may sometimes be saved time and effort.

Since the second edition of the Manual, pharmacologic investigation has continued or rather accelerated its pace. Essentially new drugs have appeared, such as insulin, ethylene, parathyroid hormone, etc. In many subjects, such as the autonomic system, chemotherapy, lead poisoning, etc., new conceptions have come to the front. The changes were so numerous that it appeared advisable to rewrite perhaps the greater part of the important matter. It was practically impossible and appeared scarcely necessary to mention all the newer work along lines that appear at present of minor importance; but the attempt was made to eliminate or revise all parts as were contradicted by more recent data. As it is, some twelve hundred titles have been added to the bibliography.

The appearance of the new (tenth) revision of the United States Pharmacopoeia necessitated a thorough review of the preparations, which have been made to conform with this standard. The nomenclature and spelling have been changed accordingly, including the final "e" for organic bases, halloids, "vitamine," etc.

I am indebted to my assistants, W. F. von Oettingen, O. W. Barlow and R. L. Howard, for their help with the bibliography; to J. L. Stingel for much of the revision of the preparations; and to M. L. Biskind and Dr. von Oettingen for their assistance in reading the proofs.

TORALD SOLLMANN.

A MANUAL OF PHARMACOLOGY

PHARMACOGNOSY

Definitions.—Pharmacognosy deals with the origin and the anatomic and chemic structure of crude drugs.

Materia Medica is an older, obsolescent title, which was used to include also the actions, uses and dosage. *Organic Materia Medica* is limited to the drugs derived directly from the vegetable and animal kingdoms.

Importance of Pharmacognosy.—An accurate knowledge of this branch is necessary to the pharmacist to insure the quality of his wares. It is much less important to the physician. However, it is useful to know the appearance, odor, taste, solubility, and perhaps the origin, at least of the more important drugs.

Vegetable Drugs.—The crude organic drugs are derived mainly from plants, either wild or cultivated; collected at the proper season to insure the maximum activity; and properly dried or otherwise prepared.

Parts Used.—The active principles are often diffused throughout the plant; but they are generally more abundant in one particular part, which is then used. The parts are designated by their usual botanic names. The following are the most important, with some characteristic examples.

Root (*Radix*).—The underground part of the plant, generally devoid of chlorophyl (green coloring matter), and which does not produce leaves (Dandelion, Belladonna, Ipecac, Rhubarb).

Tuberous Roots.—Roots swollen with accumulation of reserve food material (Sweet Potato, Aconite, Jalap). They are often called *tubers*; but true tubers (Potato) are similar formations on rhizomes.

Corm.—A thickened underground stem (Colchicum).

Bulb.—Very fleshy, closely crowded leaves, enfolding the underground base of the stem (Onion, Squill).

Rhizome.—Underground stems which bear leaves (Podophyllum, Hydrastis, Ginger, Aspidium).

Wood (*Lignum*).—The wood of trees, in fragments, chips or coarse powder (Quassia, Hematoxylon, Sandalwood).

Bark (*Cortex*).—The outer layer of the stem (Cinchona, Cascara, Wild Cherry), or of the root (Sassafras, Cotton-root). Sometimes only the inner bark is collected (Ceylon Cinnamon, Elm).

Leaves (*Folia*).—Digitalis, Uva Ursi, Belladonna, Senna.

Herb (*Herba* or *Species*).—The smaller leafy and flowering or fruiting stems (Peppermint, *Cannabis Indica*, Savin).

Flowers (*Flores*).—Chamomile, Arnica. Unexpanded flowers are: Cloves, Santonica.

Fruit (*Fructus*).—The ripened ovary, with any persistent parts of the flower, and containing the seeds (Pepper, Hops, Colocynth, Anise).

Seed (*Semen*).—The essential part of the fruit (*Nux Vomica*, *Strophanthus*, *Physostigma*, Mustard, Linseed).

Microscopic Structure of Plants.—This differs from the animal cells, especially by the thick cell walls, and by the frequent presence of protoplasmic enclosures, starch, fats, calcium oxalate, protein crystals, etc. The cell walls are chiefly responsible for the shape and physical properties of the cell. They consist primarily of cellulose, variously modified by certain allied substances (lignin in wood, suberin in cork). These are all insoluble in ordinary solvents and in the alimentary canal of man. They are therefore so much useless "ballast" in the administration of the drugs. The processes of pharmacy consist largely in isolating the active constituents from this useless material.

Pharmacognostic Importance of Microscopic Structure.—The appearance, size and arrangement of the cells and their inclosures (starch grains, etc.) is often the most important aid in identifying a drug, particularly when in the form of powder. The pharmacopeias therefore include microscopic descriptions, whenever these are important.

IMPORTANT PLANT CONSTITUENTS

Elementary and Proximate Constituents.—The *elementary* or *ultimate*, *constituents* of plants, as of animals, are mainly C, H, O, and N. The chemical compounds formed from these are called the *proximate principles* or *constituents* of the plant. These belong to the chemical groups of proteins, fats, carbohydrates, tannins, resins, alkaloids, glucosides, acids, terpenes, etc. Plants also contain inorganic salts.

Cellulose.—This is found in the cell walls. It exists in almost pure form in cotton. It is chemically an isomer of starch, having the elementary formula $(C_6H_{10}O_5)_n$. It is insoluble in all the ordinary solvents, and is not affected by boiling water. It dissolves without change in Schweitzer's reagent (ammoniated solution of copper sulphate). In older cells it is often modified by the introduction of allied molecules: wood (lignin) or cork (suberin). Cork is very resistant to reagents and impermeable to water, and hence protects the plant against evaporation and chemic injury. The cellulose may also undergo a retrograde metamorphosis into gum or pectin.

Starch $(C_6H_{10}O_5)_n$.—This is produced as one of the first stages in the assimilation of CO_2 . It occurs in the form of granules, usually showing a laminated structure around a center (hilum). The character of this lamination, as well as the average shape and size of the granules, are important in distinguishing between different plants.

Starch can be easily recognized by the blue color which it gives with iodine. It is insoluble in all the ordinary solvents, but with boiling water swells and forms a peculiar colloidal solution (paste).

Gums.—These are colloidal carbohydrates, swelling or dissolving in water to viscous adhesive fluids (mucilages or pastes). They are precipitated by alcohol. They are formed in the plant by the transformation of cellulose and cell contents, especially as the result of pathologic processes. *Pectins* are closely related substances, occurring in fruits, and

causing the boiled fruits to set into jelly. Gums and pectins do not color with iodine; they reduce copper only after inversion.

Sugar.—The various forms of sugars have a wide distribution in the vegetable kingdom. Some reduce copper in alkaline solution; others do so only after inversion. All turn the plane of polarized light. They are soluble in water; much less so in alcohol. The most important types are:

Glucose (*Dextrose and Levulose*), $C_6H_{12}O_6$; *Maltose* and *Saccharose*, $C_{12}H_{22}O_{11}$; *Mannite* $C_6H_{14}O_6$.

Glucosides.—These are ester-like combinations of sugars with various other substances, frequently with phenols. Acids or appropriate ferments hydrolyze them into sugar and the other substance. Many do not contain nitrogen. Most glucosides are neutral or weakly acid; a few are alkaloidal. They are widely distributed in plants, and include active principles such as the digitalis constituents, saponins, tannins, etc.

Saponins.—These are neutral, non-nitrogenous substances distinguished by foaming with water, emulsifying oils, and laking red blood corpuscles. Many have the formula $C_nH_{2n-8}O_{10}$. Some are glucosides. Those which are markedly toxic are sometimes called **sapotoxins**. The saponins are also of wide occurrence.

Tannins.—This term is applied to a group of phenol derivatives, distinguished by giving a bluish or greenish color with ferric salts. The greater number also form insoluble compounds with other metallic salts, with alkaloids, proteins, etc. This precipitation leads to an astringent action.

Tannins occur in many plants, especially in the leaves and bark, and in pathologic formations (nut-galls). They are non-nitrogenous; some are glucosides. They are soluble in water and in alcohol; but since they form insoluble compounds with so many substances, they often occur in plants in granular form.

Phlobaphenes.—Tannins are easily decomposed into resin-like substances called *phlobaphenes*. These exist naturally in plants, but are usually formed as artificial decomposition products in all extracts. They are dark-colored, soluble in alcohol and in alkaline liquids, insoluble in water.

Tannins and phlobaphenes, as well as most other plant constituents, are easily converted into a group of substances called *humins*. These do not exist in living tissues, and arise on the death of the cells, by the action of air and moisture. They cause the brown color which plants assume on drying; they are also present in the brown bark.

Tannins, phlobaphenes, and humins form a series, without sharp demarcation. They are rather resistant to the action of bacteria, and in this way protect plants against putrefaction.

Alkaloids.—These comprise many of the most active and important plant constituents. They may be defined as natural nitrogenous organic bases (generally tertiary amines); *i.e.*, they are organic substances, containing nitrogen, of basic character, combining with acids without the elimination of hydrogen, forming well-defined and usually crystalline salts. The salts with halogens are called hydrochlorides, hydrobromides, etc. (not chlorides, etc.).

The names of alkaloids are generally spelled with a final *e*, to distinguish them from neutral principles (thus *morphine*, an alkaloid; *salicin*, a glucoside).

Discovery of the Alkaloids.—This is an achievement of the 19th century (morphine, by Sertuerner, 1805 to 1817; strychnine, 1818; quinine and caffeine, 1820; nicotine, 1829; atropine, 1833).

Occurrence.—Only a few alkaloids occur in the animal kingdom, the most important example being epinephrine, the active principle of the suprarenal gland. Alkaloidal principles are also formed by the action of bacteria, and are called *ptomaines*. Amongst the higher plants the occurrence of alkaloids is common, the same plant containing usually several alkaloids, which are often formed from one another. They are often found in all parts of the plants, but sometimes they are strictly localized in certain portions.

The alkaloidal content of plants varies considerably according to the climate, culture and other conditions. Individual plants also show considerable variations (Sievers, 1913). They can be improved by selective breeding, although this is technically rather difficult (Sievers, 1916).

Some alkaloids contain oxygen; others do not. Those containing oxygen are solid and comparatively non-volatile, whereas those free from oxygen (nicotine and coniine) are liquid and volatile.

Properties of Alkaloids.—All alkaloids have certain properties in common: bitter taste, alkalinity to litmus, nitrogen reaction; generally profound physiologic action, without postmortem lesions.

Solubility Characters.—Free alkaloids are soluble in ether, chloroform, and oils, much less soluble in alcohol, and comparatively insoluble in water. Alkaloidal salts, on the other hand, have just the opposite solubility: They are soluble in water and alcohol, insoluble in chloroform and ether. With the alkaloidal salts, the combined acid plays a prominent rôle in the solubility.

Precipitation Reactions.—Alkaloidal salts are precipitated by iodine, mercuric-potassic iodide (Mayer's reagent); phospho-molybdic acid; picric acid; gold chloride, platinic chloride, etc. Many also precipitate mercuric chloride, potassium bichromate, tannin, etc.

Color Reactions.—Many alkaloids give characteristic colors with concentrated acids, with or without the addition of oxidizing or reducing agents.

Chemical Constitution.—The structure of many alkaloids is well understood; others are still obscure. The greater number are fairly complex derivatives of *pyridine* (coniine, nicotine); *pyrrolidine* (cocaine, atropine); *quinoline* (quinine, cinchonine); *iso-quinoline* (hydrastine, narcotine, cotarnine, berberine); *morpholine* or *phenanthrene* (morphine, codeine, thebaine).

Neutral or Bitter Principles.—This class comprises a heterogeneous collection of substances, which have not been assigned to other classes. The principles usually have a bitter or sharp taste, and are usually crystalline and non-nitrogenous. A number are *lactones*, *i.e.*, derived from alcohol-acids, by the elimination of H_2O .

Resins.—These are also a heterogeneous collection; including solid, non-volatile, amorphous substances of obscure composition, generally non-nitrogenous. The distinguishing character is their insolubility in water, and solubility in alcohol, most fat solvents (except petroleum ether) and strong alkalies. The resins are often contained in special vessels, from which they are usually obtained as exudations after incising the plant.

Mixed Resins.—When the resins occur mixed with essential oils, they are *natural oleoresins*; when mixed with gums, *gum-resins*. If they contain aromatic acids (cinnamomic, benzoic, etc.), or essential oils, they are called *balsams*.

Resinoids.—These are artificially isolated principles soluble in alcohol and insoluble in water. They are generally mixtures, often containing true resins.

Volatile Oils (Essential Oils).—These are odorous principles, of the physical characters of fatty oils, from which they differ by being volatile and soluble in alcohol. They are responsible for the odor of plants. Chemically, they are mixtures of esters, aldehydes, alcohols, ketones, and especially the terpenes (Kremers, 1898).

The constituents may separate on cooling, the liquid part being called *eleoptene*, the solid *stearoptene*. *Camphors* are analogous substances, but solid at ordinary temperature. *Rubber* (caoutchouc and gutta-percha) is related to the terpenes.

Plants also contain many other alcohols, aldehydes, organic acids, aromatic derivatives, etc.

Fats and Fixed Oils.—Typical fats (esters of fatty acids and glycerin) are abundant especially in seeds, occurring within the cells as drops or crystals. The fats are greasy liquids or soft solids; when heated, they undergo decomposition, denoted by acrid acroleine vapors. They are insoluble in water or glycerin, sparingly soluble in alcohol, and freely soluble in ether, chloroform, benzine (petroleum ether), carbon disulphide, turpentine, etc. (*fat solvents*).

Waxes.—These are more solid substances with the solubility characters of fats. Chemically, they are esters of fatty acids with alcohols other than glycerin.

Proteins.—These are, of course, represented in all vegetable cells, but are especially abundant in seeds, sometimes as crystals (aleurion). Several classes of the proteins are peculiar to plants.

Chlorophyl.—This, the green pigment of plants, is insoluble in water, soluble in alcohol and fat solvents. It is allied to blood pigment, but contains no iron. It is readily changed and discolored by reagents.

The chlorophyl occurs in the cells as granules (chloroplasts), made up of a colorless, spongy, protein groundwork, containing in its meshes the chlorophyl pigment. The latter consists really of a mixture of green and yellow colors (chlorophyl and xanthophyl). These chlorophyl granules are found mainly in the higher plants, and serve in the presence of light to assimilate CO₂, and consequently to form starch, etc. During the process of drying, especially if this occurs slowly, the pigment is acted on by acids, etc., developed under these conditions, and undergoes various changes, usually becoming brown.

Other Pigments.—Plants are rich in colors, belonging to various chemic groups, often unidentified. Many alter with changes of reaction. The brown coloring matter of barks, etc., is allied to the tannins and phlobaphenes.

Carotin.—This is the principal yellow pigment of plants. It is practically non-toxic on peritoneal injection, and also with intradermic tests (Wells, H. G. and Hedenburg, 1916).

Enzymes.—Different plants contain almost every imaginable kind of ferments, a few being used in medicine.

Extractive Matter.—This term is applied to the mixture of unidentified organic constituents; especially to the colloidal smeary mass which remains after evaporating any extract from which the important constituents have been removed.

Mineral Salts.—These are fairly abundant in plants, constituting the ash which remains on incineration. Ca and K are especially important.

These salts seem to be combined largely with the protoplasm, and exist partly dissolved, partly as crystals. Growing tissues are always richer in salts than those fully developed.

PHARMACEUTIC STANDARDS

Objects.—Pharmacy deals with the preparation and compounding of drugs for the purpose of administration. It has for its objects the separation of the active principles of drugs, their combination, and their presentation in a pleasant form.

The Need of Pharmacy.—The necessity for such an art will be readily understood. Drugs may be divided according to their origin into mineral, vegetable, and animal drugs. The last two are often too bulky to be conveniently used, and the substances which determine their action are often in such a condition that they can not readily be separated in the body, and so can not fully develop their action. One drug alone may not meet all the indications in a disease, and when several are given it is necessary to combine them in such a way that they may not interfere with one another, either chemically or mechanically. Lastly, having chosen and prepared the drugs in a proper manner, and having decided how to combine them, it is highly desirable to give them in such a form as will be least objectionable to the taste, smell, or sight of the patient.

Official Drugs.—A certain degree of uniformity in the strength and preparation of pharmaceutical products is absolutely indispensable. Accordingly, practically all civilized countries have standards established by law, to which drugs and preparations in the shops must conform. The book in which these standards are published is usually called the *Pharmacopeia*. Preparations listed in these official books are termed “official.” A pharmacopeia, therefore, is an official book of standards for official drugs.

International Uniformity.—The first effective step in this direction was taken by the Brussels Conference of 1906, the “International Conference for the Unification of the Formulas for Potent Medicines.” This conference drew up a list of the potent drugs for which uniformity was most important, and established standards of strength for them and their preparations. These have been adopted essentially by most of the civilized nations. These formulas of the Conference are designated as “I.A.” (International Agreement) by the B.P.; as “P.I.” (Protocol International) by the U.S.P.

Scope of the Pharmacopeias.—These usually aim to include only “standard drugs,” *i.e.*, those of established value. There is a healthy tendency to restrict the admission of complex mixtures.

Galenic Preparations.—“Galenicals” are, strictly speaking, medicines prepared after the formulas of Galen. The term is now used to designate standard preparations containing one or several organic ingredients, as contrasted with pure chemic substances.

Proprietary Drugs.—Drugs which are protected by a monopoly—by patents, trade marks, secrecy, etc.—are generally not admitted into the pharmacopeias, and are therefore non-official. They are thus not subject to legal control, and are often advertised under extravagant, misleading and false claims. However, some of the most valuable drugs are proprietary, and many are marketed in a strictly legitimate manner. These are described in the “N.N.R.” (see below). The pharmacopeias will doubtless give increasing recognition to patented drugs that are really valuable, non-secret, and otherwise unobjectionable.

Patent Medicines.—This term is applied to proprietary drugs that are advertised, directly or indirectly, to the laity. They are not usually patented, as the name would imply; most manufacturers preferring to rely upon secrecy to impose on the public. The medical profession is generally opposed to patent medicines as a class, and to lay advertising in particular. “The impossibility of controlling the irresponsible claims which are usually made in advertisements to the public, the well-known

dangers of suggesting by descriptions of symptoms to the minds of the people that they are suffering from the many diseases described, the dangers of the unconscious and innocent formation of a drug habit, and the evils of harmful self-medication, including the dangers of the spread of many infectious and contagious diseases when hidden from the physician, and similar well-known considerations, are the reasons for discouraging, in the interest, and for the safety, of the public, this reprehensible form of exploitation" (N.N.R.).

The United States Pharmacopeia.—This is issued decennially; the revision started in 1920 being the "U.S.P.X." It furnishes mainly the standard definitions, tests and formulas. It is a legal standard.

The U.S.P. was first published in 1820. It is revised by a Pharmacopeial Revision Committee, appointed by the United States Pharmacopeial Convention, which consists of delegates from pharmaceutical and medical organizations. The current committee of revision consists of 50 members, headed by an executive committee.

The British Pharmacopeia.—The B.P., fifth edition, was issued in 1914. It resembles the U.S.P. in scope and arrangement.

The B.P. is published by the General Medical Council, and revised at irregular intervals.

New and Non-official Remedies (N.N.R.).—This contains descriptions of the characters, actions and uses of those proprietary drugs that are marketed in a proper manner. It is issued by the American Medical Association and revised annually by its Council on Pharmacy and Chemistry.

National Formulary (N.F.).—This is a collection of formulas for less important preparations, issued by the American Pharmaceutical Association. It is also a legal standard.

Dispensatories.—These are commentaries which enlarge and explain the official texts, and generally also describe unofficial preparations. The National Dispensatory and the U.S. Dispensatory are principally used in the U.S. The British Pharmaceutical Codex (B.P.C.), and Hager's Praxis are similar works.

Useful Drugs.—This is a small manual issued by the American Medical Association, which contains only the most useful drugs with such information as is of especial interest to physicians.

Physicians' Epitome of U.S.P. and N.F.—This is another A.M.A. publication, giving a brief but critical abstract of all U.S.P. and N.F. preparations.

PHARMACEUTIC METHODS

In the making of pharmaceutical products different methods must be used, depending upon the physical and chemical nature of the crude drug, and upon the character of the desired product.

These may be roughly classified into those used in the making of many different preparations—*general methods*—and those used in only a limited number of cases—*special methods*.

The methods may be studied in the order in which they are usually applied to the drug.

PREPARATORY PROCESSES

Desiccation or Drying.—This is usually the first operation to which the crude drugs are subjected after their collection. It serves a three-

fold purpose: It reduces the bulk, assists preservation, and facilitates comminution.

Formerly the drying was done by spreading or hanging the drugs in airy lofts. At present they are usually placed on perforated trays in special drying closets and heated artificially (steam, etc.). They are often cut into smaller pieces before this drying. The degree of heat must not be so high as to injure the sometimes very unstable ingredients. The U.S.P. designates 32 to 39°C. as "gentle heat."

Comminution.—The next step is comminution, or reducing of the substance to smaller pieces.

This is usually done by machinery. Crude vegetable drugs are first sliced or chopped, often before drying. They are then bruised by pounding in a mortar and finally ground, the finer grades of powders often several times, the grinding surfaces being brought closer together each time. The mills for this purpose are constructed on the same general principles as flouring mills, employing stones, rollers, etc. The details of the process used depend upon the physical character of the drug.

On the small scale, drug mills, constructed more or less on the principle of the coffee-mill, are used for fibrous, and mortar and pestle for friable drugs. Mortars are made of iron, wedgewood, porcelain, and glass.

Pulverization is comminution to a powder.

Trituration is the process of rubbing (not pounding) a substance to a powder in a mortar.

Some points deserve special mention. Often a substance will not powder by itself, but will do so when mixed with another substance—e.g., sugar of milk. This is called "pulverization by intervention." Sometimes it is well to moisten the drug—e.g., camphor with alcohol, nux vomica with steam, etc.

Fineness of Powder.—In the process of percolation, presently to be described, it is often essential to use a powder of a certain degree of fineness. The powders are therefore sifted, and are classified according to the size of the meshes of the sieve through which they pass, thus:

No. 80 = 80 meshes to linear inch, very fine.

No. 60 = 60 meshes to linear inch, fine.

No. 40 = moderately coarse.

No. 20 = coarse.

Since the different structures in a crude drug do not powder with equal readiness, it is essential that the whole of the drug to be powdered should be passed through the sieve, else the different portions will not have the same composition.

Levigation.—This is employed to obtain very fine powders of insoluble substances, by making them into a thick paste with water, and rubbing this between polished slabs.

Elutriation is used to separate fine insoluble powders by suspending them in water and decanting.

PROCESSES OF SEPARATION

For the separation of the desired ingredients from the inert material three methods are in vogue, depending upon the nature of the active constituents. If volatile constituents are to be separated, this may be readily done by the *application of heat*—distillation and sublimation. If they are not volatile, the separation is usually effected by exposing the drug to the *action of some solvent* in which the desired principles are soluble, and the undesired constituents are insoluble. In certain cases some mechanical means are sufficient, as in the separation of fixed oils from seeds, etc., by *pressure*.

Separation by Means of Heat.—This may be used whenever the substances to be separated have different boiling-points, and are not themselves destroyed by the necessary degree of heat. The methods vary

according to whether the fixed or the volatile portion is desired, and, if the latter, according to whether it is liquid or solid.

Desiccation, Torrefaction, Carbonization, Ignition.—With all these, the object is to drive off some volatile constituent from a solid, the fixed residue being the portion desired.

When the heat employed is of such degree as not to change the chemico composition, the process is spoken of as *desiccation*.

Torrefaction.—The process of roasting; the object being to employ such a degree of heat as will alter some of the constituents without affecting others. The roasting of coffee is a familiar example.

Carbonization.—The heating of organic substances under exclusion of air. The object is to destroy the chemico composition without oxidation; carbon results in the process (vegetable or animal charcoal).

Ignition.—This is the process of heating a substance strongly, usually in a crucible, with full access of air, so as to effect complete oxidation; nothing but the ashes remain.

Evaporation consists in vaporizing the solvent from a solution, the object being the concentration of the dissolved substance.

Since the rapidity of the evaporation, aside from the quantity of heat applied, depends upon the extent of the liquid exposed to the air and to the heat, dishes as flat as possible are chosen. For ordinary pharmaceutical and chemico purposes, those made of porcelain are of most frequent service. Vessels made of glass, iron, platinum, etc., find application in special cases. The heat may be applied directly, say by means of a Bunsen flame, only a piece of wire gauze or a plate of asbestos or iron being interposed. This method can be used only when there is no danger of injuring the solution by excessive heat, either the substance being incapable of change, or the solvent sufficient in amount so that the temperature can not rise much beyond its boiling-point. If this is not the case, some method must be used of regulating the amount of heat applied, and this is done by applying the heat indirectly through a bath. This consists of an outer vessel filled with water (steam), oil, sand, or air.

The rapidity of evaporation may be considerably increased by *stirring*, thus exposing a constantly renewed surface to the air.

In cases where the evaporation must be carried on at a temperature below the boiling-point of the solvent, this may be done either by evaporation over H_2SO_4 , or in a vacuum, or by passing a current of dried air through the liquid.

Sublimation.—The process of separating a volatile from a non-volatile solid by heat.

This may be done in a distilling apparatus, provided that the cooling tube has sufficient lumen to prevent its clogging by the condensation of the sublimate. The apparatus is, however, usually modified. A simple illustration of this process is the old method of manufacturing benzoic acid from gum benzoine, a paper hood being used as condenser.

Distillation.—The process of separating a volatile liquid from a less volatile liquid or solid. (The difference between sublimation and distillation consists in this, that the product is solid in the former, liquid in the latter.)

Although distillation is such a ready and simple means of separation that one would think it must have been discovered at a very early time, such does not appear to have been the case. We find the first record of it in the writings of the fourth century alchemists.

Fractional distillation is the process of separating a mixture of liquids of different boiling-points by distillation.

Destructive distillation is the name applied to the process of heating a substance so strongly as to decompose it, and collecting the volatile products arising from this decomposition: *i.e.*, in the case of organic bodies, tar.

Solution.—This consists of incorporating a solid into a liquid in a state of "molecular subdivision."

That is, the molecules of the solid disperse themselves in the liquid and become so widely separated that no solid particles are by any means discernible. In other words, the solid is liquefied and its molecules intermingle with those of the solvent.

A *simple solution* is one occurring in the manner described, the change in the solid being physical. When a chemic change takes place, the process is called *chemic solution* (such as the solution of a metal in an acid).

A solvent is capable, under given conditions, of dissolving but a limited amount of a given solid. A solution which contains as much of the solid as the liquid can dissolve under these conditions is called a *saturated solution*. The condition which has the greatest influence upon solubility is the temperature. A liquid can usually dissolve the more of the solid, the higher the temperature. There are, however, a few exceptions to this rule.

If a solution saturated at a high temperature is allowed to cool, the originally dissolved substance will be in excess of saturation. Under certain conditions it may still remain in solution at the lower temperature, this being a *supersaturated solution*. Ordinarily, however, the excess will separate, usually in crystalline form. This process is called *crystallization*. It is frequently used as a means of purification.

A solution which contains less of the solid than it is capable of dissolving is an *unsaturated solution*. A solution which is saturated with one substance is still capable of dissolving others.

Solution is effected by placing the solvent in contact with the substance to be dissolved. The process may be hastened by applying heat, or by exposing the largest possible surface to the action of the solvent. The latter may be done by using the substance in a pulverized condition, and by constant stirring. With *circulatory solution* the substance is suspended near the surface of the solvent. As this takes up the substance, it gains in specific gravity, and hence sinks to the bottom, a new portion of liquid taking its place. The same object may be secured by a process analogous to percolation, the powder being placed in a funnel partly occluded by a pledget of cotton, etc., and the solvent allowed to percolate through it.

The process of solution applied to crude drugs has for its purpose the separation of the active ingredients from the insoluble inert material. The object is to dissolve out the greatest possible amount with the least possible menstruum. This accomplishes two results: We obtain a strong extract, and we waste neither drug nor menstruum. There are a number of methods of accomplishing this, each with its advocates. They are combinations of two extremes: maceration and percolation. Neither of these is commonly used alone in this country, the practice being to combine the two.

Maceration is by far the simpler process. It consists in simply leaving the solvent in contact with the drug under suitable conditions for a sufficient length of time.

When maceration alone is employed, a given quantity of the drug is put in a bottle or other suitable vessel with a definite proportion of the solvent (called menstruum) and left a certain time, usually a week or two. The liquid is then strained off, the residue (marc) is expressed and the mixed extract filtered. The details of the process are influenced by the fineness of the powder, the time of maceration, and the temperature.

Different names are given to the process according to the temperature at which it is carried out. Maceration proper = room temperature; 30° to 40°C. = digestion; boiling = decoction. Possible injury to some constituents by heat, or evaporation of a constituent or of the solvent, are objections to the application of heat in certain cases.

This process of maceration is the one almost exclusively employed in Europe; and it offers certain advantages, not the least being its simplicity and the constant results which it gives. Its main disadvantages are the required time and the loss of the extract retained in the insoluble residue or "*marc*." Certain drugs are physically unfit for percolation, since the moistening causes them to form into a tough mass, as good as impenetrable to the solvent.

The loss of menstruum does not, of course, weigh when an aqueous solvent is used and only small quantities are prepared. Hence maceration is used in making infusions and decoctions.

Percolation consists in passing a solvent through a thick layer of the powder to be exhausted. This exposes a large surface of the latter; the

nearly saturated solvent flows off and fresh unsaturated portions continuously replace it, insuring very rapid solution.

The principle of the method is to pack the powder into a tall vessel, with an opening at the bottom, and to let the solvent trickle through it. Usually the process is preceded by a short maceration.

The U.S. Pharmacopeia defines percolation as consisting in "subjecting a substance or a mixture of substances, in powder, contained in a vessel called a percolator, to the solvent action of successive portions of a certain menstruum, in such a manner that the liquid, as it traverses the powder in its descent to the receiver, shall be charged with the soluble portion of it, and pass from the percolator free from insoluble matter."

The details are as follows:

The powder (the fineness of which depends upon the nature of the drug and is directed for each case by the Pharmacopeia) is moistened in a jar with some of the menstruum. This moistening is for the purpose of swelling the drug, for if this took place in the percolator, the drug would become so firmly impacted that the menstruum could not penetrate through it; or it could even burst the percolator. The moistened powder is then passed through a coarse sieve and transferred to the prepared percolator, which it should fill about two-thirds.

The choice of the shape of the percolator depends upon the nature of the drug. Should the drugs have a tendency to swell, particularly if they are in fine powder or if a weakly alcoholic menstruum is used, a conical percolator is employed; otherwise, the cylindrical.

FIG. 1.—Method of percolation (Thornton).

Arrangement of Percolator.—The percolator is prepared in the following manner (Fig. 1): Into the small end there is inserted a cork perforated by a short glass tube which projects about 1 cm. inside the percolator. The outer end of this tube is attached to a piece of rubber tubing, about one-fourth longer than the percolator, and this to a U-shaped glass tube. This is held to the percolator by a rubber band in such a way that it can be raised and lowered. The percolator is then set in the stand. A pledget of absorbent cotton is loosely packed in the neck of the percolator and this is covered by a layer of clean sand, and over this goes a well-fitting disk of filter-paper. Then the moistened drug is pressed in—and this is the part of the process which requires the greatest skill and judgment, and on it depends the success of the product. It should be done very evenly, else the menstruum will choose the path of least resistance and some portions of the powder will be entirely exhausted whilst others are still scarcely affected. The firmness of the packing is also of great importance; if not firm enough, the menstruum will run through too rapidly and the percolate will consequently be weak. If too firm it can not run at all; and if any swelling occurs the percolator will be broken. Drugs in coarse powder should be packed more firmly than fine powders. An alcoholic menstruum requires firmer packing than a watery one.

The packing being completed, the menstruum is poured on until it stands an inch or two above the drug; the percolator is then covered and set aside for maceration for a specified time, the tube being raised so that no liquid flows out. When the time of maceration is completed, the tube is lowered and fixed at such a level that the outflow occurs at the rate of 2 to 15 drops per minute. New menstruum is poured on in the measure that the old flows out. Care should be taken always to maintain the layer of liquid above the powder; else cracks may appear in the latter, necessitating repacking.

The process is continued, in the case of tinctures, until a certain volume of percolate is obtained. The quality of the percolate will, of course, depend upon the care and skill of the operator, and the product is apt to vary. Maceration would, therefore, be a better process for tinctures.

This difficulty is avoided in the case of extracts, for here the percolation is continued "until the drug is exhausted," *i.e.*, until the active ingredients have become completely dissolved out. This is recognized by testing the last portions of the percolate in the appropriate manner, such as Mayer's reagent for alkaloids, water for resins, etc. A drug is usually more rapidly exhausted of its active ingredients than of its coloring-matter, so that the last portions of percolate may be colored and yet devoid of activity.

The choice of a menstruum must be determined by the nature of the constituents, so as to extract all the active ingredients and the minimum of inactive. Alkaloids and

resins require strong alcohol; gums, weak alcohol; licorice, alkaline alcohol; sanguinaria and ergot, acidified alcohol; gentian and quassia, water plus alcohol enough to keep.

Pharmaceutic Solvents.—The most useful are the following:

Water or Glycerin.—Dissolve salts (including those of alkaloids), sugar, gums, tannin, acids, alkalies, etc.

Dilute Acetic Acid.—Especially for alkaloids.

Alcohol.—Dissolves alkaloidal salts, neutral principles, resins, volatile oils. Precipitates gums and most inorganic salts.

Ether, Chloroform, Acetone.—Dissolve free alkaloids, neutral principles, resins, volatile and fixed oils, and fats.

Petroleum Benzine.—Solvent properties as the preceding, except resins.

Aromatic Spirits of Ammonia.—Dissolves resins and organic acids.

Expression.—The process of separating a liquid from a solid by pressure.

Its principal employment in pharmacy is for the recovery of tinctures from the "marc," *i.e.*, the liquid retained by the drug residue after maceration and percolation. It is also a process of separating fixed oils.

The drug is put in a coarse strong cloth and subjected to pressure in a press. These are of various patterns; screw, lever, hydraulic, or centrifugal. The pressure must be applied gradually to prevent the bursting of the cloth. Small quantities can often be pressed sufficiently by putting them into a cloth and tightly twisting the end.

Straining or Colation.—The process of separating coarse solid particles from a liquid by pouring it through a cloth or strainer.

Filtration.—The process of separating solid particles (fine or coarse) from a liquid by pouring it through a finely porous material, such as filter-paper.

There are two principal methods of folding a filter—plain and plaited. These two filters have different uses. The plaited filter offers a much larger surface for filtration and is therefore more rapid; it is the form usually employed in pharmacy. The plain filter, on the other hand, facilitates washing and removal of the precipitate, and is of more frequent use in chemistry.

Other materials are sometimes employed instead of paper. A very useful filter for large quantities of liquid is made from felt. A plug of glass-wool or asbestos placed in the tube of the funnel is especially useful for strong acids or alkalies. A cell of porous clay is also employed, as in the various forms of the Chamberland filter. With this a vacuum is indispensable.

Dialysis.—This is sometimes used to separate crystalloids (alkaloids, salts, etc.) from colloids (extractives).

Decolorization.—It is often desirable to remove the coloring-matter from a solution. This may sometimes be accomplished by choosing appropriate solvents. More often, however, the solution is filtered through recently calcined animal charcoal. This very often retains some of the active constituents as well as the coloring-matter.

Clarification.—The process of rendering turbid mixtures clear and transparent, by removing the suspended solid. When filtration does not suffice, the object is accomplished by agitating the mixture with insoluble powders (talcum, phosphate of lime, aluminum hydrate) or by adding egg-albumen and boiling; or by the centrifugal machine.

Sterilization.—The destruction of bacteria and their spores is accomplished by the various customary methods.

Glass and metal utensils may be sterilized by dry heat of 160 to 170°C. for two hours; by superheated steam of 115 to 120°C. for fifteen minutes; heating in a current of steam

for thirty minutes or boiling for fifteen minutes, especially in 0.1 per cent. sodium bicarbonate. This kills all non-spore-bearing organisms.

Solutions that are not readily decomposed by heat may be boiled in a current of steam for one-half or better one hour.

Solutions that are readily decomposed by heat are either prepared aseptically or filtered through porcelain.

Emulsions in glycerin or oil are prepared aseptically, the solvent being first sterilized by heat.

PHARMACEUTIC ASSAYING

Different samples of vegetable drugs may vary widely in the quantity of active constituents which they contain. These variations are very undesirable from a therapeutic standpoint, especially when they occur in potent, so-called "*heroic*" drugs. Inorganic drugs or other definite chemic compounds are not subject to this variation; but in many cases the removal of the last traces of innocuous impurities would greatly increase their cost without adding to their therapeutic usefulness. The pharmacopeia has therefore aimed to furnish quantitative methods of estimation, assays, wherever possible, and to establish practical standards to which medicinal substances must conform. With inorganic drugs, it states the largest permissible quantity of innocuous impurities (usually less than 2 per cent.). With crude vegetable drugs, it states the permissible limit of foreign matter, and insoluble ash, etc.; and the lowest permissible percentage of active ingredient, wherever practical methods for their determination are available. Assayed galenic preparations are directed to be diluted so as to contain a definite proportion of active constituents, corresponding to the minimum permitted in the crude drug. These preparations should therefore be preferred to the crude drug whenever accurate dosage is desired.

The assay of *inorganic drugs* involves the well-known methods of ordinary quantitative analysis, volumetric processes being preferred. Special tests are furnished for determining the permissible limits of accidental *impurities*, and the presence of harmful substances, such as metals.

A series of volatile oils are assayed for their most important ingredient. Fats and fixed oils are tested for their "iodine absorption" and "saponification values;" resins for the "acid number;" some vegetable products for their ash. These tests serve mainly for identification and the exclusion of willful adulterations.

Pepsin is assayed for its digestive power for proteins, pancreatin for starch and casein. In resinous drugs, such as Jalap, or Ipomoea, the proportion of ether- or alcohol-soluble matter is determined.

The most important class of assays refers to **drugs containing alkaloidal principles**, utilizing the method of immiscible solvents, as in toxicologic analysis. This rests on the fact that free alkaloids are generally soluble in chloroform or ether, whilst their salts are insoluble in these, but soluble in water. In principle, alkaloids are extracted by chloroform or ether, or a mixture of both, in alkaline reaction. This solution is then shaken in a separator with acidulated water, which converts the alkaloids into salts and dissolves them, leaving the impurities behind. For further purification, the watery solution is again rendered alkaline and extracted with chloroform or ether. This, on evaporation, leaves the fairly pure alkaloid which may be weighed; or titrated, by dissolving it in a known amount of acid, and titrating back with alkali. Each cubic centimeter of acid corresponds to a definite quantity of each alkaloid. It is important to observe the directions minutely to obtain reliable results. The process for extracts and fluidextracts differs merely in details (the percolation being omitted, etc.). Tinctures are first concentrated by evaporation.

This method estimates the sums of all the alkaloids present in the drug, and suffices when the important one predominates very largely over the others. When this is not the case, it is necessary to confine the assay to the particular alkaloid desired, generally a very difficult matter. In Hydrastis, advantage is taken of the comparatively greater solubility of hydrastine in ether; in Opium, of the comparative insolubility of the morphine in this solvent. In Nux Vomica, the brucine is removed by oxidizing it with nitric acid.

Bio-assay.—Drugs which depend for their activity on neutral principles are often unsuited to chemic assay; there being no reliable chemic method for estimating the constituents of such important drugs as digitalis, ergot, pituitary extract, etc. Attempts have been made to supply this deficiency by **physiologic standardization** estimating the strength of a preparation by comparing its effects on animals with those of a standard product. The more important methods are described in the U.S.P.

CLASSES OF PHARMACEUTIC PREPARATIONS

The pharmaceuticals are grouped into certain definite classes, established by long usage, such as Waters, Spirits, Tinctures, Extracts, Pills, Plasters, Ointments, etc. The student should learn to distinguish clearly between these preparations, according to the definitions given below.

WATERY SOLUTIONS

These include the Waters, Liquors, Mucilages and Syrups. Their advantage lies in the fact that water is a cheap solvent of very wide applicability, itself devoid of any therapeutic property. In the case of substances which are insoluble in it, it can not of course be employed. The greatest drawback lies in the fact that watery solutions of organic substances tend to spoil rapidly by the development of bacteria and infusoria. Solutions of chemic substances are less subject to this change, as they do not furnish a pabulum, and are often themselves antiseptic.

Aquæ, Waters (singular, Aqua; abbreviated, Aq.).—Clear aqueous solutions of volatile substances. Two very dissimilar classes of preparations come under this heading:

Aquæ Aromaticæ, Aromatic Waters, U.S.P. (Flavored Waters).—Saturated solutions of volatile oils (Aquæ Cinnamomi, etc.). These are alone included under Aquæ in the B.P. They are prepared either by distilling the plant or oil with water (B.P.); or by triturating the oil with an absorbent substance (talc, etc.) until it is finely subdivided, and then extracting this with water.

The quantity of active substance in them is just large enough to give them a pleasant flavor without imparting to them any noticeable therapeutic properties. The absence of alcohol makes them good solvents for salts, which are generally insoluble in this liquid. Hence their main use is as a pleasant vehicle (a vehicle being the substance which serves for the conveyance of another substance).

The *dose* of flavoring waters is practically unlimited (15 c.c., 4 drams, U.S.P.).

Waters, as a rule, do not keep well. Their keeping qualities may be improved by adding to them some of the oil of which they are solutions. This floats on the surface, and in this way excludes air and bacteria, and at the same time insures permanent saturation.

The second class of Waters (included under Liqueores by the B.P.) are fairly strong *solutions of gases* (ammonia, etc.) prepared by passing the gas into water. Their doses are relatively small.

In the following, the Latin names are given in the singular, as they would usually be employed in prescribing.

Liqueores (Liquor, Liq.); Solutions.—Aqueous solutions of solid chemic salts or hydrates, made either by dissolving the pure salt directly in water by trituration or heat; or, more often, by chemic decomposition (simple and chemic solution). (The British Pharmacopeia includes solutions of gases under this heading.)

The advantage of the solutions consists mainly in the convenience of measuring the relatively large volumes of the solution against weighing the small quantity of salt. Water is chosen as the solvent because salts are but little soluble in alcohol, and because the therapeutic qualities of the latter are not desired.

Solutions, when used for special purposes, receive special names, thus: *Injectiones* (*Hypodermicæ*; *Urethrales*), *Collyria* (*Eyewaters*), *Lotions* (*Washes*), *Gargarismæ* (*Gargles*), etc.

Manufacturers market a variety of unofficial solutions for hypodermic and especially for intravenous use in aseptic *ampullæ*, i.e., small sealed glass vials containing a single dose of the sterilized solutions.

Injectiones Hypodermicæ (B.P.) (*Inject. Hyp.*).—These are watery solutions of active drugs, intended for subcutaneous administration, and of such strength as to be used in the dosage of 0.3 to 0.6 c.c., 5 to 10 minims. They are sometimes preserved sterile by the addition of phenol or salicylic acid.

Mucilagines (*Mucilago*; *Mucil.*); **Mucilages**.—Aqueous solutions of gummy substances. They are used as vehicles and demulcents. Since gums are insoluble in alcohol, mucilages are incompatible with this substance. They should be recently prepared because they are very apt to mold.

Mucilages are made by either hot or cold process: the former being solution by heat, the latter by percolation. Heat should be used only when necessary (*tragacanth*), as it usually causes discoloration of the product.

Syrupi (*Syrupus*; *Syr.*); **Syrups**.—Dense saccharine solutions of medicinal substances. The syrup serves mainly as a vehicle and preservative. The dose of flavoring syrups is practically unlimited.

Simple syrup is a practically saturated solution of cane-sugar, containing 85 Gm. in 100 c.c., U.S.P. (66.7 Gm. of sugar in 100 Gm. of syrup, B.P.). Syrups are usually prepared by first making an infusion, and dissolving in this the sugar, either by heat or by percolation, according to whether or not the drug is injured by a high temperature. In special cases modifications may be introduced. Some syrups are prepared by mixing the fluidextract and syrup. *Honey* is sometimes used instead of cane-sugar, making a class of preparations called *mellita*. If acetic acid is added to this, we have *oxymellita*.

Confections (*Confectio*; *Conf.*) are thick medicated jams.

They were formerly very popular, but have now been almost abandoned. *Electuaries* were similar but somewhat thinner preparations.

Elixiria (*Elixir*; *Flix.*); **Elixirs**.—Sweetened aromatic alcoholic liqueurs, used as flavoring vehicles, similarly to the syrups. Their content in alcohol (about 25 per cent.) is apt to lead to abuses, which must be kept in mind.

The official Aromatic Elixir is flavored with orange peel, lemon, coriander and anise.

Glycerites (*Glyceritum*, U.S.P.; *Glycerinum*, B.P.; *Glyc.*).—Solutions in glycerin. Glycerin is a good solvent for many substances. It keeps well, and is useful especially for external application on account of its adhesiveness. Glycerin is also less irritant than alcohol and devoid of the pharmacologic action of the latter agent.

ALCOHOLIC SOLUTIONS

Alcohol is a specific solvent of certain substances (volatile oils, alkaloids, resins). In prescribing, these should not be mixed with an aqueous solution. Alcohol is also a good preservative; but it has distinct therapeutic qualities, which may or may not be useful.

Spirits (*Spiritus*, genitive *Spiritus*; *Sp.*).—Alcoholic solutions of volatile drugs. They are all fairly strong. They are prepared by simple or chemic solution or by distillation. Flavoring spirits contain 10 per cent. of the respective volatile oils. Their dosage is 1 to 2 c.c., 15 to 30 minims. Spirits other than flavoring vary in strength and dose.

PREPARATIONS MADE BY EXTRACTION

In these, only a part of the crude drug is dissolved. They comprise the aqueous Infusions and Decoctions; and the alcoholic Tinctures and Fluid and Solid Extracts.

Infusions (*Infusum*; *Inf.*).—Aqueous solutions of the soluble principles of vegetable drugs, obtained by brief maceration in hot or cold water.

Decoctions (*Decoctum*; *Dec.*).—Analogous preparations, in which the ingredients have been boiled with water for at least fifteen minutes.

Infusions and decoctions are especially useful when it is wished to extract some principle which is more soluble in water, or when the therapeutic effect of alcohol or the mechanical incompatibility of alcohol with salts is to be avoided. There are some inconveniences connected with their use: They take some time to prepare. Like all watery solutions, they spoil quickly, and must, therefore, be made fresh. The decoction can only be used if there are no delicate constituents to be destroyed by boiling.

The solvent being so very cheap and having no action, it is usual to make decoctions considerably weaker than tinctures. In prescribing infusions or decoctions of potent drugs, the proportion should always be stated by the prescriber. When the strength is not stated, the pharmacist is supposed to use 5 per cent. of the drug. The dose of non-poisonous infusions and decoctions lies between 15 and 120 c.c. ($\frac{1}{2}$ to 4 ounces).

Type Formulas (U.S.P.).—*Infusa*.—1,000 c.c. of boiling water are poured on 50 Gm. of the coarsely comminuted drug, the vessel is covered tightly, and allowed to stand for half an hour in a warm place. It is then strained with expression, and enough water is poured through the strainer to make the infusion measure 1,000 c.c.

Decocta.—50 Gm. of the coarsely comminuted drug and 1,000 c.c. of cold water are boiled in a covered vessel for fifteen minutes, cooled to about 40°C., strained and expressed, and cold water added through the strainer to make the decoction measure 1,000 c.c.

Preservatives.—The amount of preservative which must be added to a watery solution to insure its keeping qualities varies with its nature, and in the same direction as the amount of "extractive." The proportions generally necessary are: Alcohol, 20 to 25 per cent.; glycerin, 10 per cent.; sugar, 66 Gm. to 100 c.c. of finished product.

A bibliography of the deterioration of drugs and pharmaceutical products is given by Eberhardt and Eldred, 1914.

Tinctures (*Tinctura*; *Tr.*).—Alcoholic or partly alcoholic solutions of the useful constituents of such drugs as are not wholly soluble in the menstruum.

Exceptions of this definition are *tincture of iodine*, *tincture of ferric chloride*, and *tincture of tolu*, in which the solution is complete.

The drug-strength of the tinctures varies from 0.4 to 50 per cent.; but those containing potent drugs conform to an international standard of 10 per cent.

The tinctures are in many respects the most useful therapeutic preparations: The dose is relatively large and uniform (about 2 to 4 c.c. for the non-toxic); the quantity of solvent is sufficiently large to keep the principles in solution; the use of heat in the preparation is avoided.

The greater number of tinctures are prepared by percolation; a few by maceration. The menstruum is alcohol or alcohol and water; acetic acid or glycerin are added in a few cases; aromatic spirit of ammonia is used in the *ammoniated tinctures*.

Type-process for Percolation Tinctures (U.S.P.).—The powdered drug is moistened with the prescribed menstruum, and macerated for six hours in a tightly covered container. It is then transferred to a percolator, packed firmly, and menstruum poured on to more than cover the powder. When the liquid begins to drop, the lower orifice of the percolator is closed, and the maceration prolonged for twenty-four hours. The percolation is then allowed to proceed slowly, gradually adding sufficient menstruum to the percolator until the percolate measures the required volume.

Type-process for Maceration Tinctures (U.S.P.).—The drug is macerated in a moderately warm place with the menstruum, using four-fifths of the final volume. This is continued, with frequent shaking, for at least three days. It is then filtered, the filter being washed with menstruum sufficient to make the required volume.

Detannated tinctures are tinctures from which the tannin has been removed (as by powdered skin). They do not precipitate with iron salts.

Ethereal tinctures are made with ethereal spirit, a mixture of 7 parts of ether and 3 parts of alcohol.

Green Tinctures.—Since some drugs are supposed to lose part of their activity by drying and keeping, a class of tinctures made from the freshly collected green drugs has been introduced under the name of *Tincturæ Herbarum Recentium*. The directions are to macerate 500 Gm. of the fresh herb with 1,000 c.c. of alcohol for fourteen days, to express and filter. These preparations are justly unpopular. They are of very inconstant strength, since the natural moisture of plants is variable. Again, they can be prepared only in the localities where the plants are native and where there often are no reliable facilities for their manufacture. These remarks apply equally to the *Juices (Succus; Succ.)* of the British Pharmacopeia, made by using 1 part alcohol and 3 parts of the freshly expressed juice.

Wines (Vinum; Vin.).—These are tinctures in which wines have been substituted for alcohol. They have a more pleasant taste, but inferior keeping qualities, and are now very little used.

Aceta (Acet.) are medicated vinegars, prepared by maceration with dilute acetic acid.

Fluidextracts, U.S.P.; Liquid Extracts, B.P. (Fluidextractum; Fldext.—Extractum Liquidum; Ext. Liq.).—These are liquid alcoholic extracts, 100 c.c. representing approximately 100 Gm. of the drug. The menstruum is in certain cases modified by the addition of glycerin, acetic acid, etc. They are the most concentrated fluid preparations, and were supposed to possess considerable advantages, but many are of doubtful value.

The simple ratio of drug-strength has no special advantage in therapeutics, and has led to serious abuses such as the practice of preparing tinctures, infusions, etc., by the dilution of the fluidextracts. This is highly reprehensible, since these dilutions often differ materially from the orthodox preparations.

Concentration may sometimes be desirable to reduce the bulk of the dose, but it is often secured at the cost of efficiency. The heat which must necessarily be used in their preparation is never beneficial. Precipitates are apt to form on standing, and while these are often inactive, they may contain the active principles. They are also much more subject to precipitation on mixture with other liquids, and the dose is usually so small that they require some such admixture.

Fluidextracts are usually prepared by percolation, the first four-fifths of the percolate being set aside, the remainder evaporated to the consistency of a soft extract, dissolved in the reserved portion, and menstruum added to make the required volume.

Type-processes for Fluidextracts.—The following are described by the U.S.P.:

Type A.—The powdered drug is moistened and macerated with the menstruum as described under tinctures, the maceration being prolonged to forty-eight hours. The percolation is then started, and continued by the addition of menstruum, until 850 c.c. of percolate have been collected for 1,000 Gm. of drug. This is reserved and percolation continued, with additional menstruum, until the drug is exhausted. These later percolates are evaporated to a soft extract, below 60°C., dissolved in the reserved portion, and diluted with menstruum to make 1,000 c.c.

Type B.—This is employed when two successive menstrua are used, the first containing glycerin, acid, etc. In this case, the powdered drug is moistened and macerated

with the first menstruum. The percolation is then started, and continued with the plain alcoholic menstruum. Otherwise, the process is identical with Type A.

Type C.—Fractional or Divided Percolation.—This is used for drugs containing constituents that are volatile or injured by heat. It may also be used in place of Type A.

The drug is divided into three portions of 500 Gm., 300 Gm. and 200 Gm. The first portion is then moistened and macerated, as usual. The first 200 c.c. of percolate are reserved; and the percolation then continued, collecting five additional portions of 300 c.c. each.

The second 300 Gm. portion of drug is moistened with the first 300 c.c. percolate of the preceding percolation; and macerated and percolated, as usual. The first 300 c.c. of percolate are reserved; and the percolation continued with the successive portions of the percolate from the first drug, until exhausted. These weaker percolates are collected in 200 c.c. portions.

The third 200 Gm. portion of the drug is moistened with the first 200 c.c. percolate of the second drug, macerated and percolated with the successive weak portions of the percolate of the second drug, until 500 c.c. are obtained. This is mixed with the reserve portions of the first two drugs.

Type D.—In this, the drugs are exhausted with water and preserved by the subsequent addition of alcohol. 1,000 Gm. of the ground drugs are mixed with 5,000 c.c. of boiling water and macerated for two hours. They are then transferred to a percolator, gradually adding boiling water until the drug is practically exhausted. The percolate is evaporated on a water-bath to the specified volume. It is then cooled, and sufficient alcohol added to make 1,000 c.c.

Solid Extracts (*Extractum; Ext., U.S.P. Extractum Siccum; Ext. Sicc.; B.P.*).—Must not be confused with the fluidextracts. They are solid or semisolid preparations obtained by evaporation of solutions of the medicinal principles of drugs. Some of the solid extracts are dry, others of a "pilular" consistency, *i.e.*, like a pill-mass. They are convenient for administration in solid form, *e.g.*, in pills, ointments, plasters, etc. Nearly all the potent, and most of the other, extracts are adjusted by the addition of glucose, etc., to four times the strength of the fluidextracts.

"Powdered Extracts" are dried, and mixed with sufficient diluent (lactose or starch) to give them the same strength as the solid extracts. Most extracts are prepared by percolating and subsequent evaporation; the last and weaker portions of the percolate being evaporated first, to avoid the deleterious actions of prolonged heat on the main portion. Some of the extracts are obtained by evaporating the fluidextract. The menstruum is sometimes water, or alcohol, or a mixture of both; acetic acid being added in some cases. The finished product is assayed, if possible, and adjusted to a definite standard by the addition of a diluent powder.

Artificial resins are precipitates obtained by mixing alcoholic solutions with water. Where they constitute the active principle, this is a convenient method of isolating it in a concentrated although somewhat impure form. Their strength is fairly constant. They are practically identical with the eclectic "resinoids."

Oleoresins (*Oleoresina, Oleores.*), are extracts containing the resinous and oily constituents of the drug; obtained by evaporating ethereal, acetone or alcoholic percolates.

MIXTURES

Mixtures, in the wider meaning of the word, are fluids resulting from the mixture of fluids with other fluids or with solids. They comprise: Linimenta, Misturæ, Emulsa.

Liniments (*Linimentum, Lin.*).—These are solutions of irritant drugs in oily, soapy or alcoholic vehicles, intended to be rubbed on the skin as counterirritants.

Mixtures (*Mistura; Mist.*).—In the narrow meaning of the term, these are generally suspensions of a solid in a liquid, sometimes by the use of a gummy substance; for heavy powders can not be evenly distributed in a light liquid without this aid. The B.P. also includes some emulsions under this title.

Emulsions (*Emulsum; Emul.*).—These are mixtures of a milky appearance, made by suspending fats, oils, or resinous substances in aqueous liquids by the intervention of some viscid, usually gummy, substance.

The object of emulsification is to break up the insoluble oil into very fine particles and to envelop each of these in a coating of the emulsifying agent, usually a gum or other colloid, which is probably adsorbed by surface-condensation into a quasi-solid pellicle, on the surface of the droplets, and so prevents them from reuniting. This allows of dilution, of the admixture of other substances, and it facilitates absorption.

Milk is a natural emulsion in which the butter-fat is kept suspended by the casein. It may be taken as a type to which artificial emulsions must conform. The globules must be uniform and of about the same size as those in milk. A variety of substances may be used as emulsifier, especially gum acacia, tragacanth, yolk of egg, Irish moss, extract of malt, soap-bark and soap. The substance most commonly employed is gum acacia. This emulsifier is incompatible with large quantities of alcohol.

In making the acacia-emulsion, the oil is subdivided by trituration in the presence of the gum and enough water to make a very thick mucilage. This forms the "nucleus." The friction against this viscous solution tends to tear the oil droplets apart; and as the smaller globules form, they are at once coated with the acacia film. The trituration must be brisk; for after the acacia films have formed it is much more difficult to break up the droplets further; nor must too much water be added until the emulsification of the nucleus is completed, for this would reduce the viscosity and the film-formation. When the nucleus has been made, the films are adsorbed so firmly that they are not disturbed by contact with any quantity of water and they may therefore be freely diluted. Two methods of emulsification are in common use; the Continental method, where a nucleus is first formed from gum, oil, and water, and to which the remainder of the water may then be added; and the English method, where a mucilage is first made, to which the oil and water are added in alternate small portions.

The *Continental method* deserves the preference. To form a nucleus there should be used for each part of oil $\frac{1}{4}$ to $\frac{1}{2}$ part of acacia and 1 part of water. Stir the oil with the acacia in granular powder, then add the water at once. The mixture of the oil and the gum must not be allowed to stand too long before adding the water, otherwise it will cake. In the *English method* the acacia, the amount of which should be half that of the oil, is rubbed up with an equal volume of water and then small portions of oil and water are added alternately. If this addition should be done too rapidly, there is danger that the emulsion will separate or "crack." This does not necessarily spoil it, for it may be re-emulsionized by adding it to a fresh portion of acacia and repeating the process.

In making medicated emulsions the ingredients should be mixed in the following order: First the nucleus, then the flavoring, then the syrup, and, lastly, the water in which the solids have been dissolved.

In *yolk emulsions*, the yolk of egg is used in place of the nucleus in the Continental method. The yolk is triturated in a mortar and the oil and water are added alternately in small portions. One yolk suffices for from 1 to 2 ounces of oil. The yolk emulsions

are incompatible with the same substances as gum emulsions and do not keep nearly as well.

Soap bark has saponin for its emulsifying agent. It is not incompatible with any of the above-named substances, but possesses very decided therapeutic properties, which preclude its use in many cases. It is used in the proportion of 1 part of the tincture to 8 parts of the oil: Place the tincture in a dry bottle, add the oil in portions, and shake after each addition. Finally add the water. Crude saponin (0.3:100 of oil) can also be employed.

Extract of malt emulsifies its own weight of oil. It is used as the nucleus in the Continental method.

Solutions of alkalies may also be used for emulsification, since they form soaps, but they are usually not desirable.

Natural emulsions, such as are found ready formed in nature. Instances of these are milk, the yolk of egg, and some plant juices.

Gum-resin and seed emulsions; that is, emulsions made from such substances as contain their own emulsifier. Examples of such gum-resins are ammoniac, asafetida, and myrrh. The drugs are reduced to a coarse powder and water is added gradually. Seeds which yield such emulsions are poppy, hemp, and almond.

SOLID PREPARATIONS

These comprise the Powders and the various dosage forms, Pills, etc., for internal use; and Ointments, Plasters, for external applications.

Powders (*Pulvis*; *Pulv.*, Gen., *Pulveris*) are finely powdered drugs intended for either external or internal administration.

When intended for internal use, they are generally folded in papers (*chartule*; *chartul.*). It must be borne in mind that hygroscopic (deliquescent) substances, such as potassium acetate or citrate, can not be prescribed as powders, nor such substances as become a fluid when mixed (e.g., camphor and chloral).

In making compound powders, one should begin with the smallest ingredient and add the others in the order of their amount, triturating thoroughly after each addition. In dividing the powder, it is not always necessary to weigh out each powder. The object is often accomplished with sufficient accuracy by flattening the powder on a piece of paper, squaring off the edges, and dividing into a number of equal parts by means of a spatula. In the case of more bulky powders, such as Seidlitz powders, measures are used.

When intended for external use, as for dusting-powders, extreme fineness is the main desideratum. They should in this case be mixed with a spatula and not in a mortar, since the former insures greater smoothness.

Triturations (*Trituratio*; *Trit.*).—These are powders obtained by triturating the active substances with some inert material such as sugar of milk. Their advantage lies in the greater ease in weighing out a comparatively large amount of substance. When no special directions are given, triturations are made of a strength of 10 per cent. The trituration of elaterin is the only one official.

Eleosacchara are triturations of volatile oils with sugar in the proportion of 1:30. They are used for the purpose of flavoring other powders.

Effervescent (*Eff.*) **Salts**.—These are dried salts, mixed with sodium bicarbonate and tartaric acid, etc., so as to evolve carbonic acid when they are dissolved in water. This aids in disguising the taste.

DOSAGE FORMS

Pills, capsules, tablets, lozenges, cachets, etc., are used to divide the drug into definite doses, to avoid the inconveniences of dry powders, and to reduce the bulk. Care must be used in prescribing the dosage forms so as not to make them too large to be swallowed.

The administration of drugs in compact solid form delays solution and absorption. This is especially true of old pills, in which the excipient may become so impervious that they pass unchanged into the feces; but it applies also to many tablets. A mere delay in solution may be an advan-

tage if an intestinal action is to be procured; but difficultly soluble substances (salol, bismuth, etc.) should not be administered in these compact forms. Corrosive substances are also unsuited for solid administration.

Pills (*Pilula*; *Pil.*, *U.S.P.*).—These are defined as spherical or elongated masses of medicinal substances, of such size as to be convenient for swallowing; that is to say, containing up to 5 gr. (0.35 Gm.) of active substance. If the pill is of larger size, it is called a *bolus*. Very small coated pills are spoken of as *granules*. The quantity of drug in the official pills is adjusted so as to make the average dose two pills.

Pill-masses (*Massa*; *Mass.*, *U.S.P.* *Pilula*; *Pil.*, *B.P.*).—These are soft solid preparations of such consistency that they can be formed into pills.

A pill consists of the active ingredient and of the *excipient* (cohesive). In order to make pills, the substance is first made into a *mass* by means of this excipient. The mass must be sufficiently soft to admit of molding, but on the other hand it should be sufficiently consistent not to lose its shape. It should neither harden nor soften nor crumble on keeping.

The quantity of drug in the B.P. pills is adjusted so as to make their dose, with few exceptions, 0.25 to 0.5 Gm., 5 to 8 gr. (The exceptions are *Pil. Phosphori*; *Pil. Ferri*; *Pil. Plumbi c. Opio*; *Pil. Saponis Co.*)

Excipients.—Syrup, glycerin, acacia, vegetable extracts (*Extr. Gentianæ*), and a great variety of other substances are used, according to the characters of the active drug. The choice may usually be left to the pharmacist.

Moist Excipients.—Glycerite of acacia or tragacanth, thick flour paste, glycerin, syrup, confections, or extracts.

Solid Excipients.—Acacia, tragacanth, starch, althea, licorice powder, soap.

For chemicals which are destroyed by organic substances the best excipient is formed by a mixture of petrolatum and kaolin.

Absorption Influenced by Excipients.—These, being colloidal, all delay absorption somewhat. For iodide pills, Rieben, 1907, found the greatest delay with waxy and oily excipients, the least with vegetable extracts and syrups. Silver-foil coating produced considerable delay.

Preparation of Pills.—The ingredients are first triturated to a fine powder. In case crystalline salts are used, these must be desiccated. The excipient is then added in small portions and thoroughly triturated with the powder until the proper consistency is obtained. If accidentally too much excipient is added this can be remedied by the addition of some inert powder, such as starch, gum acacia, or powdered licorice.

The mass having been formed by thorough trituration, it is placed on a glass or porcelain slab marked with equal divisions. It is well to put a little dusting-powder on the slab to prevent the mass from sticking to it. The best dusting-powders are starch, lycopodium, or licorice, according to the color of the pill-mass. This mass is then rolled out by means of a broad spatula into a cylinder of uniform diameter, and this is cut with a sharp knife into the requisite number of equal parts. These are formed into spherical shape by rolling them between the thumb and the first two fingers. The finish may be rendered more perfect by placing the pills with a liberal amount of dusting-powder in the lid of the pill box and gently rolling them with the ball of the thumb.

Pill-coatings.—Pills are often coated with sugar, gelatin, chocolate, etc., to disguise their taste while being swallowed. The coatings tend to interfere somewhat with absorption.

In coating with sugar, the pills are moistened with a thick syrup and rapidly rotated and dried in a current of warm air until they acquire a sufficiently thick coating and a fine polish. The latter is often enhanced by a little wax. For a gelatin coating they are dipped into a strong hot solution of gelatin, which is allowed to harden in the air. When it is desired to exclude the air from the pills, they are sometimes varnished by dipping them into an ethereal solution of tolu. This is the official process for keeping phosphorus pills. A still finer polish may be given to pills by coating them with silver leaf, which is done by shaking them in a box with silver foil.

Enteric Pills.—These are pills coated with some substance (keratin, salol, stearic acid, or formaldehyde-hardened gelatin), supposed to protect them from the gastric juice, but which dissolves in the intestines. They would be useful when the drug is intended to act only after passing the stomach. Unfortunately, they fail to accomplish their purpose, for soluble drugs diffuse through them rapidly (Linossier, 1911).

Improved directions for the salol-coating of pills are given by Peacock, 1915; for stearic acid by Toplis, 1915. The latter claims that the stearic coating apparently fulfils its purpose.

Keratin (a protein derived from horn, goose, quill, etc.) was tried extensively; but it is totally unsuitable, since commercial specimens are largely soluble in artificial gastric juice (Puckner, 1911).

Formaldehydized Capsules.—These are prepared by immersing the filled capsules in water containing 1 per cent. of absolute formaldehyde, and drying. The capsules should become insoluble in acid-pepsin solution, but remain soluble in 0.5 per cent. sodium carbonate. The degree of insolubility is governed by the duration of the immersion. If they are to be used on the next day, the immersion should last six minutes; but these will have become quite insoluble in the carbonate after they have been kept a week. With immersion of thirty seconds, the capsules will be properly hardened only after storing them for two weeks; but they will preserve their proper solubility in carbonate for one year (Scoville, 1915).

Capsules.—These are small containers, usually of gelatin, intended to be filled with the drug and swallowed. Those used for powders are hard, and consist of a body and a cap. In filling these capsules, the powder is divided into the requisite number of parts, forced into the body with a spatula, and the caps placed on. Soft capsules are used for oils, etc. These are sealed with a drop of melted gelatin. These soft capsules may be made to hold as much as 4 Gm. Hard capsules should not hold more than 0.3 Gm. or at most 0.5 Gm. A somewhat larger amount may be used by making the powder into a pill-mass. The purpose of capsules is to disguise the taste of the substance.

Capacity of Capsules for Dry Powders.—The capsules are marketed by numbers, which have about the following average capacity (Caldwell, 1913); probably differing somewhat, however, for the various makes:

Size of capsules	Capacity in minims	Average capacity for most powders	
		In grains	In grams
3	5.3	3.0	0.20
2	6.5	4.0	0.25
1	8.4	5.5	0.35
0	10.0	7.5	0.50
00	15.5	10.0	0.65

Parke, Davis & Co. state the capacity of their capsules as: No. 0, 12 minims; No. 1, 9 minims; No. 2, 6 minims; No. 3, 4½ minims; No. 4, 3 minims; No. 5, 2 minims.

Pill-masses in Capsules.—Capsules can be made to hold larger quantities of powders when these are made into pill-masses. A wax-mass may be used for solidifying creosote or volatile or fixed oils, so as to make them suitable for capsules. Such a mass may be prepared by mixing 3 parts of castor oil with 1 part of melted beeswax (N. S. Davis, 1919).

Wafers are thin sheets formed of a dried flour-paste, in which the powder is enveloped. They are immersed in water and swallowed. They possess the advantage that larger quantities of the drug (up to 1 Gm.) may be administered.

Cachets are wafers, molded into concave circular forms.

Troches or Lozenges (*Trochiscus*, *Troch.*).—These are made by punching or cutting out circular or oblong disks from a mass made up from the

active substance, sugar, and mucilage or fruit base. These are then dried in the air. They are usually intended for solution in the mouth, especially for throat medication.

Tablets (*Tabella, Tab.*).—These are small disks composed of medicated powders. *Tablet triturates* are prepared from the powdered drug and milk-sugar or sugar, made into a paste with alcohol, and pressed into molds. *Compressed tablets* are formed by strong dry compression. These forms are used similarly to pills, and dissolve more readily, especially the triturates. By suitable choice of ingredients, they may be made very acceptable to children (*Tabellæ Dulces*, "Candy medication," Fantus, 1912-1914).

Variability of Commercial Tablets.—Commercial tablets are often unreliable. Variations of 10 per cent. may be excusable, but Kebler, 1914, found that nearly a fifth of the samples bought varied by 20 per cent. or more; and this even with toxic substances.

Hypodermic tablets are similar to the tablet triturates, especial care being exercised to secure quick solution.

Lamellæ (B.P.) (*Lam.*) are thin gelatin disks, softened with glycerin, and impregnated with substances acting on the pupil. They are intended to be placed under the eyelids.

Suppositories (*Suppositorium, Supp.*).—These are suitably shaped masses of solid, medicated usually fatty substances, intended for introduc-

FIG. 2.—Different forms of suppositories (H. Blair). Natural size: The largest is for use in the vagina; the cylinder is a urethral suppository or bougie; the others are various shapes and sizes of rectal suppositories.

tion into the rectum, vagina, or urethra (Fig. 2). They take the place of ointments for local treatment where these can not be readily applied.

Suppositories are made by incorporating the medicinal substance into a suitable base, and molding into masses of suitable shape and size. The ideal base is one which, whilst solid at the ordinary temperature, is melted by the heat of the body. Such is cacao-butter (*Oleum Theobromatis*). Glycerinated gelatin or a soapy base is also sometimes used, especially with urethral suppositories for which cacao-butter would be too brittle.

Rectal suppositories are cone-shaped and are usually made with sufficient base to weigh about 2 Gm.

Vaginal suppositories are globular or oviform, and weigh about 4 Gm.

Urethral suppositories are pencil-shaped, pointed at one end, and measure 7 or 14 cm., weighing 2 or 4 Gm., when made with glycerinated gelatin.

Theobroma suppositories are made either by the hot or cold process. The hot process consists in melting cacao-butter, adding the active substances, and pouring the mixture into cold molds. In the cold process the active substances are triturated with grated cacao-butter with the addition of a small amount of expressed oil of almond, or woolfat, sufficient to make it into a suitable mass, which is then rolled out and divided as for pills. They may also be formed by pressure.

Glycerin is made into a suppository by means of a very hard soap formed from stearic acid and sodium carbonate.

Ointments (*Unguentum*, *Ung.*) are soft fatty masses intended for external application. They consist of the active ingredient and the base.

The latter may be lard, petrolatum, wool-fat (lanolin) or various mixtures, such as the "simple ointment," consisting of 4 parts of benzoinated lard and 1 part of white wax.

Petrolatum.—(Vaseline), consists of the less volatile parts of petroleum.

Lanolin.—(*Adeps Lanæ Hydrosus*) is a mixture of cholesterin-like substances obtained from sheep's wool. It mixes with its own weight of water. This property is of advantage when it is desired to use crystalline salts, since these can be incorporated in the form of solution, making a much smoother ointment. *Lard* is the cheapest ointment material; but it rapidly becomes rancid. This tendency can be diminished by the incorporation of antiseptic substances. Official Benzoinated Lard is an attempt in this direction; but the dispensing of ointments in tin-tubes is the most efficient protection against rancidity as well as against dirt. It should not be used if the ingredients of the ointment attack the metal.

The physical characters of the ointment bases, their melting point and their viscosity and adhesiveness, influence their availability for different purposes. When the ointment is to be applied by friction, for instance if it is to be rubbed in the hair follicles, a non-viscid base, such as lard, would be preferred. If a thick layer is to be kept in contact with the skin, the adhesive woolfat would be better. For a protective ointment, a thin layer, for instance of petrolatum, may suffice. One of the most useful bases is a mixture of equal parts of petrolatum and hydrous woolfat.

The nature of the base influences the penetration of the ingredients of the ointment into the skin. It is sometimes stated that absorption is greater from the true fats and from woolfat than from petrolatum; but this is too broad a generalization. The absorption is high if the solubility of the substance in the epidermis is greater than its solubility in the ointment. Since this varies for each substance, no base is uniformly either favorable or unfavorable to absorption.

Preparation.—Ointments are prepared by fusion, mechanical admixture, or chemic reaction. In mixing ointments by fusion, that constituent of the ointment which has the highest melting-point is first melted, and the others are then added in the order of their melting-points. The active substance is added last, to obviate the prolonged action of heat upon it. The mechanical admixture is usually done on a slab or in a mortar. Powders must be in the finest stage of subdivision. If the quantity of powder is large, it is usually first mixed with some of the melted ointment.

Oleates (*Oleatum*, *Oleat.*).—These are solutions of metals or alkaloids in oleic acid. They are used similarly to ointments.

Cerates (*Ceratum*, *Cerat.*).—These are preparations similar to ointments but made of a firmer consistency by the addition of wax.

Plasters (*Emplastrum*; *Emp.*). These are made by spreading on a thin cloth or leather support a mass or base which is hard at an ordinary

temperature, but is softened and rendered adhesive at the temperature of the body. They are applied as adhesive or for counterirritation. A rubber composition is the base for most modern plasters. The typical old-time plaster had for its base diachylon, Burgundy pitch, or other resins. Diachylon is a lead soap made by boiling lead monoxide with olive oil and lard. To avoid the irritation resulting from the confinement of the secretions of the skin, plasters are now frequently made porous. Isinglass plaster is made by spreading a thick solution of isinglass on silk.

Chartæ are medicated papers, *i.e.*, pieces of paper covered or impregnated with a medicinal substance. Charta Sinapis is used as a plaster, Charta Potassii Nitratis for fumigation.

Collodia (*Collodium, Collod.*).—Solutions of pyroxylin (gun-cotton) in a mixture of ether and alcohol, or in acetone. By the evaporation of the solvent they form a film on the skin, and thus act like plasters. Collodia must not be brought near fire.

Poultices (*Cataplasma, Catapl.*).—These are used mainly for the purpose of supplying heat. Linseed poultice may be taken as a type: It is prepared by pouring a cup of linseed meal into $2\frac{1}{2}$ cups of boiling water, stirring constantly. The mush is spread thickly on a piece of flannel, folded so as to form a sack, and applied as hot as can be conveniently borne. Other pasty materials (flour, clay, etc.) are also used.

SOLUBILITIES

It is well to have a general idea of the solubility of the substances usually prescribed. The subjoined compilations will be found useful in this connection. A knowledge of analytic chemistry and of incompatibilities can be utilized here, for a substance appearing as a precipitate is, of course, relatively insoluble.

GENERAL SOLUBILITY OF COMMONLY USED SALTS IN WATER

I. Arranged by Acids.

Group A: Salts Mostly Soluble.

1. *Acetates and Nitrates*: all soluble (except bismuth subnitrate).
2. *Halogen group* (= iodides, bromides, and chlorides): Soluble, except Ag; Hg (ous); Pb; Bi.
3. *Sulphates*: Soluble, except Pb, Sr, Ba; Ca sparingly soluble.
4. *Tartrates and Citrates*; mostly soluble.

Group B: Salts Mostly Insoluble.

- | | | |
|---|---|--|
| <ol style="list-style-type: none"> 1. <i>Arsenates</i> <i>Arsenites</i> <i>Carbonates</i> <i>Hydrates</i> (Ca sparingly soluble) <i>Oxides</i> <i>Oxalates</i> <i>Borates</i> <i>Phosphates</i> | } | Insoluble, except those of alkali metals |
|---|---|--|

II. Arranged by Base.

The salts considered in this table are: Acetates (Ac), Halogens (H), Oxides (O), Sulphates (SO₄), Phosphates (PO₄), Oxalates (Ox), Carbonates (CO₃), Sulphides (S), Nitrates (NO₃), Citrates (Ci). Hydrates agree with oxides.

Those of the above salts which are *not mentioned* with the respective base are *insoluble*.

1. *Alkali Metals* (= Na, K, NH₄): all soluble.
2. *Lithium*: Soluble, except O and CO₃, sparingly soluble, and PO₄, insoluble.
3. *Mg, Al*: Soluble: NO₃, Ac, H, Ci, SO₄, S.
4. *Ca, Ba, Sr*: Soluble: NO₃, Ac, H, Ci, S; sparingly: O.
5. *Zn, Mn, Ni, Co, Fe* } Soluble: NO₃, H, Ci, SO₄ (mercuric iodide
Hg(ic), Cu, Sn } is insoluble).
6. *Ag*: Soluble: NO₃, SO₄.
7. *Pb*: Soluble: NO₃, Ac.
8. *Bi, Sb*: Only soluble in form of double organic salts, e.g., Bismuth and Ammonium Citrate; Antimony and Potassium Tartrate.
9. *Mercurous*: Insoluble.

Strength of watery solution, in which commonly used salts may safely be prescribed. (It must be remembered that where several salts are prescribed in the same mixture, the solubility of each is apt to be lowered.)

The following table gives the amount of very commonly used drugs which can be *safely prescribed in water enough to make 100 c.c.* These should be memorized:

50 per cent., or grams: (= ʒiv in water q.s. ʒj)	Tannin; Antipyrine; Acetate, Citrate, Salicylate, Iodide or Bromide of Potassium or Sodium; AgNO ₃ ; ZnSO ₄ ; Chloral; Cocaine Hydrochloride.
5 per cent., or grams: (= 25 grains in water q.s. ʒj)	Alum; Phenol; Borax; KClO ₃ ; NaHCO ₃ ; HgCl ₂ ; Tartar Emetic; Quinine Bisulphate; Citrated Caffeine; the majority of the soluble salts of alkalis, earths, and metals.
smaller quantities: 4 to 0.1 per cent.	Boric Acid, 4; Morphine Sulphate, 4.5; Quinine Hydrochloride, 3; Quinine Sulphate, 0.13; Strychnine Sulphate, 2.

Solubility in Different Media.—As a general rule, *inorganic substances* are more soluble in water than in alcohol.

Basic alkaloids are insoluble in water, more soluble in alcohol.

Alkaloidal salts are soluble in either alcohol or water.

Gums are soluble in water, insoluble in alcohol. *Resins* and *essential oils* are the reverse.

(In making mixtures, it must be remembered that spirits, tinctures, and fluidextracts all contain alcohol.)

Glycerin stands intermediate between alcohol and water as a solvent.

The following substances are much more soluble in glycerin than in water; Boric acid, alum, phenol, mercuric chloride.

Terms Used in Defining Solubility.—The following terms (Wilbert, 1909) are employed in "Useful Drugs" to describe the approximate solubility, which is often sufficient for prescribing. Substances that are solu-

ble in less than 1 part of solvent = very soluble. From 1 to 10 parts of solvent = freely soluble. From 10 to 100 parts of solvent = soluble. From 100 to 1,000 parts of solvent = slightly soluble. From 1,000 to 10,000 parts of solvent = very slightly soluble. From 10,000 to 100,000 parts of solvent = nearly insoluble. More than 100,000 parts of solvent = practically insoluble.

Official Solubilities.—The U.S.P. and B.P. state the solubility of articles, as grams of substance to cubic centimeters of solvent; *i.e.*, a solubility of 1:10 means that 1 Gm. of substance requires 10 c.c. of solvent for solution, at the standard room temperature, 25°C., 77°F., U.S.P.; 15.5°C., 60°F., B.P. The standards given in this book are those of the U.S.P. In percentage solutions, 10 per cent. signifies that 100 c.c. of solution contain 10 Gm. or c.c. of the substance.

INCOMPATIBILITY

This subject is often very confusing to the student. However, it rests only upon an application of the ordinary chemic reactions, and when the latter have been mastered, the subject is comparatively easy. It may be helpful to remember that *substances are usually incompatible if they are used in testing for each other or if they form antidotes.*

In the following compilation it has been attempted to arrange the incompatibilities into general groups.

In this generalization, it is not feasible to take account of individual exceptions. Care has been taken to err on the safe side. It is much more important for the physician to remember that mercuric chloride is generally incompatible with alkaloids, than it is to know that it may be prescribed with some.

Definitions.—Incompatibility is said to exist *when the constituents of a mixture interfere with one another in a way not intended by the prescriber.*

If an interference is intentional, it is called an *intentional incompatibility.*

If a chemical change occurs, the incompatibility is called *chemical.*

When it consists in a precipitation of the substance by a change in the solvent, or when a chemic incompatibility does not interfere with the active substance, but produces an unsightly appearance, the incompatibility is *pharmaceutic.*

If the interference is with the solubility, or if liquefaction or deliquescence occurs, the incompatibility is *mechanic.*

When without causing any chemic changes it interferes with the physiologic action of the ingredients, it is *therapeutic.*

Chemic Incompatibility.—This may result in explosion, precipitation, or the production of new substances with undesired properties.

Explosives.—Powerful oxidizing agents are apt to explode when mixed in concentrated form with easily oxidizable substances.

The most important oxidizing agents are: chromic acid; concentrated nitric acid and nitrates; permanganates; chlorates; peroxides.

The most important oxidizable substances are: All organic substances; Sulphur, sulphides, sulphites, and hyposulphites; Iodine and iodides; Phosphorus, phosphites, and hypophosphites; Reduced iron.

Explosions may also result from mixing iodine with ammonia or turpentine; and chlorine with ammonium chloride.

Explosions occur only when the substances are dry or at least concentrated, and when they are heated or percussed.

Dilute solutions may be mixed without danger if not heated. Glycerin, phenol, and in some cases alcohol, behave like dry solids.

Potassium permanganate or chromic acid or nitrate of silver decompose organic substances even in solution, but in this case without explosion.

Powders may be mixed without concussion, but even this should be avoided, since conditions favorable to explosion may arise after they leave the hands of the dispenser.

Pills containing these easily decomposed substances are best made with inorganic excipient (clay and vaseline).

Substances containing loosely combined oxygen may explode on concussion or heating when no reducing substances have been added; this is due to their containing dust or other organic matter. They should therefore be handled with care.

Gradual Evolution of Gas.—This occurs especially on mixing acids with carbonates or sulphides; also when mixing strong acids with alcohols (= esters), or with chlorate (= Cl); also on mixing strong HCl and HNO₃. Formaldehyde effervesces copiously with oxidizing substances, even in solution (hydrogen peroxide).

Incompatibility by Precipitation.—*Alkalies* precipitate earths, metals and alkaloids from their salts. Under alkalies may be included oxides, hydroxides, carbonates, phosphates, borates, arsenates and arsenites.

Chlorides, bromides and iodides precipitate salts of Ag, Pb, and some alkaloids. Iodide also precipitates mercuric salts, redissolving with an excess.

Sulphates precipitate Pb, Ca and the other earthy metals, except Mg.

Salicylates, phenol and tannin precipitate or color iron salts. Tannin also precipitates most other metals, alkaloids, and some glucosides and neutral principles. Salicylates precipitate quinine.

Salts of metals are precipitated by alkalies, sulphides, tannin and proteins. They precipitate some alkaloids and acacia. *Mercuric salts* are often incompatible with other metals. *Silver and lead salts* are precipitated by chlorides, bromides, and iodides. *Silver salts* are also incompatible with organic substances. *Iron salts* are colored by tannin, salicylate and phenol.

Calcium salts are precipitated by alkalies, phosphates and sulphates; *Magnesium salts* by alkalies and phosphates.

Alkaloidal salts and synthetic bases (antipyrine, etc.) are precipitated by alkalies, tannin, iodine, potassium-mercuric iodide, and some by iodides or metallic salts.

Acacia is precipitated by alcohol, borax, Tr. Ferri Chlor.

Production of Substances with Undesired Qualities.—*Iodides* liberate iodine on the addition of acid and oxidizing agents, including H₂O₂, nitrites, salicylic acid, etc. They oxidize mercurous to the dangerous mercuric salts.

Chlorates liberate chlorine with concentrated acids.

Chloral liberates chloroform with alkalies.

Glucosides (f.i., glycyrrhizin) are destroyed by acids.

Pharmaceutic Incompatibilities.—*Alcohol* should not be added to: Acacia, gelatin, proteins, emulsions, strong salt solutions.

Water should not be added to:

Alcoholic liquids in general (such as tinctures, spirits, fluidextracts, with some exceptions); or to ethereal liquids (oleoresins), or oils.

(Phenol should not be mixed with collodion.)

Liquefaction occurs when chloral is rubbed with camphor, menthol, phenol, salol, etc. Any of these, when rubbed together, or with coal-tar antipyretics, are apt to liquefy.

Especially Incompatible Drugs.—The following are most likely to give incompatibilities, and any combinations should therefore be scrutinized with special care: Acids, alkalies and carbonates; permanganates; iodides; salicylates; mercury, iron, silver and lead salts; tannin; alkaloids; methenamine.

METROLOGY

A ready working knowledge of weights and measures is indispensable in prescribing.

Formerly every country, even every State, and some cities, had their own system of weights and measures, resulting in endless confusion and loss of time. This state of affairs still exists to some extent. In the United States and Great Britain no less than five different systems are in common use. It is a hopeful sign that the United States and British Pharmacopeias and the U. S. government medical services employ the metric system. This system originated in France near the close of the 18th century. It has been adopted in science to the exclusion of all others, and possesses a number of advantages which should cause all other systems to be discarded. This is the ultimate tendency, and the student is urged to learn the doses and practice prescription-writing in the metric system. Since, however, the common systems are still used in many hospitals and journals, these must also be mastered, and the conversion of the systems practiced.

The Metric System.—This is based on the decimal system, and has for its unit the measure of length, the meter (M.).

This was intended to be a natural unit, viz., the ten-millionth part of the distance from the pole to the equator of the earth at a particular meridian. Subsequent measurements have given a slightly different value to this distance. The meter is therefore an arbitrary standard—the length of a platinum bar, the original of which is preserved in Paris.

The meter is divided into 10, 100, and 1,000 parts, called respectively decimeter (dm.), centimeter (cm.), and millimeter (mm.). The thousandth part of a millimeter is a micron (μ).

The contents of a cube whose edges measure a decimeter, or 10 cm., form the unit of capacity, the liter (L.) The thousandth part of this is a cubic centimeter (c.cm., or, briefly, c.c.; also termed a "milliliter" or "mil"). The unit of weight is given by the weight of a liter of distilled water at 4°C. *in vacuo*: this is the kilogram (Kg.). A thousandth part of this is a gram (Gm.). The tenth part of the unit is expressed by prefixing the Latin numeral deci; one-hundredth, centi; one-thousandth, milli.

Thus:

1,000 Gm.	=	Kilogram (Kg.). ¹
1 Gm.	=	Gram (Gm.)
0.1 Gm.	=	decigram (dg.)
0.01 Gm.	=	centigram (cg.)
0.001 Gm.	=	milligram (mg.)

In quantities including several denominations only one unit is used: thus, 1.234 Kg. would be read as 1,234 Gm.; 0.0002 Gm. as 0.2 mg., etc. The quantities are always denoted by Arabic figures placed before the appellation. Fractional parts are always converted into decimal fractions.

¹ Some authors begin all the abbreviations with capitals; others employ capitals for the units; gram, liter and meter, and their multiples; and small letters for fractions (as in the above lists). The latter plan has some advantages.

In continental Europe the liquid measure is very little used in pharmacy, liquids being usually weighed.

Milliliter.—The B.P. designates the cubic centimeter as milliliter, and employs the following divisions and abbreviations. Their use does not seem advisable, as they tend to introduce complications and confusions that may retard the final adoption of the metric system.

Liter (Lit.)	= 1,000	Gm. of water at 4°C.
Milliliter, Mil, Ml.	= 1	Gm. of water at 4°C.
Decimil, Dl.	= 0.1	Gm. of water at 4°C.
Centimil, Cl.	= 0.01	Gm. of water at 4°C.

Common Systems of Weights and Measures.¹—The denominations are the following:

APOTHECARIES' OR TROY WEIGHT

(USED IN PRESCRIPTIONS)

Grain (gr.)		
[Scruple (℥)]	=	20 gr.]
Drachm ² (℥)	[= 3℥]	= 60 gr.
Troy ounce (℥)	= 8℥	= 480 gr.
[Troy pound	= 12℥	= 5,760 gr.]
(℥ j of water under standard conditions ³ measures 504.83 minims.)		

AVOIRDUPOIS OR IMPERIAL WEIGHT

(A SYSTEM USED IN COMMERCE)

Grain	= same as Troy grain.	
Ounce (oz.)	=	437½ grains.
Pound (lb.)	= 16 oz.	= 7,000 grains.
Ton	= 2,000 lb.	

UNITED STATES APOTHECARIES' OR WINE MEASURE

(USED IN UNITED STATES FOR BOTH PRESCRIPTION AND COMMERCIAL PURPOSES)

Minim (℥ or min.) (approximately equal to 1 drop or to 1 grain of water—more exactly, 0.95 grain).

Fluidrachm (fl ℥)	= 60℥.	
Fluidounce (fl ℥)	= 8 fl ℥ = 480 ℥ (fl ℥ j of water under standard conditions ³ weighs 456½ grains).	
Pint (pt., or Octarius, O)	= 16 fl ℥ = 7,680 ℥.	
Quart (qt.)	= 2 pts. = 32 fl ℥.	
Gallon (gal., or Congius, C)	= 8 O = 128 fl ℥ = 61,440 ℥.	
A gallon holds 231 cubic inches.		

Another system of liquid measure is in use in *Great Britain*, and must not be confused with the American system. It is the

IMPERIAL MEASURE

		UNITED STATES SYSTEM
Minims (min.)	=	0.96 ℥
Fluidrachm (fl. dr.)	= 60 min.	= 0.96 fl ℥
Fluidounce (fl. oz.)	= 8 drachms	= 0.96 fl ℥
Pint (O)	= 20 fluidounces	= 1.2 O
Gallon (C)	= 8 pints	= 1.2 C

In writing the apothecaries' measure in prescriptions, the figures are written in the Roman system and placed after the appellation. Thus, gr. xx, not 20 gr. The ones are always dotted, and the last one is formed like a j: thus ℥iij, ℥vj, etc. The fl. before the sign is often omitted with liquids.

Fractions are written as common fractions: gr. 1/10, not gr. 0.1.

Popular Measures.—These are formed of utensils commonly found in the household, and are, of course, inexact. They should be displaced by

¹ Those in square brackets are practically obsolete.

² Also spelled dram.

³ At 4°C. in vacuum.

graduated medicine glasses, which can be obtained cheaply. Spoons are supposed to be filled so that the fluid stands level with the rim.

The usually accepted equivalents of these measures are:

1 drop (gtt.)	= 1 minim ¹	= 0.05 c.c.
1 teaspoon	= 1 fl $\frac{3}{4}$ ²	= 4 c.c. ³
1 dessertspoon	= 2 fl $\frac{3}{4}$	= 8 c.c.
1 tablespoon	= 4 fl $\frac{3}{4}$ ($\frac{1}{2}$ $\frac{3}{4}$)	= 15 c.c.
1 wine-glass	= 2 fl $\frac{3}{4}$	= 50 c.c.
1 tea-cup	= 4 fl $\frac{3}{4}$	= 125 c.c.
1 tumbler	= 8 fl $\frac{3}{4}$	= 200 c.c.
1 knife-pointful (tableknife)	= 15 to 30 gr.	= 1.0 to 2.0 Gm.

Advantages of the Metric System.—These will now be manifest.

1. The metric system is widely used, and is understood throughout the civilized world.

2. There is a simple relation between linear, solid, and liquid measures.

3. The decimal feature simplifies multiplications, since only a change of a decimal point is required to change one denomination into another. It is also much easier to write the quantities.⁴ Calculations involving specific gravity are also much more easily made.

4. The adherents of the common system claim that the grain, minim, and drachm are more convenient doses than the gram or cubic centimeter. This advantage, however, is insignificant.

Equivalents of Metric and Common Systems.—Doses and formulas may need to be calculated from one system into the other. For this, it is only necessary to remember that 1 Gm. = 15.4 gr. However, this always entails the possibility of some error in reckoning, which may have serious consequences. The student is therefore advised to learn the dosage in both systems, and to construct prescriptions directly in whichever system is chosen. If a transposition must be made, the following approximate equivalents (which should be thoroughly memorized and practiced) are sufficiently exact for prescription purposes; and being simpler, they are less apt to lead to arithmetical errors, than the exact equivalents.

APPROXIMATE EQUIVALENTS

1 Gm.	} = 15.5 grains or minims	1 grain or minim	= 0.065 Gm. or c.c.
1 c.c.		1 dram	= 4.0 (—) or c.c.
1 milligram	= $\frac{1}{64}$ grain	1 ounce	= 30.0 (—) or c.c.
1 Liter	= 1 quart (+)	1 pint	= 0.5 Liter (—)
1 Kilogram	= 2.2 lb.		

EXACT EQUIVALENTS SPACE

1 meter	= 39.370 inches	1 inch	= 0.0254 M. = 2.54 cm.
	= 3 ft. 3.370 inches	1 ft.	= 30.48 cm.
	= 1 yd. 3.370 inches	1 yd.	= 91.440 cm.

¹ The size of a drop varies according to the nature of the fluid and of the container; there may be from 50 to 150 to a fluid drachm. The International Protocol authorized a standard dropper, designed to deliver exactly 20 drops per cubic centimeter of water.

² Really from $\frac{1}{2}$ to 2 fl $\frac{3}{4}$.

³ As a matter of fact, the actual capacity of teaspoons averages 5 c.c., when filled level (Wilbert, 1905).

⁴ An example will make this clearer: Take 40 Gm.; in the United States system this must be written $\text{℥j } \text{℥ij gr. xvij}$. Should it be necessary to calculate five times this quantity, one multiplication will suffice with the metric system: $5 \times 40 = 200$ Gm. But with the Apothecaries' system, the operation would be much more complicated:

$$5 \times \text{℥j } \text{℥ij gr. xvij} = \text{℥v } \text{℥x gr. lxxxv}$$

This must be reduced:

$$\begin{array}{r} \text{℥v} = \text{℥v} \\ \text{℥v} = \text{℥j } \text{℥ij} \\ \text{gr. lxxxv} = \text{℥j gr. xxv} \end{array}$$

$$\text{Answer} = \text{℥vj } \text{℥ij gr. xxv}$$

CAPACITY (UNITED STATES)

1 c.c. = 16.23 m
 1 L. = 33.815 fl ʒ
 = 2.113 pts.
 = 0.2642 gal.

1 m = 0.06161 c.c.
 1 fl ʒ = 3.7 c.c.
 1 fl ʒ = 29.574 c.c.
 1 pt. = 0.4731 L.
 1 gal. = 3.7854 L.

CAPACITY (BRITISH)

1 L. = 1.760 pints
 = 0.2209 gallons

1 pint = 0.5679 L.
 1 gallon = 4.5435 L.

WEIGHT

1 mg. = $\frac{1}{16}$ gr.
 1 Gm. = 15.432 gr.
 = 0.03527 oz. Av.
 = 0.03110 ʒ Troy.
 1 Kg. = 2.2046 lb. Av.

1 gr. = 64.8 mg. = 0.0648 Gm.
 1 ʒ = 3.888 Gm.
 1 oz. Av. = 28.3495 Gm.
 1 ʒ Troy = 31.1035 Gm.
 1 lb. = 0.4536 Kg.

GENERAL TOXICOLOGY

Toxicology is the science of poisons. The details of the actions and symptoms will be considered in connection with the individual poisons; but certain matters of general application may be discussed here.

Definition of Poison.—A poison (from potion, a draught), by the broadest definition, is a substance the administration of which is injurious to health. However, injurious mechanical, physical, or bacterial agencies are not commonly classed as poisons; nor are the substances which produce injurious effects only in very large doses (say over 50 Gm.). It is very difficult to give a definition which will not be ambiguous in some cases (see, *f.i.*, the collection of definitions by Murray and Frame, 1914). The following covers most of the points which must be considered in classing a substance as a poison:

A poison is any substance which, acting directly through its inherent chemic properties, and by its ordinary action, is capable of destroying life, or of seriously endangering health, when it is applied to the body, externally, or in moderate doses (to 50 Gm.) internally.

Etiology of Poisoning.—Poisoning may result through criminal or suicidal intent, or through accident.

The statistics of the relative frequency of the different forms of poisoning vary from year to year, and with each country. A classified list of deaths from poisoning in the U. S. registration area is given by Wilbert, 1916. Suicidal poisoning is probably the most frequent, nearly a half of the suicides in the United States being due to poisoning.

At that time, probably five-sixths of all suicidal cases in this country were due to phenol. There is, however, a fashion in poisons, as in other things.

Symptoms of Poisoning and Classification of Poisons.—*Suspicion of poisoning* is aroused if a person, previously in good health, manifests rather suddenly marked pathologic symptoms, which become rapidly worse. The suspicion becomes more firm, if the phenomena appear a short time after swallowing some substance which may perhaps have an unusual odor or taste;¹ if they agree in character with those produced by some group of poisons, and if they do not agree with any other disease.

¹ It may appear strange that poisons which possess a pronounced and disagreeable taste could be used for criminal poisoning, except with infants; but a moment's thought will show that if a liquid is taken unsuspectingly, the taste is not noticed until a large amount has been swallowed.

Symptomatic Classification of Poisons: The following classes are generally recognized.

1. **Irritants.**—These produce inflammation; if they are taken by the mouth, there is pain throughout the alimentary canal, vomiting, purging, delirium, coma. So many poisons are to some extent irritant, that these symptoms are very commonly present. The irritants can be subdivided into *corrosives*, which produce direct destruction of tissues; and *simple irritants*, which do not. If corrosives are taken by the stomach, the vomit is often bloody.

2. **Nerve Poisons.**—These act on the neuromuscular apparatus, and include most of the poisons which are fatal in minute doses. They are subdivided into: **Convulsants**, which cause spasms; **Somnifacients**, causing sleep and coma; and **Cardiac poisons**, which stop the heart.

3. **Blood Poisons.**—Those which alter the hemoglobin or blood corpuscles. These include the toxic gases, the nitrites, etc. Their action is generally characterized by cyanosis.

It must not be supposed that the action of a poison is confined generally to one class of structures or functions. All functions suffer directly or indirectly, and whatever the class to which the poison belongs, the final *cause of death* is, in almost all cases, paralysis of respiration, preceded by the phenomena of *asphyxia*. In virtue of the latter, or through other causes, the urine often contains sugar.

The irritants, and especially the corrosives, produce lesions which can be demonstrated at **AUTOPSY**. With other poisons the postmortem examination is generally negative. The **SPECTRUM OF THE BLOOD** shows characteristic changes with some poisons. These are also apt to cause ecchymotic discolorations of the skin. Antiseptic poisons *delay the putrefaction* of the body, so that mummification may result. Convulsive poisons quicken the onset of *rigor mortis*.

Duties of the Physician in Cases of Poisoning.—These are twofold: to save life or suffering, and to forward justice. The former object requires the removal of the poison, the administration of chemical antidotes, and the treatment of the symptoms.

For the *detection of the poison*, and to aid in fixing the guilt on the proper person, the physician must carefully observe the symptoms, take possession of any suspected material, medicine, vomit, etc., and in case of autopsy, preserve the stomach and its contents, the intestines and contents, blood, liver, kidneys, and portions of other organs, *separately*, without antiseptics,¹ in clean, hermetically closed, glass vessels, which should be sealed with wax.² An exact *written record* of all the observations should be made as soon as possible.

The *symptoms* in cases of suspected poisoning are rarely sufficient to affirm the presence or nature of a poison, although they may be of great aid to the analyst. The final proof rests generally on the results of the *chemic examination*.

So much depends on this analysis, that it should never be undertaken by one who has not had extensive experience in this class of work, and who has not the necessary facilities. It lies entirely outside of the scope of the practicing physician. The latter should, however, be familiar with the general outline of the process used for isolating poisons; and with such chemic tests as may be quickly applied. These tests are often valuable for diagnostic and therapeutic purposes. The physician is also expected to give expert testimony on toxicologic questions, and to do this intelligently, he must have at least an elementary knowledge of toxicologic analysis, such as is furnished in the following section.

Some poisons can be demonstrated much better by tests on animals than by any chemic tests. For this object, they should be isolated in as pure a form as possible, by the methods laid down in this section. The application of these life tests, falls peculiarly into the province of the pharmacologist.

¹ Even glucoside and alkaloid poisons can be isolated for a long time (160 to 270 days) from putrefying masses. Some poisons, however, disappear rapidly (Phosphorus, Cyanide, Picrotoxin, Phenol, etc.). Strychnine and morphine are very persistent.

² In emergency, a rare or specially marked coin, or a key may serve to impress the seal.

OUTLINE OF TOXICOLOGIC ANALYSIS¹

Precautions.—The first duty of the analyst is to guard the material confided to him from *the wilful or accidental introduction of poisons*. For this purpose, precaution must be taken that no other person has access to the material; and every reagent and apparatus must be tested personally.

As a rule, the different organs must be kept strictly separated throughout the analysis. It will depend on circumstances whether the analysis of the individual organs is made at the same time, or successively. If the latter is decided on, the largest organ, or that most likely to contain the poison, is examined first. It may be advisable, however, to mix a weighed quantity (one-fourth or one-third) of the comminuted organs, and to use this mixture for the first analysis.

Since the material to be analyzed is limited in amount, and cannot be replaced, the examination must be arranged in such a way that as many tests as possible can be made successively on a single sample of the material. An economy of time and material is also secured by obtaining, as quickly as possible, some idea of what poisons may be present. This may be done by some easy preliminary tests, or by using so-called "group-reactions" which, if negative, will exclude a number of substances. The symptoms may also have furnished important hints, but should never prevent the complete examination of the substance.

During the isolation and the preliminary search for the poison, only the most important tests should be applied. When the poison has been isolated, however, it should be subjected to every known test. A sample of the isolated poison should be preserved, in stable form.

Preliminary Examination.—The systematic examination is begun by a careful inspection of the portions of the alimentary canal. These are opened, and extended on an inverted evaporating dish, mucous surface upward. Pathologic lesions are looked for, as also particles of the poison which may be adherent. A magnifying lens should be employed. (Granules of arsenic have often been isolated in this way.) The contents of the alimentary canal, or vomited matter, are subjected to a similar close inspection. The odor should be carefully observed. During this examination, the **reaction to litmus paper** should be noted (caustic acids or alkalies).

Each organ is then hashed, carefully weighed, and placed in hermetically sealed jars.²

Isolation of the Poison.—No routine schema of analysis can fit all cases, since each presents its own problems. However, the following illustrates the usual procedure.

Division of Material.—Ordinarily, each organ, after comminution, is divided into the following portions carefully weighed: One-third is reserved for control; one-twentieth for preliminary tests. The remainder is divided into four parts, used respectively for the search for volatile, fixed organic and inorganic poisons, and for reserve. If the quantity of material is very scanty, two equal portions will suffice: one is reserved for preliminary tests, easily decomposable poisons, and control; the other is examined successively for easily volatile poisons, for fixed organic poisons, and for metals.

Volatile Poisons.—A portion of the material is acidulated with tartaric acid (adding water if necessary), and distilled from a flask or retort connected with a Liebig's condenser.³ It is advisable to pass a slow current of live steam through the mass. The distillation is continued until about two-thirds of the liquid have been collected, in three portions. The odor

¹ This section should be studied in connection with the practical exercises. Gadamers "Lehrbuch der chemischen Toxicologie" is an excellent reference book.

² As soon as the absence of volatile poisons has been proven, the contents of the jars may be covered with 95 per cent. alcohol.

³ See next paragraph for special arrangement to be used when phosphorus is present.

is noted (volatile oils, chloroform, ether, etc.), and the characteristic tests applied for phosphorus, phenol, cyanides, alcohol,¹ chloroform, chloral, etc.

Phosphorus.—A preliminary test for this element must be made with silver nitrate and lead acetate papers before the distillation is begun. If this test indicates its presence, the condenser is set vertically downward, and the distillation is carried on in a darkened room. All air is expelled from the apparatus by a stream of carbon dioxide. This is then shut off, and replaced by live steam, the flask being heated at the same time. If phosphorus is present, a luminous ring appears in the tubes or condenser, shifting its position when the heat applied to the flask is altered (*Mitscherlich's method*). The appearance of this phenomenon proves the presence of phosphorus absolutely.

There are, however, a number of substances which interfere with the formation of this ring. Almost any volatile substance may do so; turpentine, chloroform, ether, alcohol; and alcohol is often present, as it is usually given as an antidote.

The absence of the ring does not, therefore, prove the absence of phosphorus. The distillate will contain phosphorus in the lower stages of oxidation, as phosphorous or hypophosphorous acid. The best way to prove phosphorus in this is to add some bromine water to the distillate and to evaporate to dryness. This results in phosphoric acid, which may be demonstrated by magnesia mixture or ammonium molybdate. The quantitative determination of phosphorus is not important; because if it is present at all, it is present as a toxic agent.

Cyanides.—Mere traces of hydrocyanic acid in the distillate are not proof of poisoning, since these may have been introduced in the way of food (almonds or other seeds). A *quantitative estimation*, by means of silver nitrate, may be necessary. The qualitative proof also requires two further precautions:

With the method which we have given, ferrocyanides might also be decomposed and give rise to hydrocyanic acid; and since ferrocyanides are not toxic, this would lead to wrong conclusions. To eliminate this, the original liquid is filtered and the Prussian blue test applied to it directly. Mercuric cyanide does not yield its hydrocyanic acid in this treatment. If it is suspected, the material must be treated with hydrogen sulphide.

Distillation from Alkaline Solution.—It is sometimes recommended to add water to the residue in the retort, to make it alkaline with sodium carbonate, and to distill again. The distillate contains ammonium, amines, chloroform (if chloral was present), and the volatile alkaloids. This step may generally be omitted, as these poisons are discovered in other parts of the process; or a small sample may be heated in a test-tube with sodium carbonate, and the odor noted.

Extraction of Fixed Organic Poisons.—The extraction, separation and purification of these poisons are based on their special solubility in certain solvents. As a rule, they are fairly soluble in acidulated water and alcohol. The neutral principles are removed from the acid watery solution by ether or chloroform. The alkaloids are dissolved by these substances only after the addition of an alkali.

In brief outline, the suspected material is first extracted with boiling acidulated water and alcohol. The acid watery extract is then treated with ether, which dissolves *neutral principles* and various impurities, but which leaves the *alkaloids*. These are extracted later by fresh ether, after rendering the solution alkaline.

Various methods are in use. The most practical is that of **Stas-Otto**, slightly modified:

§1. The poisons are first *brought into solution* by boiling the material, if solid, with about 5 parts of water for fifteen minutes (or the residue remaining after the distillation of the acid solution may be used). The mixture is cooled and strained. This *removes fat, coagulable protein, fiber, etc.*²

§2. The strained solution is evaporated at a low temperature to a syrupy consistency, and boiled with twice its volume of alcohol, for fifteen minutes. The evaporated alcohol is replaced. It is then filtered, and the filter washed with alcohol. This *removes salts, non-coagulable proteins, etc.*

¹ Alcohol is only important if it is present in large amounts. Smaller quantities may be present accidentally or as antidote.

² It is understood that the remaining mass should be washed, in every instance of filtration or straining.

§3. The alcoholic filtrate is diluted with an equal volume of water and filtered. *This removes resins, fats, etc.* (The residue may be examined for cathartic resins and croton oil.) (For further purification, the filtrate may be again treated by §§2 and 3.)

§4. The filtrate, which should have an acid reaction, is now shaken in a separatory funnel with 10 c.c. of ether. This is drawn off, and the same process is repeated twice. The ether *removes neutral principles, picric acid, and salicylic acid.* It is filtered and allowed to evaporate in a glass capsule, and the residue is purified and tested for these acids, for caffeine, cantharidine, colchicine, digitaline, picrotoxine, and the coal-tar antipyretics.

§5. The watery solution, remaining from the extraction with ether in the last paragraph, is now made fairly alkaline with sodium carbonate (*to liberate the alkaloids*) and again extracted with ether, as in the last paragraph. From this alkaline solution, the ether *removes all alkaloids except morphine.* The ethereal layer is filtered and evaporated, the residue is purified, and tested, first by potassium mercuric iodide, then for physostigmine, apomorphine, nicotine, coniine, veratrine, strychnine, brucine, atropine, cocaine, codeine, narcotine, emetine, and aconitine.

§6. *To isolate the morphine*, the watery liquid remaining in the last paragraph, is made acid, then alkaline by ammonia, and shaken at once with acetic ether, or with hot amyl alcohol.

§7. To test for *oxalic acid*, the original substance is partly dried, extracted with 5 c.c. of hydrochloric acid and 20 c.c. of boiling alcohol, for half an hour, filtered, evaporated, extracted with water, and tested. *Santonin* and *meconic acid* must be also be extracted by special methods.

Dragendorff's Method.—In this, a more extensive separation of the poisons is obtained, by multiplying the solvents and operations. The preliminary treatment is as per §§1, 2, and 3. The acid solution is then exhausted successively by petroleum ether, benzol and chloroform; and then in alkaline solution by the same sequence of solvents, and finally by amyl alcohol.

Kippenberger's Method.—This possesses the advantage of separating the poisons in purer form from the start, but it involves technical difficulties. It depends on the insolubility of the tannates of proteins in glycerin, whilst the organic poisons are soluble in this medium. The solid material (say 100 Gm.) is digested for two days at 40°C. with 10 Gm. tannin, 1 Gm. tartaric acid, and 100 Gm. glycerin. The mass is expressed; the residue is washed with the tannic glycerin. The fluids are diluted with water, heated to 50°C., and filtered. The filtrate is then extracted twice with petroleum ether, which removes mainly fats. The glycerin layer is then extracted as in the Stas-Otto method (§§4 and 5), but using chloroform in place of ether.

For the *purification of the alkaloids*, the residue, left by the evaporation of the chloroform, is dissolved in acidulated water, neutralized, and at once precipitated by iodine-potassium-iodide. The precipitate is collected on a small filter, washed with cold water, dried, and dissolved in hot acetone. The filtered acetone solution is treated first with alkali, then with acid, then with water; the acetone is expelled on a water-bath, and the remaining watery solution is decolorized by sodium hyposulphite. The solution is then made alkaline with sodium carbonate and extracted with ether or chloroform.

Physiologic Tests.—The poisons isolated by these methods are often not sufficiently pure to give the typical chemic tests; furthermore, certain of the tests are closely simulated by ptomaines. This holds true also of the physiologic tests, *i.e.*, the effects on animals. The only way to distinguish with certainty between these is to use both the chemic and the physiologic tests. For, as far as is known, there are no ptomaines which give both the chemic and physiologic tests of one alkaloid.

The physiologic tests can generally be obtained with fairly impure preparations. They are most typical in the case of strychnine, atropine, physostigmine, aconite, digitalis group, picrotoxin, veratrine, cantharidine, croton oil. The subject is elaborated in Fuehner's "Nachweiss von Giften."

Isolation of Fixed Inorganic Poisons.—The residues of the preceding operations may be used for the search of these poisons. The usual methods of inorganic analysis are followed; but it is superfluous to test for non-poisonous constituents.

The absence of many metallic poisons can be quickly shown by Reinsch's test. This does not, however, dispense from further tests. Only an outline can be given here:

A: Destruction of Organic Matter and Solution. *Method of Fresenius and Babo.*—Organs or syrupy residue, plus 300 c.c. to 500 c.c. of arsenic-free HCl (1:2) in liter flask; heat lukewarm. Add 4 to 6 Gm. KClO₃ in 0.5 Gm. portions, till dissolved. Evaporate

to about 100 c.c. (no free Cl). Dilute to 400 c.c. Add 2 c.c. dilute H_2SO_4 . Stand overnight. Filter. *Filtrate* = B. *Residue* = K.

Filtrate B.—Pass through filter, add water to just 500 c.c. Use 50 c.c. for Marsh's test (see L). If As is present, use balance for quantitative (see C). If not, evaporate small sample, dissolve in 10 c.c. water, add NH_4OH : blue = Cu.

C.—Heat balance of filtrate B to 80°C . and pass arsenic-free H_2S^1 for two or three hours, until cool. Heat again, and repeat. Stopper and set aside in warm place for twenty-four hours. *Precipitate* may contain As, Sb, Hg, Cu, Pb. It may be used for the quantitative estimation of As, or for further identification by D. *Filtrate* = I.

D (*H_2S precipitate of C*).—Wash with H_2S water, warm with 4 c.c. ammon. sulphide, 4 c.c. ammonia, 8 c.c. water. Filter. *Filtrate* = E. *Insoluble* = F.

E (*Filtrate of D*).—Evaporate till dry; heat with HNO_3 till pure yellow; heat to expel HNO_3 ; add Na_2CO_3 and NaNO_3 ; fuse; extract with boiling water; add 2 Gm. NaHCO_3 . Filter. *Filtrate* contains As and may be used for quantitative. The *insoluble* = Sb. (Apply tests.)

F (*Insoluble of D*).—Oxidize residue and filter in capsule with HCl and KClO_3 ; filter; dilute; heat; pass H_2S ; filter; wash precipitate with warm HNO_3 . *Filtrate* = G. *Precipitate* = H.

G (*Filtrate of F*).—Add 10 drops dilute H_2SO_4 ; evaporate; take up with water. *Residue* = Pb. *Filtrate* = Cu. (Apply tests.)

H (*Precipitate of F*).—Oxidize with aqua regia; evaporate; filter; dilute; test for Hg.

I (*Filtrate of C*).—Use half for zinc, half for chromium.

Zn. Neutralize with KOH; acidulate with CH_3COOH ; precipitate with H_2S ; wash precipitate with $\text{H}_2\text{C}_2\text{O}_4$ in H_2S water (1:5); incinerate precipitate and filter; dissolve in dilute H_2SO_4 , plus a little HNO_3 ; evaporate dry; dissolve in H_2O ; test for Zn.

Cr. Evaporate to just moist; mix with KNO_3 ; dry; fuse; dissolve; test for chromate.

K (*Residue of A*).—Fuse with KNO_3 , Na_2CO_3 , and NH_4NO_3 . Suspend in H_2O ; pass CO_2 ; boil; filter. Dissolve precipitate in dilute HNO_3 . Test this solution for Ag, Ba, and Pb.

Marsh's Test (see B).—Produce hydrogen in flask by acting on pure zinc with arsenic-free HCl; pass through CaCl_2 , through tubes drawn out at several places. Heat to redness at the thick portion of a segment. (This blank test should be continued for six hours.) If no mirror appears, introduce the suspected solution. Black mirror occurs with arsenic or antimony. They may be distinguished as follows:

ARSENIC

Mirror beyond heated portion.
Garlic odor on heating in air.
Dissolves in hypochlorite.
Easily volatilized when heated in hydrogen.
Heated in air, yields easily volatilized white crystals.
Heated in H_2S , yellow, insoluble in HCl.
Dissolved in HNO_3 , evaporated, plus AgNO_3 , plus vapor of NH_3 , red or yellow precipitate.

ANTIMONY

Mirror at heated portion.
No odor.
Not soluble in hypochlorite.
Not easily volatilized.
Amorphous white residue, not easily volatilized.
Red (black on strong heating); soluble in HCl.
No color in cold; black (metallic Ag) on heating.

TREATMENT OF POISONING

Whilst every case of poisoning needs to be considered by itself, yet certain general principles are all but universally applicable. These are the more important since the nature of the poison is so often unknown.

The first peculiarity of poisoning to deserve especial attention is the rapid course. This demands that whatever measures are taken, they *must be taken quickly*. The physician should therefore be thoroughly familiar with the general rules of treatment, so that no hesitation or delay occurs. On this account also, the antidote nearest to hand should be used in preference to one which can only be obtained with delay, even if the latter should be theoretically preferable.

¹ H_2S purified by passing through water, calcium chloride, and a tube, 30 cm. long, filled with alternate layers of glass-wool and iodine crystals.

The treatment of poisoning is directed against the cause and the symptoms. The former consists in *removing the poison*, or in *rendering it harmless*. Since neither of these objects can usually be attained absolutely, both are generally attempted at once.

Removal of the Poison.—The measures directed to this end vary with the site to which the poison was applied.

On the skin and on accessible mucous membranes this will be accomplished by a thorough washing with water. This will also be useful by diluting the poison. If the poison is only sparingly soluble in water (as phenol) alcohol may be employed. Soap may be useful, but should be avoided if the poison is an alkali. The appropriate chemical antidote should also be added to the wash water (for acids or bromine: soap or sodium bicarbonate or borax or lime water; for alkalies: diluted vinegar or lemon juice). The poisons which are important in these situations are all irritants, and the further treatment consists in the application of oils or salves.

If the poison has been applied *hypodermically or to wounds*, the systemic effects may be lessened by preventing or retarding the absorption of the poison. If the suction absorption can be delayed sufficiently so that the drug is excreted as fast as it is absorbed, doses which would otherwise be fatal may cause no effect. The best means for this purpose is a firm ligature applied centrally to the wound. Where this is not feasible, suction, cautery, or excision may be practiced.

If an irritant poison has been *taken by the mouth*, the oral cavity and the pharynx demand the same treatment as would the skin.

With **gaseous poisons**, the treatment consists in free ventilation of the lung, using artificial respiration, and oxygen, if necessary.

Removal from the Alimentary Canal.—If the poison was taken by mouth, the stomach should be emptied by lavage or by an emetic, even though vomiting has occurred spontaneously; and even if the patient is not treated till several hours after swallowing the poison; for some poisons remain in the stomach for a long time. The only contraindications are extensive corrosion and advanced strychnine poisoning. These require judgement and caution.

After the stomach has been evacuated, 15 to 30 Gm. of magnesium sulphate should be administered, in water, to clean the intestines of slowly absorbable poisons. Metallic poisons are excreted in the intestines and then reabsorbed, so that catharsis should be maintained for some days. Oily cathartics should be avoided, as they facilitate the solution and absorption of some poisons.

Evacuation of the Stomach.—Lavage has advantages over emesis. It cleanses the stomach much more effectually, particularly of small undissolved adherent particles; it is less depressant to the patient; and it permits the convenient use of chemic antidotes. It is indispensable with depressant poisons which paralyze the vomiting center (such as deep morphine or chloral poisoning).

The complicated stomach pump has been replaced by the more convenient stomach tube. In emergencies, 6 feet of rubber gas tubing, with a funnel attached, answers very well. The tube should not be *forced* down, but should be *gently* pushed to the pharynx, where the pharyngeal muscles will grasp it and push it further. Care should be taken to avoid overdistention of the stomach; it is better to use small quantities of fluid frequently. Against organic poisons, a 0.5:1,000 solution of potassium permanganate may be used. If there is trismus, or the patient resists, the tube may be passed through the nose.

Emetics have the advantage of greater convenience, and avoid struggling. They should be repeated every fifteen to thirty minutes, if necessary.

Apomorphine.—[5 mg. (grain $\frac{1}{10}$) in 1 per cent. solution = 0.5 c.c. or mX, hypodermically], is the only emetic which can be given by the skin, and is therefore particularly useful if the patient resists. It is prompt and certain, but rather more depressing than the following emetics:

Cupric Sulphate or Zinc Sulphate.—These act promptly and with a minimum of depression, but should not be given if the poison is a corrosive. Zinc sulphate is less irritant than the copper, and nearly as efficient; 2 Gm. may be given in a glass of water. The dose of copper sulphate is 0.5 Gm. at once, or three doses of 0.3 Gm., fifteen minutes apart. If it is ineffective it must be removed by lavage.

Ipecac.—A teaspoonful of the powder in water, or a tablespoon of the syrup. Uncertain, and produces considerable depression.

Mustard.—A teaspoonful stirred in a tumbler of warm water. This is the most uncertain of these emetics, but useful in emergencies.

Neutralization of the Poison—Chemical Antidotes.—These are intended to render the poison incapable of acting, or of being absorbed, by enveloping it with an impenetrable coating, or by precipitating it, or by destroying it. Since these antidotes are hindered in their action by the presence of food, and since the precipitates are not perfectly insoluble, it is advisable to combine them with lavage or emesis, adding the antidotes to the wash water, or giving them in the interval between vomiting; they must be repeated frequently.

Demulcents (raw eggs, acacia, boiled starch or flour, milk, ad libitum). These act by diminishing absorption; by allaying inflammation; and in the case of metals, by precipitation. *Charcoal*, especially animal charcoal (bone-black), is an effective adsorbent for alkaloids.

Precipitants.—The most universally applicable of all precipitants is *tannin* (a teaspoonful of tannic acid, or preferably, very strong hot tea, ad libitum). The effect is increased by the addition of sodium acetate or bicarbonate, and diminished by alcohol and acids, since the precipitates are soluble in these media.

From the experiments of Kiefer (1892), on tannin, and Sollmann (1901), on tea, it may be deduced that these are *useful* against: Apomorphine, cinchona alkaloids, hydrastine, strychnine, veratrine, digitalis, antipyrine, colchicine, and the metals: Pb, Ag, Al, Co, Cu, Ni, Ur, Zn, Fe.

Scarcely useful against: Cocaine, brucine, aconitine, lobeline, nicotine, pilocarpine, codeine, muscarine, physostigmine, solanine.

Practically useless against: Atropine, coniine, morphine, As, Sb, Hg.

Of other, *specific precipitants*, the following should be remembered:
For

Alkaloids.—Tincture of iodine, 15 drops in half a glass of water.

Metals (especially mercury).—Raw eggs.

Arsenic.—Arsenic antidote (see Index).

Barium.—Sulphates (Glauber's or Epsom salt).

Oxalates.—Calcium (limewater, chalk, whiting).

Phosphorus.—Cupric sulphate or oxidized (old) turpentine. (The former envelops the phosphorus with an insoluble coating of metallic copper.)

Antidotes Which Destroy the Poison in the Alimentary Canal.—(These, for the most part, will not be useful after the poison is absorbed.)

Acids.—Alkalies (burnt magnesias, soap, chalk, baking soda).

Alkalies.—Weak acids (vinegar, lemon juice).

Organic Poisons (Alkaloids, Glucosides, Etc.) and Phosphorus.—Oxidizing agents, especially potassium permanganate, 2 grains (a pen-knife-point full in emergency) to the tumbler, repeated as often as it is vomited; or for lavage, a liter of 0.05 per cent. Care must be taken that no undissolved crystals are administered. In case of snake bite, the powdered permanganate may be rubbed into the wound, after free incision.

Hydrogen peroxide is another useful, though less powerful oxidant.

Hydrocyanic Acid.—Permanganate, arsenic antidote, hydrogen peroxide, and thiosulphate of sodium ("Hypo").

Antidotes Which Destroy Absorbed Poisons.—To be effective, these must be given hypodermically or intravenously. The best known examples of this class are the antitoxic sera. The following are also useful: Sodium thiosulphate against hydrocyanic acid; and sodium carbonate against mineral acids.

Removal of Poisons after Their Absorption.—This can be attempted by increasing the excretions, but is usually not very successful. The elimination by the alimentary canal has been discussed. The principal remaining channels are the urine and sweat, of which the former is more important.

Diuretics.—Water, especially as weak tea or carbonated drinks; theobromine; potassium acetate (irritant diuretics should be avoided).

The usefulness of diuresis for the removal of poisons is at best very limited, even for such substances as strychnine (Hatcher). With tetanus toxin, intravenous hypertonic alkaline saline or glucose failed to prolong the life of the animal, even when used under the most favorable conditions (Sansum, 1918).

Diaphoretics.—Hot drinks; heat; pilocarpine (if not contraindicated by pulmonary edema).

Infusion of normal saline solution (1 Liter of 0.85 per cent. injected under the skin of the subclavicular region) increases elimination by all channels. *Bleeding* may be resorted to in some cases. Up to a liter of blood may be drawn, a double quantity of salt solution being injected.

Symptomatic Treatment.—The symptoms produced by poisons can often be lessened or removed by the use of drugs having an opposite action. These *physiologic antidotes* may not really abolish the action of the poison; they may only mask its symptoms. But by tiding the patient over the dangerous period, and by preventing exhaustion, they may be potent means of saving life. It must be remembered, however, that large doses of the antidotes often cause effects similar to those of the poison, which may add to the fatality of the latter. They must therefore be used in appropriate small doses.

It is not purposed to enter in this place into the special physiologic antidotes, but only to take up those measures which are generally useful.

These measures are directed, in the *order of their importance*, to: supporting the respiration, heart, and vasomotor tone; to lessen cooling, pain, convulsions and coma.

Respiration.—This is usually the first function to fail, and this accelerates the other actions of the poison through the convulsant and paralytic effects of asphyxia, and by preventing the destruction of poisons through oxidation. For these reasons, it is well not to wait with the supporting measures until the respiration has actually failed, but to begin as soon as it shows signs of weakening. The measures consist in direct or reflex stimulation of the respiratory center; in artificial respiration; and in the administration of oxygen.

Reflex stimulation of the respiratory center is the quickest, but can not be kept up as long as the direct stimulation. It may be secured by

inhalation of ammonia water or smelling salts, or by aromatic spirits of ammonia (half a teaspoonful in a glass of water); the alternate application of heat and cold (whipping with wet towels); friction with alcohol; hypodermic injection of camphorated oil, whiskey, or ether; mustard plasters; faradization.

Direct Stimulation of the Respiratory Center.—This is attempted with rather limited success by strong hot coffee, strychnine (0.002 Gm.) or atropine (0.001 Gm.). The respiration may also be raised by improving the circulation. Saline infusion is useful.

Artificial Respiration.—This should be applied whenever the above measures are ineffectual.

Very prolonged and violent artificial respiration may injure the lungs. It should also be remembered that artificial respiration is apt to induce apnea, so that the patient does not breathe spontaneously simply because there is not enough CO₂ in the blood to stimulate the respiratory center. If the heart is strong, the artificial respiration should therefore be intermitted occasionally for a short time.

Oxygen.—This is useful if an asphyxiant gas is the cause of the poisoning.

Circulation.—It is sometimes possible to improve a failing heart by reflex stimulation, for instance, by the hypodermic injection of diluted alcohol; by the inhalation of diluted ammonia; by swallowing the aromatic spirit of ammonia; by the hypodermic injection of camphor in oil; or by the intravenous injection of normal saline solution, perhaps with the cautious addition of epinephrine (1:100,000). Lowering the head and bandaging the extremities also adds to the blood-supply of the brain and heart. Intravenous strophanthin may be very effective, but is also somewhat dangerous. Strychnine and atropine are generally ineffective.

If a heart has been arrested through asphyxia, rather than through a direct cardiac action of the poison and if it has not stopped longer than a very few minutes, it may sometimes be resuscitated by cardiac massage, combined with epinephrine, by intravenous, or more effectively by intracardiac injection (see index, Epinephrine).

Cooling.—This is prevented by the application of external heat; **pain** by morphine; **convulsions** are controlled by the cautious inhalation of chloroform; **coma** by reflex stimulants, coffee, and atropine.

Methods of Administering Antidotes.—Physiological antidotes should be given hypodermically or intravenously, if possible. This obviates the loss of the antidote through vomiting, and the action is more prompt and more certain.

If the circulation is low the absorption of hypodermic injections may also be slow. It is therefore well thoroughly to massage the site of the injection, and if the circulation has almost stopped, to employ vigorous rapid rhythmical compression of the heart (this maintains a fairly efficient artificial circulation even after the heart has stopped beating).

Résumé of the General Treatment of Poisoning.—Promptness is of vital importance. The physician should be familiar with antidotes; he should have these antidotes readily accessible; he should plan his treatment on his way to the patient. If he finds the condition of the patient dangerous, he should at once proceed to relieve the symptoms. Otherwise he should first administer the chemical antidote and evacuate the stomach; apply heat; attend to the respiration, to pain, to any other symptoms; give a diuretic, and, finally, a cathartic.

Antidotes for First Aid.—Every physician (and every drug store) should keep the following antidotes together, in a special satchel ("Antidote-Bag") so that they can be readily transported. The dose should be written on each container. Amyl nitrite pearls; Apomorphine tablets, 2 mg.; Atropine tablets, 1 mg.; Caffeine-sodium benzoate; Charcoal, animal, powdered; Chloroform; Cocaine hydrochloride tablets, 0.03 Gm.; Cupric sulphate, powdered; Epinephrine tablets, 1 mg.; Lime water; Magnesia, calcined; Morphine sulphate tablets, 10 mg.; Olive oil; Potassium permanganate, 1 per cent. solution (to be diluted twenty times); Sp. Ammon. Arom.; Tannic acid; Tr. iodine; Whiskey; also a hypodermic syringe in good order, and stomach-tube with funnel.

The following should be demanded at the house of the patient: Boiled water; Coffee (strong, hot, and black); Eggs; Hot-water bags; Milk; Mustard; Salt; Soap; Starch, boiled; Tea; Vinegar.

PRESCRIPTION WRITING

Parts of the Prescription.—A prescription is an order for medicine sent by a physician to a pharmacist. It consists of the following parts (in this order):

1. *Superscription*.—The heading (℞). The ℞ stands for *recipe*, take thou. The stroke is generally considered an ancient invocation to Jupiter; but probably it is simply a sign of abbreviation (McGuigan, 1913).

2. *Inscription*.—The ingredients and their amounts.

3. *Subscription*.—The directions to the dispenser.

4. *Signature*.—The directions to the patient.

The prescription should also bear the signature of the physician, the date, and the name of the patient.

The *Inscription* may consist of but one ingredient. If several are used, they should be placed in the following order:

Basis: the principal substance.

Adjuvant: the substance which is used to aid the action of the basis.

Corrective: whose purpose it is to modify or correct an undesirable action of the basis.

Vehicle: the indifferent substance used to dilute the active ingredients.

The following is the *type of a complete prescription*:

<i>Superscription</i>	℞	Gm. vel c.c.
<i>Inscription</i> : Basis.....	Tincturæ Aconiti.....	0 45
Adjuvant.....	Spiritus Ætheris Nitrosi.....	15
Corrective.....	Liquoris Ammonii Acetatis.....	15
Vehicle.....	Elixir Aromatici.....	30
<i>Subscription</i>	Misce	
<i>Signature</i>	S. Teaspoonful ¹ every hour in half a glass of water.	
	Dr. X.....	
	Jan. 1, 1905.	
	For Mr. Y.....	

The names of the ingredients and the directions to the pharmacists are generally written in Latin, usually with abbreviations; but they may be written in English. With liquid mixtures, the directions to the pharmacist may often be confined to M. (misce, mix).

The *directions to the patient* (signature; abbreviated Sig. or S., for "signa," sign) are always written in English, so that the patient can read them. The directions should be explicit, and should include everything which it is necessary for the patient to know. The habit of giving verbal

¹ Plural, "teaspoonfuls."

instructions to patients and of having the medicine labeled "use as directed" should be discouraged. The patient or relatives, when the prescription is given to them, are usually in a more or less excited frame of mind, and can not be relied upon to remember what is told them. Medicines intended for external application should be plainly labeled to that effect, and when a medicine contains poison, it should be so labeled, except when there is special objection to this.

The custom of having prescriptions "*refilled*" obtains in many localities. If the physician wishes to avoid this, he may write "*non repetatur*" on the prescription.

When the patient is very poor, the druggist may be invited to charge the lowest terms by writing *P. P.* (*Pauperissimus*) under the prescription. It is, of course, not just to do this if the physician himself receives a regular fee.

Prescriptions for Habit Forming Drugs.—The federal law requires that prescriptions for cocaine, or for opium or its alkaloids or derivatives, must contain: the signature of the physician in full; his address; his registry number; and the name and address of the patient.

Such prescriptions cannot be "*refilled*." If their administration is to be continued the physician must write a new prescription.

Forms of Administration.—If the medicine is to be used *internally*, it may be prescribed as:

Solution.—If the ingredients are soluble in water, alcohol or glycerin.

Mixtures or emulsions, i.e., suspended by acacia, if insoluble in water.

Powder.—If the substance does not have a very bad taste. These are preferred to the following preparations if the dose is bulky, or if the substance is to be dissolved in water before swallowing.

Pills, Capsules, Etc.—If the substances are solid or semisolid, and possess a disagreeable taste; or if they are to act locally on the alimentary canal.

If the medicine is intended for *external use*, it may be prescribed as:

Plaster.—If the action is to be prolonged and superficial.

Ointment.—If the action is to be deeper, or briefer.

Lotions or Injections, Eye-waters, Gargles, Etc.—If it is soluble in water.

Liniment.—If it is soluble in oil or alcohol.

Size of Prescriptions.—Fluids should be prescribed so as approximately to fill the bottles in current use (15, 30, 60, 90, 125, 150, 200, 400 c.c.) ($\frac{1}{2}$, 1, 2, 3, 4, 6, 8 and 16 ounces).

For drop doses and eye-waters, the usual amount is 15 to 30 c.c. ($\frac{1}{2}$ to 1 $\frac{3}{4}$); for teaspoon doses, 30 to 125 c.c. (1 to 4 $\frac{3}{4}$); for gargles and injections, 60 to 150 c.c. (2 to 6 $\frac{3}{4}$); lotions, 120 to 200 c.c. (4 to 8 $\frac{3}{4}$); tablespoon doses, 150 to 400 c.c. (6 to 16 $\frac{3}{4}$). Pills are prescribed in numbers of 5 to 25; powders, 1 to 24; ointments, 10 to 30 Gm. ($\frac{1}{2}$ to 1 $\frac{3}{4}$).

The Need of Practice in Prescription Writing.—The art of prescription writing often presents considerable difficulties to the student. The principles upon which it is based are few, simple, and easily memorized. The difficulties appear when he tries to put these principles into practice, and nothing but practice will give expertness.

The student who would master this subject must not rest content with doing the few exercises which can be given him in class. As he studies each drug, or as he reads up the treatment of diseases, he should himself compile such prescriptions as the subject suggests. This will not only aid him in prescription writing, but in pharmacology and therapeutics as well. It is only in this way that he can acquire the necessary self-confidence and skill. In this home practice, method and detail should be cultivated, for in these lies the secret of the art. The following rules may prove helpful.

Routine Construction of Prescriptions.—When writing a prescription for a given condition, put down, first, the name of the best remedy. Ask yourself whether there is any other drug which may be employed to aid or usefully modify this. Put this down also.

Then consider in which form the medicine should be administered, whether as liquid, powder, salve, etc. This will usually determine which preparation of the ingredient is to be employed. Put this down also.

Then ask yourself what may be added to render the mixture agreeable to the patient. Add the vehicle. When this is written, all the ingredients will be represented.

Now look over this carefully and see that there are no incompatibilities and that the constituents are soluble if the mixture is to be a liquid. Write the directions to the dispenser. Assure yourself that the prescription is grammatically correct (especially the endings).

Decide how many days the mixture is to be taken, and how many doses a day (on the basis of sixteen hours to the day). Decide whether the dose of the total mixture is to be a teaspoonful, tablespoonful, etc. By multiplying the total number of doses with the size of the single dose, ascertain the approximate size of the mixture. Round this off to a convenient figure. Multiply the single dose of each ingredient by the total number of doses (again reducing the quantities to round numbers, unless the constituent is very active).¹ Check the doses. Write the directions to the patient. Consider whether a *non repetatur* is advisable. Affix your signature, the date, and the name of the patient. This finishes the prescription. Look over the result carefully in the same order.

It would seem almost superfluous to mention that it is extremely essential in writing prescriptions to use as *legible handwriting* as possible. It is astonishing, in view of the dire results that may follow, how often this self-evident rule is disregarded. The same remarks apply to *abbreviations*. While it is justifiable to employ abbreviations even extensively, it is necessary to make these in such a way that they can not possibly be misinterpreted. It is, therefore, advisable to employ the official abbreviations which are given under the "Preparations."

A useful aid in acquiring practice in writing prescriptions is to look over a druggist's prescription file, when this may be done.

The copying of a prescription, ingredient for ingredient and dose for dose, is as much empiricism as the use of any other ready-made compound. The physician should be well enough educated to devise his own prescriptions and to select the ingredients that will best suit the special needs of the case in hand.

Simplicity in Prescription Writing.—Formerly prescriptions were usually written with many ingredients, mainly with the hope that among these many some might fit the patient. As medicine has become more scientific, it has aimed toward simplification; prescribing several drugs only when there is evidence that this gives useful results. This makes it more feasible to watch and to control the effects; and incidentally makes it easier to avoid incompatibilities. When it is necessary to prescribe at the same time, drugs which differ markedly in quickness of action, absorption or elimination; or habit-producing drugs with others that will presumably be used for long periods, these should be administered in separate prescriptions.

¹ One may also write the quantities for a single dose, and state in the subscription the number of doses required: "*Fac tales doses no XX*" (make 20 such doses).

If the prescription includes a number of mixtures, each containing several ingredients, such as the numberless preparations now put on the market by many firms, the result is, of course, as much a "shot-gun" prescription as if the prescriber had enumerated all the ingredients.

Posology (Doses).—The dosage of drugs must be adapted to the individual patient. The Pharmacopeia states "*Average Doses*" (adult) for each preparation that is likely to be used internally. These are defined as "the doses which may be expected ordinarily to produce the therapeutic effects for which the preparation is most commonly employed." They are not intended to be binding on physicians. They are, however, convenient approximations for memorizing. The metric and apothecaries' doses in the U.S.P. are not intended as mathematical equivalents, but represent rather the quantities that would be used by prescribers in these systems.

The doses of crude drugs are given mainly as a basis for calculating the preparations.

Maximal Doses.—The pharmacist is supposed to check the quantities of the ingredients, and not to dispense a prescription containing an *unusual dose of a powerful poison* without convincing himself that the physician prescribed this intentionally. While this does not in any way lessen the responsibility of the physician, it is a safeguard which deserves all encouragement. To avoid delay, it is customary to mark large doses in such a way that the pharmacist will have no doubt that they are intentional. Thus:

Tr. Digitalis, ̄3iv or ̄3iv! ; or ̄3iv Q. R. (quantum rectum), the last being the best.

Most foreign pharmacopeias (but not the U.S.P. or B.P.) give tables of "Maximum Doses;" not with the purpose of restricting the physician, but as a guide to the pharmacist. The latter is not permitted to dispense doses larger than these, unless the physician indicates specifically (as explained above) that the larger doses are intentional. The maximum doses in this book are taken from the compilation of the U.S.P. Digest, 1912, pp. 40-42.

Table of Maximal Doses.—An extensive table based on the data of foreign pharmacopeias is given by Wilbert, 1917 (U. S. Hyg. Lab. Bull. 107, p. 22).

PRESCRIPTION LATIN

It is customary, but not compulsory, to write the inscription, and often the subscription, in Latin. It is assumed that the student who intends to use this language is fairly familiar with its grammar. The following is intended to recall some of the more important facts.

Advantages of Latin.—The use of the Latin names of drugs is generally urged because they are more definite and concise, and less liable to change than common names; and because they serve to keep the patient in ignorance of the nature of the drugs. This is sometimes desirable, *f.i.*, to guard against drug habits. However, the official English names are equally definite; and as either names are usually abbreviated, there is little difference. As a matter of fact, less than 5 per cent. of the U.S.P. "Latin" names are really classical Latin (Oldberg, 1910).

In the directions to the dispenser, Latin has no advantage, except in the brevity of the customary abbreviations. Indeed, unusual Latin terms are apt to lead to mistakes. The discarding of Latin in prescription writing is being actively discussed (Fantus, 1916).

Grammatical Rules.—The superscription, *R* (recipe: "take thou"), requires the name of the substance to be in the genitive, if the quantity is given, the quantity itself being in the accusative (the latter is, of course, very rarely written out in full). When the quantity is not given, the name of the substance is to be placed in the accusative. Adjectives agree with their nouns in gender, number, and case.

These rules will generally be understood by translating into English: *e.g.*, Take thou of tincture of aconite 1 ounce.

The following rules for the formation of the genitive case will be found valuable ("Mann's Manual"):

RULE 1.—All nouns ending in *a*, form the genitive in *æ*; as *Quinina*, *Quininæ*. *Exceptions*: *Aspidosperma*, *Physostigma*, and *Theobroma* form the genitive in *atis*. *Folia* is plural; genitive, *foliorum*.

RULE 2.—All nouns ending in *us*, *um*, *os*, *on*, form the genitive in *i*; as *Conium*, *Conii*. *Exceptions*: *Rhus*, gen. *Rhois*; *Flos*, gen. *Floris*; *Fructus*, *Cornus*, *Quercus*, *Spiritus*, do not change.

RULE 3.—All other nouns of whatever termination make the genitive in *s*, or *is*, *f.i.*, *Elixir*, gen. *Elixiris*.

Some lengthen the termination thus:

as, genitive	atis; as <i>Acetas</i> ,	<i>Acetatis</i> .
is, genitive	idis; as <i>Anthemis</i> ,	<i>Anthemidis</i> .
o, genitive	onis; as <i>Persio</i> ,	<i>Persionis</i> .
x, genitive	icis; as <i>Cortex</i> ,	<i>Corticis</i> .

There are a few exceptions. *Mas*, gen. *Maris*; *Phosphis*, *Sulphis*, etc., gen. *itis*; *Mucilago*, gen. *Mucilaginis*; *Solidago*, gen. *Solidaginis*; *Pulvis*, gen. *Pulveris*, etc.

The following words do not change in their genitive: *Buchu*, *Cannabis*, *Catechu*, *Condurango*, *Cusso*, *Fructus*, *Digitalis*, *Hydrastis*, *Jaborandi*, *Kino*, *Matico*, *Sassafras*, *Sago*, *Sinapis*, *Spiritus*, *Gambir*, *Sumbul*.

The **accusative** is rarely employed. It is formed according to the following rules (Mann):

RULE 1.—Nouns singular ending in *a*, are feminine, and make the accusative singular in *a* and the plural in *as*. Example: *Drachma*, acc. sing. *Drachmam*, pl. *Drachmas*.

RULE 2.—Those ending in *um* or *us*, make the accusative singular in *um*. The accusative plural of those in *us* is *os*, and of those in *um* is *a*. Those in *us* are masculine, those in *um* are neuter:

Congius, acc. sing. *Congium*; acc. pl. *Congios*.
Granum, acc. sing. *Granum*; acc. pl. *Grana*.

RULE 3.—Those whose genitive ends in *is*, form the accusative in *em*, plural *es*.

The student must not forget that adjectives change their endings.

The following *prepositions* are frequently used, and command the following cases:

ad.....	to.....	accusative.
ana ¹	of each.....	genitive.
cum.....	with.....	ablative.
in.....	into.....	accusative.

The following **Latin words and phrases** occur frequently in prescriptions (adapted from Mann):

ad.....	to, up to
ad libitum.....	at pleasure
adde.....	add (thou)
ana (āā).....	of each
aqua bulliens.....	boiling water
aqua destillata.....	distilled water

¹ From the Greek, "at the rate of."

aqua fervens.....	hot water
aqua fontana.....	spring water
bene.....	well
bis in die (b.i.d.).....	twice daily
cape, capiat.....	take, let him take
charta.....	a paper (medicated)
chartula.....	a small paper for a powder
cibus.....	food
cochleare magnum.....	a tablespoon
cochleare parvum.....	a teaspoon
cola, colatus.....	strain, strained
collyrium.....	an eye wash
congius (C.).....	a gallon
cum.....	with
dilute, dilutus.....	dilute (thou), diluted
dimidius.....	one-half
dividatur in partes æquales.....	let it be divided into equal parts
divide (Div.).....	divide (thou)
dividendus.....	to be divided
dosis.....	a dose
fac, fiat, fiant (ft.).....	make, let be made, let them be made
fac tales doses.....	make such doses
filtra.....	filter (thou)
gargarisma.....	a gargle
gutta, guttæ (gtt.).....	a drop, drops
haustus.....	a draught
hora.....	an hour
hora decubitus.....	at bed time
hora somni.....	just before going to sleep
instar.....	like (with genitive)
lac.....	milk
libra (lb.).....	a Troy pound
magnus.....	large
mane primo.....	very early in the morning
misce (M.).....	mix
more dictu.....	as directed
non repetatur.....	do not repeat
numerus, numero (No.).....	a number, in number
octarius (O.).....	a pint
ovum.....	an egg
pars.....	a part
partes æquales (P. æ).....	equal parts (governs genitive)
parvus.....	small
pilula (pil.).....	a pill
pro re nata (p.r.n.).....	according to circumstances, occasionally
pulvis (gen., pulveris).....	a powder
quantum sufficiat (q. s.).....	as much as is necessary
quaque die.....	every day
quaque hora.....	every hour
quater in die (q.i.d.).....	four times a day
secundum artem.....	according to the usual practice
semel in die.....	once a day
(cum) semisse (ss.).....	and a half
signa.....	sign
sine.....	without
si opus sit.....	if necessary
solutio.....	a solution
solve, solutus.....	dissolve, dissolved
statim.....	immediately
talis.....	such
ter in die (t.i.d.).....	three times a day
tere simul.....	rub together
tritura.....	triturate
vitellus.....	the yolk (of an egg)

COLORING AND FLAVORING

COLORING

Liquid prescriptions intended for internal administration should be clear if possible. It might be well to mark such prescriptions "filtra." The appearance may often be materially improved by the addition of some coloring-matter, and this may also prove useful through its suggestive element. The nature of the coloring-matter must vary according to the nature, and especially the reaction, of the mixture. The usual colors for internal use are red, brown, and yellow. Aniline dyes should be avoided, except methylene blue and gentian violet for external preparations.

The most useful dyes are:

Red or pink: Tr. Persionis (red in acid and neutral, purplish in alkaline reaction); Tr. Cardamomi and Liq. Carmini (not suitable for acid); for powders, Carmine.
Brown: Fldext. Glycyrrhizæ (not suitable for acid); Caramel.
Yellow: Tr. Hydrastis; Tr. Curcumæ.

PREPARATIONS—RED COLORS¹

Coccus, Cochineal, U.S.P., B.P.—The dried female insect of *Coccus cacti*.

Tr. Cocc., B.P.—10 per cent. Dose, 0.03 to 0.1 c.c., 5 to 15 minims, B.P.

Carminum, N.F. Carmine.—A precipitate obtained from decoction of cochineal by alum or cream of tartar. Soluble in alkalies, brightened and precipitated by acids. Also soluble in alcohol. Contains carminic acid. Used in powders, etc. (1:500).

Liquor Carmini (Liq. Carm.) N.F.—An extract of *carmine* in ammonia water, glycerin and water. Pink to deep red in alkaline solutions, precipitated by acids. Used in the proportion of about 1 per cent.

Tr. Cardamomi Co. (Tr. Card. Co.)—An aromatic alcoholic (50 per cent.) vehicle, colored with cochineal. Used undiluted (see Index).

* *Tr. Persionis* (Tr. Persion.) N.F.; Tinct. of Cudbear (a lichen allied to litmus).—Red in neutral or acid, purplish in alkaline solutions. Used in the proportion of about 1.5 per cent.

Santalum Rubrum (Santal. Rub.), U.S.P.; *Pterocarp. Lign.*, B.P., Red Saunders.—The heart-wood of *Pterocarpus santalinum*. Used in Tr. Lavand. Co.

BROWN COLORS

Caramel is a concentrated aqueous solution of carbonized sugar. Commercial caramel is generally made by heating glucose with a little alkali, until the sweet taste is destroyed and a uniform dark mass results. It is probably a complex mixture. Caramel from cane-sugar according to Stolle, 1899, is a single substance, $C_{12}H_{18}O_9$, formed by the elimination of two molecules of water from sucrose. Caramel has been tried in diabetes, being apparently well tolerated (Grafe, 1914; Umber, 1915).

Fldext. Glycyrrhizæ and *Elix. Glycyrrh.* (see Index).

"U.S.P." stands for preparations official in the United States Pharmacopeia; "B.P.," British Pharmacopeia; "N.N.R.," New and Non-official Remedies; "N.F.," National Formulary; "B.P.C.," British Pharmaceutical Codex.

The following abbreviations will be used in connection with solubilities. Alc. = alcohol; glyc. = glycerin; eth. = ether; chlorof. = chloroform. The figures refer to the parts of the solvent required to dissolve 1 part of drug (*f.i.*, 1:0.5 = 1 part of drug dissolves in 0.5 part of solvent). The solubilities refer to 25°C. (room temperature), unless otherwise stated.

YELLOW COLORS

Crocus, Saffron, has been used as abortifacient; but it apparently lacks this action and is practically non-toxic (Cevidalli, 1914).

Tr. Curcumæ (Tr. Curcum.) (Turmeric) precipitates with water, but sufficient remains in solution to impart a yellow color. Used in ratio of 1 per cent. Curcuma changes to reddish brown in alkalies.

Tr. Hydrastis (Golden Seal) is used similarly (see Index).

¹ The preparations of each class are generally arranged alphabetically under the crude drugs. The important preparations, which the student is expected to study, are marked *. In addition to these, he should glance over the descriptions of the corresponding crude drugs.

FLAVORING

Suitable flavoring is a reasonable concession to the feelings of the patient; secures more effective cooperation; and may be necessary to obtain the retention of the medicine in the stomach.

Patients may fail to take a disagreeable medicine, and the physician should be on the lookout for such cases. He should approximately control the amount taken by judging as to the quantity left in the container.

Some patients carry the deceit further and pour away the appropriate amount of the medicine, and if the physician does not obtain the anticipated results, it may be well to prescribe some test medicine, such as salol (0.3 Gm.), or potassium iodide (0.5 Gm.), which can be detected in the urine.

Improving the Taste of Liquid Medicines.—This may be done by dilution; sweetening; demulcents; aromatics; alcoholics; acids; bitters; and drugs which paralyze the taste-endings. Several of these means are often combined.

Simple Dilution.—This is often most effective for salts, alkalies, chloral and other hypnotics; and in general, substances with disagreeable but not very marked taste. These should be taken in a half-glass or glass of water, milk, tea, or carbonated water.

The Most Important Flavors.—The following will be found to be generally sufficient:

To disguise bitter taste: Aromatics (Tr. Cardamomi Co.; Elixir Aromatic; Syr. Aurantii); for children, Syr. Glycyrrhizae, Aq. Anisi, Syr. Tolutani.

To disguise acrid taste: Aromatics as above; also syrups, acacia, acid flavors (Syr. Aurant.).

To disguise salty or alkaline taste: Dilution with simple or carbonated or aromatic water or milk.

To disguise oily taste: Aromatics (Oil or Spirit of Peppermint, lemon, orange, wintergreen or almond, according to personal preference).

For insipid drugs: Aromatics and acids (Syr. Aurantii).

SWEETENING AGENTS

The property of sweetness, like that of bitterness, is possessed by a considerable variety of substances. It is a common characteristic of the different sugars, which differ, however, in the degree of their sweetening power. The most intense sweetening power, however, is possessed by the otherwise rather inert gluside or saccharin. Licorice owes its taste to a glucoside, glycyrrhizin, which is sweet in alkaline, but not in acid liquids. Other substances of sweet taste are glycerol and chloroform. Although all these substances are "sweet," there are qualitative as well as quantitative distinctions in their taste. Attempts to connect sweetness with the chemic structure (Haycraft, 1882; Sternberg 1898) have not been very successful.

All sugars are foods, and dextrose and levulose, lactose and maltose will be described in that connection.

The most suitable agent for sweetening liquids is sucrose, in the form of its saturated watery solution or "syrup." This is improved by the presence of flavors with more distinctive taste, such as glycyrrhiza, tolu, and orange; or a mixture of aromatics and alcohol, as in the Elixir Aromaticum. Honey and fruit syrups and jams and jellies are admirable flavors that can be added in the household. Gluside is used for diabetics, and in

pill-coatings. Powders may be sweetened with lactose, which also, because of its hardness, assists in grinding the powders.

Intensity of Sweetening Power.—If that of sucrose is taken as 1, then levulose would be $1\frac{3}{4}$; glucose, $\frac{3}{4}$; maltose and galactose, $\frac{1}{3}$; lactose, $\frac{1}{6}$ (Biester et al., 1925). Gluside has 300 to 500 times the sweetening power of sucrose.

PREPARATIONS

Syrupus Acidi Citrici (Syr. Acid. Cit.), U.S.P.—A 1 per cent. solution of citric acid, flavored with sugar and lemon peel.

* *Elixir Aromaticum* (Elix. Arom.), U.S.P. (Simple Elixir).—Syrup containing about 25 per cent. of alcohol and flavored with aromatics (Comp. Spir. Orange).

Syr. Aromat., B.P.—Flavored with orange and cinnamon. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Aurantii Amari Cortex (Aurant. Amar. Cort.), U.S.P.; *Aurant. Cort. Sicc.*, B.P.; Bitter Orange Peel.—The dried rind of the unripe fruit of *Citrus Aurantium amara*. *Dose*, 1 Gm., 15 gr., U.S.P.

Aurant. Cort. Rec., B.P.—The fresh peel.

Inf. Aurant., B.P.—5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Inf. Aurant. Co., B.P.—25 per cent., with lemon and cloves. *Dose*, 15 to 30 c.c.; $\frac{1}{2}$ to 1 ounce, B.P.

Ol. Aurant., U.S.P.—*Dose*, 0.1 c.c., 1½ minims, U.S.P.

Sp. Aurant. Co., U.S.P.—20 per cent. of orange oil, with oils of lemon, coriander and anise.

Syrup. Aurantii, B.P.; Syrup of Orange,—Flavored with orange peel. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Tr. Aurant. Amar., U.S.P., 20 per cent. *Tr. Aurant.*, B.P., 25 per cent. of fresh peel.—*Dose*, 4 c.c., 1 dram, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 dram, B.P.

Vin. Aurant., B.P.

Aurantii Dulcis Cortex (Aurant. Dulc. Cort.), U.S.P.—The fresh outer rind of *Citrus Aurantium sinensis*.

* *Syrupus Aurantii* (Syr. Aurant.), U.S.P.—5 per cent. of *Tr. Aurant. Dulc.*, $\frac{1}{2}$ per cent. of citric acid.

Tr. Aurant. Dulc., U.S.P.—50 per cent. of the fresh rind. *Dose*, 4 c.c., 1 drachm, U.S.P.

Aurant. Cort. Ind., B.P.

Aq. Aurant. Flor., U.S.P.—Stronger Orange Flower Water. The saturated aqueous distillate prepared by distilling the fresh flowers of *Citrus Aurantium amara* with water.

Aq. Aurant. Flor., B.P.; Orange Flower Water.—A 33 per cent. dilution of the Stronger Water.

Syr. Aurant. Flor., U.S.P.; B.P.; Syrup of Orange Flowers.—*Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm.

Glycyrrhiza (Glycyrrh.), U.S.P.; (*Glycyrrh. Rad.*), B.P.—The dried rhizome and roots of *Glycyrrhiza glabra typica*, Spanish Licorice; or of *Glycyrrhiza glabra glandulifera*, Russian Licorice. *Dose*, 2 Gm., 30 gr., U.S.P.

Elix. Glycyrrh., U.S.P. (Elix. Adjuvans).—Fldext. 1; Elix. Arom. 7.

Ext. Glycyrrh., U.S.P.—Commercial Extract of *Glycyrrhiza* (licorice).

Ext. Glycyrrh. Pur., U.S.P.; *Ext. Glycyrrh.*, B.P.—An evaporated watery, pilular extract.

* *Fluidextractum Glycyrrhizæ* (Fldext. Glycyrrh.), U.S.P.; *Ext. Glycyrrh. Liq.*, B.P.—A watery extract of *Glycyrrhiza* (licorice root), preserved with 25 per cent. of alcohol. The U.S.P. contains some ammonia to dissolve the sweet glucoside, *Glycyrrhizin*. This is precipitated by acids, which are therefore *Incompatible*. It is miscible with water or alcohol. Mixed in the proportion of 1:7 with syrup or elixir, it is a good vehicle for quinine, etc. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Glycyrrhizin belongs to the saponins, although it does not have the typical formula and does not hemolyze (Kobert, 1915; he also describes a new chemist test). The bark likewise contains resins. Composition: Houseman, 1916.

Limonis Cortex (Limon. Cort.), U.S.P., B.P.—Lemon peel (fresh).

Ol. Limon., U.S.P., B.P.—A volatile oil obtained by expression from the fresh, ripe peel of *Citrus medica* var. *Limonum*. *Dose*, 0.1 c.c., 1½ minims, U.S.P.; 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Syr. Limon., B.P.—About 50 per cent. of lemon juice, flavored with lemon peel.

Tr. Limon., U.S.P.—50 per cent.

Tr. Limon., B.P.—25 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.
Mel, U.S.P.—Honey.—*Mel Depuratum*, B.P.—Honey (Clarified).
Oxymel, B.P.—Honey with $\frac{1}{4}$ acetic acid. *Dose*, 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms.
Rhæados Petala, B.P.—Red Poppy Petals.
Syr. Rhæad., B.P.—*Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.
Rosa, U.S.P.; (*Ros. Gall. Pet.*), B.P.—Rose Petals.
Conf. Ros. Gall., B.P.—25 per cent. of fresh Rose Petals.
Mel Rosæ, U.S.P.; Honey of Rose.—*Fldext.*, 12 c.c. Honey, to make 100 gm.—*Dose*, 4 c.c., 1 drachm, U.S.P.
Fldext. Ros., U.S.P.—*Dose*, 2 c.c., 30 minims, U.S.P.
Syr. Rosæ (*Syr. Ros.*) B.P.—*Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.
Sucrosum (*Sucros.*), U.S.P., *Saccharum Purification* (*Sacch. Pur.*), B.P.; *Sucrose*, Sugar (Cane or Beet), $C_{12}H_{22}O_{11}$.—Very sol. in water (1:0.5), slightly in alc.² (1:170). Used for sweetening powders, for the administration of volatile oils (eleosacchara), and the preparation of syrups, elixirs, etc.
^{*}*Syrupus* (*Syr.*), U.S.P., B.P.; *Syrup.*—A strong aqueous solution of sugar containing 85 Gm. of sugar in 100 c.c. of syrup, U.S.P. (66.7 Gm. in 100 Gm. of syrup, B.P.). Miscible with water or alcohol. It is more commonly employed in the form of the flavored syrups. Their dose is ad libitum.
Syrupus Tolu (*Syr. Tolu.*), U.S.P.; *Syr. Tolu.*, B.P.—Prepared from *Tr. Tolu.* *Dose*, 10 c.c., 2 $\frac{1}{2}$ drachms, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

GLUSIDE (SACCHARIN)

This substance, which is also sold under many trade names, has the formula, $C_6H_4SO_2CO-NH$, and is the anhydride of ortho-sulphamido-benzoic acid (the para-isomer is not sweet). In common with a number of other benzol derivatives, it has an intensely sweet taste, even in very dilute solutions. It passes through the body almost quantitatively unchanged, 75 to 90 per cent. being excreted by the urine within twenty-four hours, and the remainder in the feces. Consequently it has a very low toxicity. Small doses, up to 0.3 Gm. per day, continued for months, produced no deleterious effects, so far as ascertainable by available methods of investigation. Large doses, 0.75 to 1.5 Gm. per day, are also practically harmless, except for occasional minor disturbances of digestion (Herter and Folin, 1911). Single doses of 5 Gm. have been given without much effect (Adduco and Mosso, 1887).

Uses.—Saccharin is used as a substitute for sugar in diabetes (tablets of 0.03 Gm., $\frac{1}{2}$ gr. = an ordinary lump of sugar); as flavoring agent and adulterant of sweet foods; and as a mild antiseptic in fermentative dyspepsia (0.2 Gm., 3 gr., several times daily). Saccharin itself is but little soluble in water, but its sodium salt "*soluble saccharin*" dissolves readily. It may be prepared by adding 12 parts of sodium bicarbonate.

Sweetening Power.—This is 300 to 500 times as great as that of cane sugar. It is perceptible in dilutions of 1:100,000; 1:10,000 is agreeably sweet; with 1:1,000 it becomes bitter and disagreeable. Even with the more dilute solutions the quality of the taste is somewhat different from that of sugar and on continued use the persistent after-taste becomes very objectionable.

Effects of Continued Use.—Long-continued and detailed investigations were made for the Referee Board by Herter and Folin, 1911; Herter administered the sodium salt, Folin the free saccharin, in "small" doses to 0.3 Gm. per day, and "large" doses of 0.75 to 1.5 Gm., corresponding in sweetening power to 150 Gm. and to 375 to 750 Gm. of cane sugar respectively. The small doses produced no discoverable effects whatever. The large doses were also negative as to *metabolism* (total nitrogen, ammonia, uric acid, creatinine, sulphur—except that of the saccharin—chlorides, acidity and phosphates). The *kidneys* were not affected (no diuresis or sediments). There were no *general symptoms* or blood changes etc. The *digestive functions* were also generally unaffected (motor and secretory functions of the stomach, bulk of feces, etc.) even in patients with hyper- or hypo-chlorhydria; but occasionally there was slight hyperacidity and indications of

slight increase of intestinal putrefaction (urinary oxy-acids, indican, fecal H_2S , skatol, indol and acidity. The fecal gas flora remained unchanged). *In vitro*, the efficiency of all the digestive ferments was not altered by the concentrations which might occur in the body (except by the acidity of free saccharin, a factor which had been neglected in some of the earlier investigations; Riegler, 1895; Matthews and McGuigan, 1905). The *antiseptic action* was very slight.

The older literature contains reports of digestive and other disorders (Bornstein, 1900), especially after continued use (v. Jaksch); but these observations were not made with the same degree of accuracy.

The toxicity for animals is very low (Adduco and Mosso, 1887). Matthews and McGuigan observed depression, stupor, convulsions and nephritis. Herter, administering soluble saccharin to rabbits by stomach, found no effects with 4 to 5 Gm. per kilogram; double this dose was fatal in two hours, the autopsy showing violent gastro-intestinal irritation.

Use of Saccharin in Foods.—The preceding investigations show that no serious damage need be apprehended from the quantities of saccharin which would ordinarily be used. Larger quantities, however, tend to produce minor derangements, which could perhaps become more accentuated in pathologic conditions. The peculiar taste may also become repulsive and thus diminish appetite. For these reasons, and because saccharin has no food value, its indiscriminate use as a mere sweetening agent should be condemned, except in cases in which sugar is inadmissible.

Pouchet, Robin and Hayem, 1917, claim to have observed digestive disturbances, etc.; from the excessive use of saccharin. This was endorsed by the French Acad. de Med. Reynier, on the other hand, observed no bad effects in animal or human experiments.

PREPARATIONS

**Glusidum* (Glusid.), U.S.P., B.P.—Gluside, Saccharin, Benzosulphinidum; $\text{C}_6\text{H}_4\text{SO}_2\text{CONH}$, the anhydride of orthosulphamido-benzoic acid.—White, crystalline powder; odorless, or having a faint, aromatic odor, and intensely sweet taste in dilute solution. Slightly sol. in water (1:290); sol. in alc. (1:31); easily sol. in alkalies. *Dose*, as sweetening agent in diabetes, etc., 1:10,000 (0.1 gm. per liter, $\frac{1}{20}$ grain per ounce); or 0.03 gm., $\frac{1}{2}$ grain in place of ordinary lump of sugar (U.S.P.).

Glusidum Solubile (Glusid. Sol.), U.S.P.—Soluble Gluside, Soluble Saccharin, Sodium Benzosulphoxide, $\text{C}_6\text{H}_4\text{COSO}_2\text{NNa}_2\text{H}_2\text{O}$. Colorless prisms, or white, crystalline powder odorless; intensely sweet taste. *Dose*, as Gluside.

AROMATIC WATERS, SPIRITS, OILS AND TINCTURES

Aromatic Waters.—These are miscible with water or alcohol. Their dose is ad libitum.

Aromatic Spirits.—These are used in alcoholic and oily liquids, in the proportion of 2 per cent. They are immiscible with water.

Aromatic Oils.—These may be used for flavoring alcoholic or oily liquids, in the proportion of 0.2 per cent. However, the spirits are generally preferred.

Aromatic Tinctures.—These are used similarly to the Spirits. None of the simple tinctures are especially important.

Some flavors, such as Gaultheria, etc., have also more important actions, and will not be discussed here.

PREPARATIONS

Ol. Ajowan, B.P.—Volatile oil of fruit of *Carum copticum*. *Dose*, 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Anethi fructus, B.P.—Dill Fruit. From *Peucedanum graveolens*.

Aq. Aneth., B.P.—Dill Water.

Ol. Aneth., B.P.—Volatile oil. *Dose*, 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Anisi Fructus, B.P.—The dried ripe fruit of *Pimpinella Anisum*. *Dose*, 0.5 Gm., 8 gr.

Aq. Anisi, U.S.P., B.P.—Anise Water. *Dose*, 15 c.c., 4 drachms, U.S.P.

Sp. Anisi, U.S.P., B.P.—10 per cent. *Dose*, 1 c.c., 15 minims, U.S.P., 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

Ol. Anisi, U.S.P., B.P.—The volatile oil. *Dose*, 0.1 c.c., 1½ minims, U.S.P.; 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Cardamomi Semen, U.S.P., R.P.; Cardamom Seed.—The dried seeds of *Elettaria Cardamomum*. *Dose*, 1 Gm., 15 gr., U.S.P.

Tr. Cardam., U.S.P.—20 per cent. in 50 per cent. alcohol. *Dose*, 2 c.c., 30 minims, U.S.P.

**Tinctura Cardamomi Composita* (Tr. Cardam. Co.), U.S.P., B.P.—2 per cent. of Cardamom, with Cinnamon, Caraway and Cochineal, in 56 per cent. alcohol, U.S.P. *Dose*, 4 c.c., 1 drachm, U.S.P., 2 to 4 c.c., ½ to 1 drachm, B.P.

Carum, U.S.P.; *Carui Fruct.*, B.P.—The dried fruits of *Carum Carvi*. *Dose*, 1 Gm., 15 gr., U.S.P.

Aq. Carui, B.P.—Caraway Water.

Ol. Cari, U.S.P.; *Ol. Carui*, B.P.—Volatile oil. *Dose*, 0.1 c.c., 1½ minims, U.S.P.; 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Cinnamomum, U.S.P.; *Cinnamomi Cortex*, B.P.—Cinnamon. The dried bark of *Cinnamomum Loureirii*, U.S.P.; the dried inner bark of *Cinnam. zeylanicum*, B.P. *Dose*, 0.25 Gm., 4 grains, U.S.P.

**Aqua Cinnamomi*, U.S.P., B.P.—Cinnamon Water. A saturated solution of cinnamon oil, U.S.P.; water distilled from the bark, B.P. *Dose*, 15 c.c., 4 drachms, U.S.P.

Ol. Cinnam., U.S.P., B.P.—The volatile oil from *Cinnam. Cassia*, U.S.P., *C. zeylanicum*, B.P. *Dose*, 0.1 c.c., 1½ minims, U.S.P.; 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Pulvis Cinnamomi Compositus, B.P.—(*Pulvis Aromaticus*.) Equal parts of Cinnamon, Cardamom and Ginger. *Dose*, 0.6 to 4 Gm., 10 to 60 grains, B.P.

Sp. Cinnam., U.S.P., B.P.—10 per cent. of oil. *Dose*, 2 c.c., 30 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

Tr. Cinnam., B.P.—20 per cent. of the bark. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

Coriandri Fructus, B.P.—Coriander. The dried ripe fruit of *Coriandrum sativum*.

Ol. Coriandri (Ol. Coriand.), U.S.P., B.P.—Volatile oil. *Dose*, 0.1 c.c., 1½ minims, U.S.P., 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Fœniculi Fructus, B.P.—(Fennel seed.) The dried ripe fruits of cultivated varieties of *Foeniculum vulgare*.

Aq. Fœnic., U.S.P., B.P.—Fennel Water. *Dose*, 15 c.c., 4 drachms, U.S.P.

Ol. Fœnic., U.S.P.—The volatile oil. *Dose*, 0.1 c.c., 1½ minims, U.S.P.

Fenchon is a constituent of fennel oil. It is isomeric with camphor, but is liquid. It is used as a counter-irritant, as such or diluted with alcohol; to 1:10 (Schlesinger, 1914).

Ol. Graminis Citrati, B.P.—Oil of Lemon Grass. *Dose*, 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Ol. Lavand., U.S.P., B.P.—A volatile oil distilled from the fresh flowering tops of *Lavandula spicata*. *Dose*, 0.1 c.c., 1½ minims, U.S.P.; 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Spir. Lavand., 5 per cent. of oil, U.S.P.; 10 per cent., B.P. *Dose*, 2 c.c., 3 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

Tr. Lavand. Co., U.S.P., B.P. (Compound Spirit of Lavender).—Lavender, Rosemary, Cinnamon, Clove, Myristica, Red Saunders, in 75 per cent. alcohol, U.S.P. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., ½ to 1 drachm, B.P.

**Aqua Menthe Piperite* (Aq. Menth. Pip.), U.S.P., B.P.—Peppermint Water. *Dose*, 15 c.c., 4 drachms, U.S.P.

Aqua Menthe Viridis (Aq. Menth. Vir.), U.S.P., B.P.—Spearmint Water. *Dose*, 15 c.c., 4 drachms, U.S.P.

Oliveri Cort., B.P.—The bark of *Cinnam. Oliveri*.

Tr. Oliver. Cort., B.P.—10 per cent. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

**Aqua Rosæ* (Aq. Ros.), U.S.P., B.P.; Rose Water.—A 50 per cent. dilution (33 per cent., B.P.) of Stronger Rose Water.

Aqua Rosæ Fortior, U.S.P.—Prepared by distilling the fresh flowers of *Rosa centifolia* with water.

Ol. Ros., B.P. (Otto of Rose).—The volatile oil of the fresh flowers of *Rosa damascena*.

Oleum Sassafras (Ol. Sassaf.), U.S.P.—A yellow or reddish yellow volatile oil distilled from *Sassafras* root. *Dose*, 0.1 c.c., 1½ minims, U.S.P.

ERIODICTYON (YERBA SANTA)

The leaves of this plant disguise bitter taste (not sweet, salt or acid taste). It is, however, therapeutically objectionable. It probably renders alkaloids insoluble, and as for ordinary bitters, it is extremely probable that the therapeutic action is connected with the bitter taste. One c.c. of the fluidextract covers the taste of 0.012 Gm. of quinine sulphate or 1.5 Gm. of quassia.

Similar properties are found in the following plants: *Gymnema sylvestre*; *Bulme-nia dulcifica*, and *Phrynium Danielli*. *Gymnema* contains gymnemic acid, which destroys bitter and sweet taste, not acid or salt.

PREPARATIONS

Eriodictyon, U.S.P. (*Yerba Santa*).—The dried leaves of *Eriodictyon californicum* (Composition, Tutin, 1910). *Dose*, 1 Gm., 15 gr., U.S.P.

Fldext. Eriodict., U.S.P.—*Dose*, 1 c.c., 15 minims, U.S.P., precipitated by water.

THE ADMINISTRATION OF DRUGS

The methods of administering drugs vary according to whether a strictly local action is desired, or whether it is aimed to have a drug distributed through the body, to secure "systemic effects." In the latter case, there are a considerable number of methods available, which have special advantages and disadvantages.

Local applications may have the object of protecting a surface, or of producing reflex effects; or they may be used as antiseptics or local stimulants; or for absorption and systemic actions.

METHODS OF ADMINISTRATION USED CHIEFLY FOR SYSTEMIC EFFECTS

These require that the introduction or absorption of the drug should be sufficiently quantitative, or at least uniform, to insure definitely controllable effects. This condition is usually best met by the alimentary tract, and by injection under the skin, into the muscles, or directly into the circulation. Gaseous substances are administered by inhalation.

Absorption and systemic effects may occur from other surfaces, mucous membranes, serous cavities etc., which are utilized primarily mainly for local administration. They may then lead to toxic side-actions.

Oral Administration.—This is the most ancient, the most natural, and still the most widely used method of administration. Its chief advantages are its convenience to the patient and its relative freedom of local damages. However, irritant drugs do give rise to disturbance of digestion. This can be minimized by giving them in such a form that they will not be rapidly dissolved in the stomach (pills), or by giving them at a time when the stomach is filled with food. Absorption is, of course, also delayed by these means. *Pills* should never be employed for insoluble powders or for corrosive drugs which require dilution.

Absorption from Alimentary Canal.—The absorbing power of the stomach is relatively low, even for water and soluble substances (Hirsch, 1892); so that the main absorption does not occur until the drug has reached the small intestines. The effects, with gastric administration, are therefore relatively slow and may be too slow for emergencies. The passage is quickest if the drug is taken when fasting and with water; somewhat slower with milk, soup or wine; slowest after eating, especially when administered dry (Moritz, 1898).

The conditions in the *small intestines* are very favorable for absorption, which is aided by the long sojourn, the extensive surface, the folds and villi, the segmental movements, etc.

The *relative rôle of the stomach and intestine* in absorption varies for different drugs and animals. Strychnine, *e.g.*, is absorbed from the stomach with dogs and cats, but not with rabbits and guinea pigs; whereas sodium salicylate and iodide give just the opposite result. Inoye and Kashiwado (1905) have shown that atropine and rhubarb are not absorbed from the dog's stomach, whilst salol is absorbed. The data as to man are insufficient.

Alterations of Drugs in the Alimentary Canal.—Some drugs are destroyed so extensively in their passage through the intestines, that oral administration is not sufficiently effective. This applies, for instance, to the antitoxins, insulin, epinephrine and arsphenamine. Glucosides are also partly destroyed, so that the oral dose must be larger. On the other hand, drugs which require the action of the digestive juices for their solution (resins, oils, etc.) are more efficient by mouth than by other channels. The oral route is of course the only one for drugs intended to act locally on the upper parts of the digestive tract. With absorbable drugs, however, the actions on the alimentary tract are chiefly systemic; *i.e.*, absorbable drugs are apt to act on the intestine more powerfully when they are administered by vein, than when they are taken by mouth (Uhlmann and Zwick, 1920).

Rectal Administration.—The stomach and small intestine may be avoided by giving the drugs per rectum, either in the form of enema or suppositories. The rectum is a fairly good absorbing surface for many soluble substances; so that the effects are often greater or more prompt than with oral administration (*f.i.*, for salts, narcotics etc.).

Enemata, when introduced for the absorption of the medicine, should be as small as possible, but not so strong as to produce local irritant effects. 1 or 2 ounces is usually the proper quantity, the rectum being first cleansed with warm water. When enemata are employed for their mechanical effects, the amount must, of course, be much greater—1 or 2 pints. These should be raised to the body temperature.

The time of administration influences the action of drugs. Hypnotics and cathartics, for instance, are most effective when their action coincides with the natural time of sleep and defecation, and if the external conditions are favorable. Stomachics are best given shortly before meals. Drugs which are to be absorbed rapidly are given on an empty stomach, whereas irritants are administered just after meals, when the stomach is protected by food; etc.

Subcutaneous or Hypodermic Administration.—The injection of solutions through a hollow needle into the loose subcutaneous tissue has the advantage of securing quicker and more certain effects, and more exact dosage.

Hypodermic injections are generally made into the forearm, arm, thigh, or nates. For very bulky injections, *e.g.*, for antitoxin or for saline solution, the loose areolar tissue of the subscapular or mammary region is chosen. The subcutaneous dose may often be made somewhat smaller than the oral dose. The *rapidity of absorption* from hypodermic injections may be hastened by massage, by distributing the injection over several places, and by dissolving the drug in a *small* amount of fluid. The concentration in salts should not exceed that of the blood, or the injection will be painful. Normal saline solution is the least irritant solvent for alka-

loids. Subcutaneous injection is naturally inadmissible, if *local* effects in other parts of the body are desired (e.g., for stomachics, cathartics, locally acting emetics, etc.).

The hypodermic injection of drugs that are not local irritants produce little discomfort and no after-effects, provided that reasonable asepsis is preserved. Irritant drugs, however, cause severe pain, and may be followed by induration, sloughing and abscess.

Hypodermic injection was probably first practiced by E. Rynd, 1844, but was introduced practically by Alex. W. Wood, in 1853. Pravaz invented his syringe in 1853, for the injection of aneurisms (Macht, 1916).

Intramuscular Injections.—These are made by thrusting the needle through the skin deep into the substance of the gluteal or lumbar muscles. The absorption is more rapid than with subcutaneous administration (Meltzer and Auer, 1904), and the irritation and tendency to abscess formation are less. Auer and Meltzer, 1911, advise the sacro-spinal muscles in preference to the gluteal, as giving better absorption with less pain and other complications.

Relatively insoluble powders suspended in oil, may be injected intramuscularly, to establish a depot for the gradual absorption and continued action of a drug, such as mercury salicylate in the treatment of syphilis. Mineral oils must not be injected under the skin, as they are not absorbed and give rise to tumors.

Precautions in Intramuscular Injections.—A careful technic is necessary for injections near any nerve; for instances, *scialic neuritis* has followed arsphenamine injection (A. Kissmeyer, 1916).

Intravenous Injection.—The injection of aqueous solutions into the blood stream may be necessary in the case of a few substances for which other methods are not available; for instance, those that are decomposed in the digestive tract, and those that are not satisfactorily absorbed or that produce irritation from the subcutaneous tissues. Arsphenamine is the most important example. Intravenous administration may also have a very important field in emergencies, to secure an immediate action. Aside from such definite indications, intravenous injections should be avoided, for they always imply a greater risk to the patient than do the other methods of administration. The danger is not so much in errors of the surgical technic, which is generally rather simple; but in the fact that the injection of a foreign substance into the blood stream alters the equilibrium of its colloids, and this may result in alarming and even fatal reactions. Substances that are definitely incompatible with blood, such for instance as acids or metallic salts, are especially dangerous; but almost all substances may apparently produce such reactions in some individuals, under conditions that are not understood and cannot be foretold (Hanzlik and Karsner, 1920; Hanzlik, de Eds, and Tainter, 1925; see index, Allergic Reactions). With many substances accidents are so rare that there should be no hesitation in giving these intravenously, if an emergency demands the immediate effect of the drug, or if the drug cannot be given effectively by the less risky channels; but unless special indications such as these exist intravenous therapy is not justifiable.

Intravenous injections are usually made into the veins of the arm. Slowness of injection reduces the liability to reactions.

Intravenous medication has been employed quite extensively for substances and under conditions for which it presents no serious advantage, but rather decided disadvantages.

The instantaneous action is only necessary in emergencies; otherwise it is not an important advantage, and is generally undesirable, especially if continued rather than acute effects are desired. The concentration of the drug during the injection rises materially above the level of the continuous dosage, and may result in brief but stormy reactions that differ in kind as well as in degree from the ordinary actions of the drug. The "primary fall of blood-pressure" that is apt to occur with all kinds of intravenous injections has always been an annoying complication to experimenters on animals; and it is no less annoying in clinical practice.

Exact dosage has been claimed as an advantage of intravenous therapy, but the claim is somewhat misleading. Intravenous injection controls the quantity of drug introduced, but exact dosage really means the exact adjustment of the quantity to the desired effect. This is often more difficult with intravenous than with oral administration; for with the latter, the physician can begin with a relatively small dose, and add further doses, according to the response of the individual patient. With intravenous injection, such frequent repetitions are usually not very practicable, and consequently the dosage is often too large or too small.

Avoidance of gastro-intestinal irritation is also a rather misleading claim; for the most difficult element of these disturbances is often central, and in that case (for instance, with digitalis) the nausea and emesis are not diminished by intravenous injection. The strictly local irritation can often be avoided by suitable methods of oral administration, for instance, free dilution with water or food, etc.

On the other hand, drugs that directly irritate the alimentary tract are also likely to irritate the walls of the veins, and produce fibrosis and thrombosis. Aside from the temporary discomfort, this renders the vein unsuitable for further injections; this may be a serious matter later, should a real occasion for intravenous therapy arise.

Intravenous injection was tried rather extensively in the seventeenth century, but its modern application dates from Landerer, 1881, and F. Mendel, 1903 (history, Epstein, 1915; Macht, 1916; Eggleston, 1917).

Inhalation.—This method is used only for gaseous medicines, such as anesthetics or oxygen.

When giving drugs by inhalation, it must be borne in mind that the effect does not depend upon the quantity given, but the concentration of the gas and the time during which it is administered. The rich capillary area of the alveoli is one of the best absorbing surfaces, so that the action is very rapid. The lungs also absorb fluids and dissolved substances rapidly, if these are introduced through the trachea.

Absorption of Fluid from the Lungs.—This far surpasses ordinary conceptions: Semmla states that Gobier poured about 30 liters of water into the trachea of a horse. Instead of killing the animal, the water was absorbed. Colin ran a *continuous* stream of warm water into the trachea of a horse, at the rate of six liters per hour: This eventually killed the animal by direct water-injury of the lungs and tissues: but no trace of the water was found in the lungs. Dogs received 200 c.c., rabbits 30 to 40 c.c. of fluid into the trachea without damage. Similar observations are described by Winternitz. One accidental experiment on man was recorded by Bichat. A stomach tube was inadvertently introduced into the trachea, and through it bouillon was poured into the lung and absorbed "without disturbance."

If the fluid is injected much more rapidly than it can be absorbed, it will of course produce asphyxiation.

Absorption of Dissolved Substance from Lungs.—This is also very rapid. If ferrocyanide in solution is injected into the trachea, it can be demonstrated in the carotid blood in 2 minutes. Claude Bernard showed that opium alkaloids are much more active by trachea than when injected hypodermically.

METHODS OF ADMINISTRATION USED CHIEFLY FOR LOCAL EFFECTS

Subcutaneous Injection for Local Anesthesia.—Solutions of substances that paralyze the sensory nerves are injected into and under the skin,

and into nerve trunks. Since absorption would diminish the local action and increase the undesired systemic effects, it is often advantageous to restrict the local circulation, either by the injection of epinephrine, or by compressing the blood-vessels.

Intracutaneous Injections.—Injections made into the tissue of the skin proper (instead of under the skin) are used for provoking local reactions, for instance diagnostic skin reactions (protein idiosyncrasies, tests for susceptibility to diphtheria and scarlatina, tuberculin reaction); also for local "infiltration anesthesia." They are not suited for systemic administration; for the paucity of the blood-vessels makes the absorption much slower than with hypodermic injections. However, even solid elements may be gradually absorbed (Kasahara, 1916).

Intracerebral injections (i.e., into the substance of the brain) have been used experimentally. The injections are at once conveyed to the ventricles and produce local and mechanical effects often different from the systemic action of the drug.

Subdural Injections.—These are used if the drug is to act directly on the spinal cord or nerve roots, especially for spinal anesthesia, and for colloidal drugs that do not readily penetrate the nervous substance from the blood; for instance, tetanus antitoxin, arsphenamine in cerebral syphilis, etc. The technic is that if lumbar puncture, some cerebrospinal fluid being withdrawn before the injection is made. The procedure may be dangerous; especially if the poison produces local effects or is conveyed directly to the medulla.

Drugs intended to act on the central nervous system are generally more active if administered in this way. For instance, Lewandowsky, 1900, found that strychnine is ten times as efficient when injected intraspinally than when injected intravenously.

The efficiency of the absorption of drugs from subdural injections into the general circulation is in dispute. Becht, 1920, found no systemic effects after subdural injection of epinephrine, nicotine and secretin, so that their absorption must be very poor. He attributes the contrary results of Meltzer and others to direct entrance into veins.

Irritation on Permeability of the Meninges.—The observations appear discordant. Stollmann and Swift, 1915, found no change in the absorption of arsphenamine. Carnier, 1916, claims that the inflamed meninges are very permeable to phlorhizin. Mehretus and West, 1917, state that they are less permeable to phenolsulphonephthalein.

Subarachnoid Irrigation.—This has been tried experimentally (Weed and Wegforth, 1919). Normal saline produced toxic effects, but Ringer's solution appeared harmless and prolonged the life of animals with meningeal infection.

Subnasal Injection.—Injection under the mucous membrane of the nasal septum gives extremely rapid absorption, the efficiency approaching intravenous injection (Pilcher, 1914, 1915).

Intrapericardial Injections.—Solutions are quite rapidly absorbed from the pericardial sac into the heart-muscle. Gunn and Martin, 1915, suggest that this could be utilized in epinephrine-resuscitation.

Intracardiac injection is now more commonly employed for this purpose; see under Epinephrine.

Intraperitoneal and intrapleural injections are used in experimental technic, and resemble subcutaneous injections, the drug being absorbed more rapidly. Intraperitoneal injections in man have been made by Schmidt and Meyer (1905), but are not recommended. The pleura absorbs through the parietal and pulmonary surface; but the absorption is less than from the peritoneum (Naegeli, 1913). In both membranes, it occurs by the blood rather than lymph. Gravity plays a part, the absorption being rather better with pelvis down position (Dandy and Rowntree, 1914).

Intrahepatic Injections.—Waddell, 1923, suggests that these may be utilized in place of intravenous injections, for small laboratory animals, i.e. frogs, turtles and rats.

Applications to Mucous Membranes.—Antiseptics, protectives (demulcents) and other drugs are applied as washes, injections, gargles and ointments in the local treatment of accessible mucous membranes.

Systemic effects may arise, since practically all mucous membranes absorb readily (Macht, 1917, 1923). There are quantitative differences, however; for instance, the urinary bladder absorbs poorly, the urethra very easily.

Electrophoresis.—This process has been employed in dentistry to facilitate the penetration of cocaine, but it has not as yet found very extensive adoption in medicine and surgery. It is a process by which the molecules are carried from the + to the - pole. The solution to be introduced must possess a higher conductivity than the liquid of the tissues.

Respiratory Tract.—The nasal mucous membrane may be reached by dropping or snuffing a solution or ointment into the nostrils; by douching, by swabbing, by inhalation and by spraying. It is very sensitive to metallic astringents and even to water. Solutions should therefore be made isotonic, or the drugs may be dissolved in liquid petrolatum.

The Mouth, Pharynx and Epiglottis.—These are reached by gargling, with the added benefit of mechanical cleansing. A small amount of the fluid may reach the glottis.

Inhalations for Local Action.—These are most effectively applied by evaporating the substance with steam; either by placing it on boiling water and inhaling the steam through a funnel; or by a "steam-atomizer." The steam itself is usually beneficial. It condenses, with the evaporated substance, on the surface of the upper respiratory tract, and so forms a depot which continues the inhalation of the drug for a time after the steaming.

To reach the lower air passages, the steam should be inhaled deeply with the nostrils closed, the mouth wide open, and the tongue protruded. Even so, the numerous branching surfaces prevent the spray from reaching any but the larger bronchi (Semmola). However, the churning of the respiratory movements tends to distribute the condensed material rather widely through the lungs, and so give an extensive surface favorable to evaporation.

"Sprays."—These behave similarly to the steams, but are generally not inhaled as deeply, and lack the heat of the steam. They are used mainly for effects on the nose, pharynx, larynx and sometimes the trachea.

Intratracheal Injections.—Small quantities, 2 or 3 c.c., of oily solutions (for instance, of menthol) may be injected directly into the trachea, usually through the glottis. They are then distributed by respiration, similarly to the sprays and steams (Balvay, 1921; J. A. Thompson, 1897). Their advantage does not seem very apparent.

Conjunctiva.—This absorbs easily, so that systemic effects often follow the application of drugs, for instance, atropine, to the eyes. A few milligrams of apomorphine applied to the conjunctiva of a dog suffices to produce vomiting (Macht, 1917).

Vagina.—This absorbs freely, and clinical poisoning by this channel is frequent, especially in connection with the improper use of mercuric chloride douches (Macht, 1918, references).

Uterine Cavity.—This is also an absorbing surface (iodine, Higuchi, 1908).

Urethra.—This absorbs very readily, so that poisoning has frequently occurred from the excessive application of local anesthetics.

The laws of the absorption of local anesthetics have been studied by Sollmann, 1918 (*cf.* Local anesthetics). The rapidity of absorption is

illustrated by the injection of 1 per cent. apomorphine into the urethra of a male dog; vomiting occurs in 3 to 5 minutes (Macht, 1918).

Urinary Bladder.—This absorbs very poorly. Strychnine, apomorphine and morphine are almost harmless when injected into the bladder, if the urethra has been tied (*cf.* Macht, 1918). Even salts and water are absorbed poorly.

Ureter and Renal Pelvis.—These absorb fairly well. This enjoins caution in the use of silver salts etc., for skiagraphs (Macht, 1918).

Wounds.—These naturally absorb readily if their circulation is good. This includes abraded surfaces, blisters etc. Old ulcers, with defective circulation, may absorb poorly.

Application to the Skin.—This is practiced especially in the following forms: Ointments and plasters, especially for prolonged contact; liniments, especially for reflex stimulation; watery or alcoholic solutions, watery “washes” or moist dressings, especially for antiseptics; dusting powders; poultices etc. They are generally intended for local actions, for absorption from the skin is poor and uncertain. It is not negligible, however, and systemic effects sometimes arise when they are not desired. The most important use of the skin for systemic therapy is in mercurial inunction. In this case the ointment is vigorously rubbed into the skin, so as to press the liquid mercury into the hair follicles and gland ducts, where it is gradually changed into absorbable compounds.

The lower layers of the skin absorb readily, but the stratum corneum is very little permeable to most substances. Absorption is therefore greater where the epidermis is thin, in the axilla, loins, and the inner surface of the arms and thighs. The permeability also increases if the epidermis is saturated with water, by prolonged maceration or by perspiration. Increased vascularity of the skin favors absorption by carrying away the absorbed drug and thus maintaining a steeper concentration-gradient. Oils and ointments delay the absorption of fat-soluble substances, such as phenol, mustard oil, or dichloroethyl sulphide, analogous to the partition of a substance between good and poor solvents in a test tube (Sollmann, 1918). The influence of the ointment base varies, therefore, according to the substance (Sauerland, 1912).

CONDITIONS INFLUENCING ABSORPTION

The time required for absorption into the body and into the cells ranges from a few seconds (*e.g.*, hydrocyanic acid), to several weeks (*e.g.*, lead). The rapidity of absorption depends upon the nature of the drug, the place of administration, and a number of accessory factors. The place of administration has been discussed in the preceding section.

Solubility.—Only soluble drugs can be absorbed (except the small quantities taken up by phagocytosis); but the solubility in the protein containing fluids of the body is not necessarily the same as the solubility in water. The solubility may also be modified by chemical changes produced by the digestive or tissue juices.

Solid Substances.—These are practically unabsorbable from the alimentary tract, although Koellicker and many others, on feeding rabbits with carbon, found particles in the prevertebral and mesenteric ganglia.

There is always considerable uncertainty in the absorption of solid substances, even when they are soluble. They should therefore be avoided unless a very slow action is desired.

Influence of Colloids, Etc.—Oil, gums, extractives, kaolin and other colloids hinder absorption, partly by adsorption of the drug, partly by hindering its access to the absorbing surface. The presence of food in the alimentary canal has a similar action. The isolated active constituents (alkaloids, etc.) are preferred if a quick systemic action is desired, whilst the galenic preparations (extracts, tinctures, pills, etc.) are used for local effect. In case a crude drug contains several active ingredients, the employment of the isolated constituents also gives more definite results.

Fuller's Earth on Alkaloids.—Fuller's earth (hydrous aluminum silicate) has a high adsorbing power, especially for alkaloids—varying, however, in degree with different samples (Lloyd, 1916; Fantus, 1915; Seidell, 1918). McGuigan, 1914, found that this renders strychnine insoluble in acid fluids, so that the bitter taste develops quite slowly; and that it delays and diminishes the tetanic action in frogs. Fantus, 1915, finds that the combination is not dissolved in the stomach, but dissociates gradually in the intestines. He also investigated the suitability of the earth as alkaloidal antidote, and found it very limited. It is somewhat improved by the addition of tartaric acid or acid sodium phosphate; it is highest against morphine, cocaine, nicotine and ipecac; and least efficient against strychnine, aconitine and colchicine. The effects of kaolin and related substances were also investigated by Friedberger and Tsuneoka, 1913.

Clowes and Walters, 1920, claim that the fuller's earth adsorbate is not broken up by sodium bicarbonate as assumed by the other authors; but that this requires the presence of soap or other unnamed constituents of protoplasm. Sollmann had found that bile salts, whose general properties resemble those of soaps, do not liberate demonstrable quantities of emetine.

Sabbatani, 1913, found considerable antagonism between strychnine and colloidal carbon when mixed *in vitro*. The intravenous injection of the carbon also furnished some protection against the oral administration of strychnine; but this was too uncertain for practical application.

v. Paulucci, 1915, showed that fatty substances (including petrolatum) diminish the toxicity of strychnine, both hypodermically and with direct application to the nerve centers.

Concentration.—The absorption varies generally in the same direction as the concentration, especially for hypodermic injections; but the relation is not a simple one. Absorption tends also to increase with the *extent of absorbing surface* (e.g., by making multiple hypodermic injections). This seems to be less important in the intestines (Sollmann and Hanzlik, 1911–1913).

Changes of the Absorbing Cell.—In the alimentary canal, injury to the absorbing cell may either facilitate or hinder absorption; astringents tend to have the latter effect, corrosives and simple irritants the former.

Sollmann and Hanzlik found that phenol, alcohol, iodide, and probably other substances tend to inhibit their own absorption; so that the absorption, at first very rapid, is promptly slowed.

Circulation.—The rapidity of absorption is proportional to the rapidity with which the drug is removed; just as a burning lamp-wick absorbs the oil more quickly (Mialhe). It therefore increases with the rapidity of the circulation and of the lymph flow. Active hyperemia (hot air; Klapp, 1901) and hemorrhage hasten absorption: while it is delayed by venous stasis, passive congestion, deficient heart action, vasoconstriction, catarrh, etc. Increase of lymph flow, by moderate *distention* and *massage* also quickens absorption. Excessive distention diminishes absorption by slowing the local lymph flow (Hamburger, 1907).

Absorption in Absence of Circulation.—Considerable absorption occurs when the circulation has stopped. Thus, strychnine and morphine are absorbed by frogs with ligated hearts, producing interesting modifications in their actions (Meltzer, 1911–

1913). Abel, 1912, and Abel and Turner, 1914, believed that the solutions in cardiac-tomized frogs are circulated by the lymph hearts; but Meltzer, 1914, Joseph, 1914 and Githens and Meltzer, 1915, affirm that general effects from the local injection of strychnine, fuchsin or epinephrine may occur even when all the lymph hearts are definitely excluded, the absorption occurring through the lymph spaces.

The absorption in frogs is delayed by destruction of the spinal cord (Filippi, 1912). *Considerable absorption occurs also in dead animals* (Solimann and Hanzlik, 1913), probably by diffusion.

Absorption by Blood and Lymph.—Most soluble substances are absorbed from the alimentary canal by the blood, rather than the lymph. This also holds for the serous cavities; methylene blue injected into the peritoneum or pleura, for instance, appears in the urine before it is seen in the thoracic duct (Starling and Tubby). A few drugs, however, take the lymphatic path. Tetanus and diphtheria toxin, and perhaps other toxins, are absorbed from the local injections by the nerve sheaths, and reach the central nervous system along these (Meyer and Ransom, 1903; Meyer, 1915; C. W. Field, 1907). These toxins are more active on hypodermic or intramuscular than on intravenous injection, since apparently they reach the nerve centers in more concentrated form by the lymph than by the blood.

DISTRIBUTION AND CHANGES IN THE TISSUES

Sojourn in the Blood.—The passage of absorbed or injected substances from the blood into the tissues is a very rapid process for diffusible substances, and materially slower for colloids.

Masoin (1903) found the time which elapses before just toxic doses disappear practically completely from the blood, after intravenous injection, to be for arsenic, nine-tenths to thirty seconds; cyanides, two to six minutes; diphtheria toxin, four minutes; antitoxin, several hours.

Sojourn of Dyes in Blood-stream.—This has been investigated in the development of methods for measuring the blood volume. One group remains in the plasma for long periods; another group is excreted rapidly by the urine; and a third group disappears from the plasma, but is not excreted by the kidneys. These groups have no apparent relation to the chemical structure (Dawson et al. 1920).

Distribution of Drugs Within the Body.—Drugs are not distributed uniformly, but accumulate especially in certain cells, according to their permeability and physical and chemical affinities. This influences their action; either by bringing them in contact with reactive tissues, or by storing them in places where they may be inactive. The distribution has been studied in relatively few cases, especially for inorganic poisons; but the data are not sufficient to permit generalizations. The distribution appears to be altered by disease; e.g., degenerating tissue takes up more iodide, etc.

Storage Places.—The chlorides, bromides, and related ions accumulate in all organs, but mainly in the skin and blood. The thyroid stores a relatively high percentage of iodine as iodothylin. The bones retain the earthy metals and fluoride. The heavy metals are deposited as loose organic compounds, especially in the liver and spleen; mercury as a loose globulin compound; arsenic as a more stable nuclein combination (Vamossy, 1905). The iron deposits serve as a reserve stock of this metal. Little is known about the distribution of organic poisons, mainly for want of suitable assay methods.

Chemical Changes in Drugs.—The majority of poisons are more or less altered in the body, and generally rendered less harmful. This is effected by the oxidation, reduction, hydration or dehydration, or other decomposition of the poison, or by the storage of the poison in certain organs, or by its combination with other substances which render it harmless. This process of disintoxication is of great practical importance. It makes it necessary to administer the drugs progressively in order to maintain their effect; it often requires the use of continuously increasing

doses as the power of disintoxication becomes more developed; and were it not for the power of the body to destroy or remove poisons, and thereby to recover from their action, all therapeutic use of drugs would be impossible.

On the other hand, the alteration of the drug by the body may result in a more toxic substance, as in the case of the nitriles; or may render it more effective therapeutically as with arsphenamine.

Decomposition by Digestion.—The digestive juices destroy some organic poisons by hydrolytic cleavage; especially the proteins, toxins and antitoxins, and the glucosides. On the other hand, they are necessary to saponify and liberate the active constituents of insoluble esters, *e.g.*, phenyl salicylate. The acidity of the gastric juice is important for the solution of bases. It also often splits off acyl groups.

Decomposition in Tissues.—Strychnine and many other poisons are partly oxidized in the body. Morphine is largely destroyed, especially by those accustomed to its use. Reid Hunt (1905) has shown that feeding with *thyroid* markedly diminished the toxicity of acetonitrile, by preventing its conversion into cyanide. The resistance to morphine is also modified. It has been claimed that excision of the thyroids increases the toxicity of a number of other poisons; but Lerda and Diez, 1905, obtained negative results with caffeine, strychnine, urine, and tetanus and diphtheria toxin. Organic compounds of metals (cacodyl, etc.) only develop the metal action after oxidation. Many organic acids (citric, etc.), alcohol and formaldehyde, are oxidized, and thus disintoxicated. Methenamine is activated by the liberation of formaldehyde in acid urines. The benzol ring is very resistant, most of the changes occurring in the side-chains.

Disintoxication by the Liver.—This is believed to be especially active in disintoxication, partly by destroying, but particularly by storing poisons, so that the same dose is much less effective (perhaps one-half) when given by the mesenteric, than by the jugular vein. This has been demonstrated for curare, strychnine, morphine, cocaine, veratrine, quinine, atropine, and the metals. Perfusion of alkaloids, glucosides, toxins, barium, etc., through excised liver, also decreases their toxicity (Woronzow, 1912). Liver emulsions seem to be less active. They did not destroy strychnine, but attacked caffeine (Petron, 1905). Experiments with Eck's fistula gave rather negative results (Rothberger and Winterberg, 1905).

Other Organs.—Perfusion through excised *muscle* also produced disintoxication, but weaker than the liver, with chloral, atropine, physostigmine, curare and alcohol, not with muscarine and ricin (Woronzow, 1912). Excision of the *spleen* is said to increase the toxicity of most alkaloids, but not all. The *phagocytes* accumulate and thus disintoxicate poisons, especially colloids. The *serum* of atropine-resistant animals destroys atropine.

Disintoxication by Adsorption.—The disintoxication is sometimes apparently an adsorption phenomenon. For instance, pilocarpine is detoxicated for excised intestine by digestion with serum; but may be recovered from this in fully active form by extraction with acid alcohol, so that it was not destroyed. The nature of the adsorbing substance is not known. It is abundant in rabbit serum, less in that of cats or oxen, and is absent from dog's blood (v. Leeuwen, 1918, Beutner, 1925).

Disintoxication by Combination.—Phenols and other aromatic compounds are rendered less toxic by combining with sulphates; many metals by the proteins; toxins by antitoxins; acids by alkalies; aldehydes, camphor, chloral and ethereal oils by glycuronic acid; cyanides by sulphur; benzoic acid by glyccoll; etc. The extent of the disintoxication depends upon the activity of the metabolic processes which are concerned, or on the amount of neutralizing substance present in the body.

THE EXCRETION OF DRUGS

Channels of Excretion.—This occurs mainly through the urine and feces, and with volatile drugs through the lungs. The sweat and, indeed, all the secretions play a minor part. The relative importance of the different channels varies for each drug, the reasons being but little understood. The rapidity is proportional to the circulation and to the functional activity of the excretory organs, and may be increased by the factors which stimulate these.

The excretion of certain drugs appears to be limited by their existing in the body in the form of combinations. The elimination of these is favored by substances which displace them from the compounds. This is probably the explanation of the increased excretion of iodides on the administration of chlorides, and possibly of the favorable effect of iodides in chronic poisoning by metals.

Excretion of Sweat.—A considerable number of drugs are thus excreted (iodides, bromides, borates, phenol, salicylates, antipyrine, methylene blue, As, Hg). The quantities are too small to make them significant for elimination, but they may help to explain exanthemata.

Excretion by Saliva.—This is rather limited, and is only important for the haloids (iodides) thiocyanates, K and NH_4 , Hg and Pb, menthol and guaiacol, methenamine, and some alkaloids (morphine and quinine). The excretion generally begins within twenty minutes and may last over nine hours (Howe, 1912).

Passage into Cerebro-spinal Fluid.—Inorganic substances are excreted into this only in a slight degree; iodides and bromides are generally present. Many organic substances pass into it much more freely. Alcohol, chloroform, acetone and methenamine occur constantly in about one-third the concentration of serum (Hald, 1911).

Aniline dyes are not generally found in the cerebro-spinal fluid or in the gray matter after intravenous injection. Those that are liposoluble are found in the gray matter.

The passage into the cerebro-spinal fluid varies also with the species. Picric acid penetrates in dogs, cats and guinea pigs, but not in rabbits (L. Stern and Gautier, 1918).

Passage to Fetus.—The more important drugs which have been demonstrated are: ferrocyanide (Mayer, 1871); chloroform, ether, CO , ethyl bromide, atropine, morphine, scopolamine, chloral, salicyl, quinine, benzoic acid, phlorhizin, alcohol, nitrate, urea, methylene blue, As, Hg, KI, KBr (Kehrer, 1907).

Toward colloids, the placenta acts as an ultrafilter; so that colloidal dyes, and presumably proteins, do not pass into the fetal circulation (Shimidzu, 1923).

DOSAGE (POSODOLOGY)

Definition.—Drugs are administered to produce a desired effect, and the dose must be sufficient for this purpose, and neither too small, nor too large. Since the effect is influenced by numerous conditions, it is impossible to state exact doses for any drug; experience is the only safe guide. However, the doses vary under ordinary conditions only within rather narrow limits, so that it is feasible to state the *customary* or *average dose*, as is done in the U.S.P. and in this book; *i.e.* the dosage which will ordinarily produce the typical effects. Unless otherwise stated, these doses apply to adults of average size, and to oral administration.

The "*maximum dose*" signifies the largest dose which can be safely used in ordinary cases; the "*minimum dose*" is the smallest dose which produces therapeutic effects; a "*toxic dose*" is one which produces dangerous effects; the "*just fatal dose*" is that which is just sufficient to cause death; the "*physiologic dose*" (a rather indefinite term), is used in physiologic experiments on animals.

Variations According to Administration.—The different methods of administration, by altering the rapidity of absorption, produce quantitative differences in the effects, and therefore in the dosage. Since these vary with each drug, they must be determined by observation. General ratios of oral, rectal and hypodermic doses, supposed to apply more or less to all drugs, are dangerous (Hatcher, 1910; Hatcher and Eggleston, 1914).

The same dose acts the more profoundly, the more rapidly it is introduced; mainly because there is less excretion and destruction before the full dose has entered; also because it reaches the heart and other centers before being distributed through the body. This must be taken into account in fixing the minimal fatal dose. Extremely rapid intravenous injection may simulate a higher fatal dose, if death occurs during the

injection; because in this case really more poison may have been administered than was necessary for death (I. Simon, 1905).

Action and Dose.—With some drugs, the fatal and active dose are far apart (atropine); with others, they are close together (strychnine). The distance may vary even for different actions of the same drug with the delicacy of observing the active dose.

Daily Dose.—The single doses are usually calculated on the assumption that sufficient time is allowed to elapse between the doses for the greater part of the drug to be excreted. This constitutes a *periodic medication*. The exact time varies of course with the nature of the drug, but in most cases the drug is administered three or four times a day; so that the *daily dose* is about three or four times the single dose. If a *continuous action* is desired, correspondingly smaller doses are given at shorter intervals.

Repetition of Dose.—Cash, 1908, found that doses of indaconitine, repeated at sufficiently close intervals, gave imperfect summation of the temperature action; but if the interval exceeded two hours, with doses less than one-half fatal, the later doses produced actually less effect.

Effect of Weight.—Other things being equal, the effect of a given dose is inversely proportional to the weight of the individual (exclusive of the adipose tissue). It is rarely necessary to make allowance for the weight in adults (twenty to sixty years), but it may be used for calculating the doses for children.

Body Surface.—This is regarded by some as a more accurate although less convenient index of the dose (Moore, 1909; Dreyer & Walker, 1914); but the subject is in dispute (Kisskalt, 1915).

Calculation of Doses for Children.—In most cases, the adult dose is reduced in simple proportion to the weight of the child—either by direct calculation, or by the use of empiric rules based on averages, as described below. The dosage so obtained is generally sufficiently exact. It is inadmissible only with extremely young children; and with drugs the action of which is influenced specifically by age.

Clark's Rule.—Multiply the adult dose with the weight of the child (in pounds) and divide by 150 (the weight of the average adult). This rule gives the most exact results.

Cowling's Rule.—Multiply the adult dose with the age of the child at the next birthday, and divide by the adult age, taken as twenty-four. *F.i.*, the dose for a child of three years would be $\frac{3}{24} = \frac{1}{8}$ of the adult dose. This rule is simple, easily remembered, and gives data agreeing sufficiently well with the average weight curve; more accurately than Young's Rule. The results are rather too low, below four years and above fifteen years, but the error is on the safe side.

Young's Rule.—Multiply the adult dose with the age of the child (in years), and divide by the age plus 12. *F.i.*, the dose for a child of three years would be $\frac{3}{15} = \frac{1}{5}$. As compared with Cowling's Rule, it gives somewhat higher doses below twelve years, and somewhat lower above this age.

Fried's Rule for Infants.—Divide the age in months by 150 and multiply it by the adult dose; *f.i.*, for a baby of five months, the dose would be $\frac{5}{150} = \frac{1}{30}$.

The dose for aged people is generally taken as somewhat less than that for adults. Above sixty years, the adult dose is reduced to four-fifths or two-thirds; and in extreme senility, to one-half.

Specific Influence of Age on Drug-action.—These (*i.e.*, apart from the difference due to weight) are known definitely only for a few drugs. *Children* are comparatively tolerant to cathartics, strychnine, iodides, iron, belladonna, calomel, digitalis and sparteine (A. Jacobi, 1907). *Old age* is generally less resistant to drugs; purgatives and emetics are especially debilitating. The frequent existence of atheroma makes it dangerous to use drugs which raise the blood pressure, directly or indirectly.

Influence of Sex.—Women usually require somewhat smaller doses than men (one-half to four-fifths). The greater susceptibility is in large part due to the lesser weight, but in part also to the anatomic and functional peculiarities. The influences of sex are of course most pronounced with drugs which act on the generative organs. **Pregnancy** also modifies the action of drugs, and contraindicates the use of irritant cathartics (because of the danger of inducing abortion) and of irritant diuretics (on account of the tendency to nephritis), etc.

INFLUENCE OF CONDITIONS ON DRUG ACTIONS

Pharmacologic reactions vary with the concentration of the drug and with the excitability of the tissues. The latter is influenced by a number of physiologic and pathologic conditions; and among the latter, by the simultaneous action of other drugs.

Quantitative Relation of Concentration and Action.—The pharmacologic response naturally tends to increase with the concentration of the drug; but the increase is not generally in simple proportion. There is usually a "minimal threshold," all concentrations below this being apparently ineffective. At the other extreme, once the "maximal response" has been reached, further increase of concentration can produce no further effect. Between these points, every increase of concentration increases the action, generally as a logarithmic function; *i.e.*, the increment being the greater the lower the original concentration, in accordance with the Weber-Fechner law of stimulation.

For instance, when the concentration of ouabain was doubled from 0.00125 to 0.0025, the action was increased 4.6 times; when the concentration was doubled from 0.005 to 0.01, the action increased only 1.28 times (Sollmann, Mendenhall and Stingel, 1915; the paper also discusses the reasons for the phenomenon). Data on the concentration-relations of other pharmacologic phenomena are given by Shakell, 1924.

The relation to the concentration becomes complicated if the drug produces several effects with different optima; for instance if the higher concentrations produce injury. Sometimes it appears as if the drug acted only while passing through the cell-membrane, a phenomenon that has been termed "*exodic gradient*" (Straub, 1907; Trendelenburg, 1912; Kuyser and Wijsenbeek, 1913); but the observations could perhaps be explained by changes in excitability produced by increasing concentrations of the drug.

Temperature.—This has marked effects on pharmacologic reactions, seen especially in cold-blooded animals and in excised organs.

In cold-blooded animals, digitalis, veratrine, nicotine, strychnine, tetanus toxin, chloral, and alcohol, are rendered more active, morphine and curare, less active, by raising the temperature. The temperature quotient of strychnine was investigated by Schlomovitz and Chase, 1916.

The influence is especially marked with poisons that have to undergo a transformation in the body. At 37°C., the susceptibility of frogs to atoxyl is increased 12 times, that for colchicine 50 times, above ordinary room temperature. With muscles,

the activity of drugs increases in a mathematical ratio with the temperature within certain limits (Veley and Waller, 1910).

The temperature relations of digitaloids are fully discussed by Sollmann, Mendenhall and Stingel, 1915.

In mammals, cooling generally increases toxicity by adding its direct depressant action.

Temperature on Spinal Reflexes.—In decapitated *cats*, reflexes are optimal at 38°C.; but the changes are very slight between 35 and 37°. In *frogs*, the optimal temperature for reflexes is 5° for winter-frogs, 6.8° for summer-frogs. A second optimum is reached between 19 and 21°; but this is much less efficient than the first optimum (van Leeuwen and van der Made, 1916).

Seasonal Variations.—The susceptibility of animals to a number of poisons varies considerably with the season. With cold-blooded animals, this would be referred mainly to differences of temperature; but considerable variations exist also in mammals. Guinea pigs, *f.i.*, are more resistant to ouabain, and less resistant to acetonitrile and diphtheria toxin during November to January than in the spring and summer months (Haskell, 1912).

Seasonal changes in internal secretions, connected with the sexual activity, probably play a prominent part. The diet is also an important factor.

Diet.—This has a marked effect on the resistance of animals to many poisons (Hunt, 1910; Opie and Alford, 1914); but little is known of this in man.

The people of the undernourished war-countries were said to show greater susceptibility to the toxic manifestations of mercury and arsphenamine; to the narcotic action of morphine, and to cutaneous reactions for various drugs (Zernick, 1919; Rumpel, 1919).

The calcium content is important in influencing cutaneous irritation (Luithlen, 1911, 1912). Barium is better absorbed from a Ca-poor diet (Alsberg and Black, 1912).

The acid-base content of the food is also an important factor, especially in relation to renal irritations (Salant and Bengis, 1917; Salant and Swanson, 1917; MacNider).

Ion-ratios.—The responses of excised or perfused tissues especially to the autonomic poisons, are greatly modified by the hydrogen-ion concentration and the ratio of calcium, potassium and magnesium ions (Salant, 1924). They are of minor importance in the living body, which does not readily change its normal ion-ratios.

Sensitization by Colloids.—The effects of autonomic drugs are generally greatly enhanced by the previous exposure of the excised organs to colloids or colloidal precipitants (Thienes, 1926).

The Combined Action of Drugs.—The effects of drugs are also influenced by the unusual conditions induced by the simultaneous administration or presence of other drugs. A quantitative change may occur either in the sense of increasing the efficiency (synergism), or of diminishing it (antagonism). There may also be qualitative changes. In other cases, new actions are developed by the reaction of the drugs on each other, with the production of new compounds. For instance, the presence of acids renders the basic salts of bismuth soluble and toxic; oxidizing substances may liberate iodine from iodides; the iodides also decompose calomel and render it irritant.

Antagonism of action is employed in the treatment of poisoning; or sometimes to remove undesired side effects. When it interferes with desired effects, it constitutes "*therapeutic incompatibility*."

Combination Therapy.—Synergism is utilized to secure the summation of the desirable effects of several drugs, whilst the side actions are not increased or may even be neutralized. The efficiency itself may be increased, especially when the drugs attack a given cell or function simultaneously by several different mechanisms. Chemo-therapy has furnished some illustrations of this (Ehrlich, 1909). Formerly, combinations of drugs were very popular, but on the empiric principle of the shotgun mixture—that of many ingredients, some at least might fit the disease. Such indiscriminate mixtures are not scientific. It is better to employ the fewest possible drugs, until it has actually been shown that combinations give superior results in the particular condition. In giving

several drugs of similar actions, the dosage of each must be correspondingly reduced.

Variations of Combined Action.—When several drugs are administered together, each may act independently, as if it were present alone. The result would then be a *simple algebraic summation* of the effects, either synergistic or antagonistic. In many cases, however, the combined action is greater or smaller than would be calculated (*potentiated* and *deficient summation*). The relations may differ entirely according to dosage.

F.i., stimulants are antagonistic to depressants only in small doses. Large doses often become synergistic, the depression being greater than if the depressant were used alone. Instances of this are atropine and pilocarpine on embryonal growth (Sollmann, 1904); caffeine and alcohol toxicity, (Pilcher, 1912); atropine and physostigmine toxicity (Fraser); Fothergill gives other interesting examples of antagonism.

Sometimes, an action develops only in the presence of another drug; *f.i.*, pilocarpine provokes the action of minute doses of atropine on the intestine.

Instances of Synergism.—The best-studied examples are from the group of narcotics. The simple lipolytic narcotics (alcohol, ether, chloroform, etc.) show practically only simple summation; but the addition of the alkaloidal narcotics (morphine and scopolamine) gives considerable potentiation (Knell, 1907; Fuehner, 1911; Kochmann and pupils, 1913). Bromides give simple summation with lipolytic and alkaloidal narcotics (Klammer, 1913). The different opium alkaloids potentiate each other in interesting ways (Straub, 1913; Macht). The organic local anesthetics do not usually potentiate (Schmid, 1913). Fuehner, 1912, has worked out the summation of hemolytic agents.

Mechanisms of Potentiation.—There are several possible explanations, but few definite data. One drug could modify the penetration of another. Fuehner, 1913, showed that this is true of the solubility coefficient of the narcotics; or it might alter the chemic affinity, either by acting as an amboceptor, or by closing the combining groups of the cell or of the drug (antitoxins); or it might attack the cell from a different point.

Mansfield and Hamburger, 1915, believe that magnesium potentiates urethane; and that ether potentiates chloral or morphine, by favoring the distribution of these agents in the nervous system; for they find that the augmented action of the combinations persists after the magnesium is neutralized by calcium; or after the ether has been eliminated.

Those interested in summation and antagonism should read Chapter VIII of Verwor's "Erregung und Lachmung."

Buerger's Law.—Buerger, 1910-1912, proposed a universal explanation of synergism but his generalization is doubtless too sweeping. He announced that potentiation occurs, always and only, when two drugs have different points of attack in the cell; because two different receptors could take up more poison in a given time than could a single receptor from the double quantity of a single drug. Fuehner, 1912; Issekutz, 1913; Zorn, 1913, and others have pointed out numerous important exceptions to this "law." It is certainly not universally applicable.

Influence of Pathologic States.—The effects of drugs in disease may differ materially from those on healthy animals. The pathologic conditions may diminish absorption (diarrhea) or increase it (corrosion); they may hasten the destruction of the poison (alcohol produces less intoxication in fever); or they may alter the effects entirely. Some of these modifications are readily explained by the functional or anatomic changes of disease; others are obscure.

The antipyretics reduce the temperature in hyperpyrexia, but do not affect it when it is normal; digitalis is an efficient diuretic in cardiac disease, but not in health; the antiseptics and antitoxins are active only in infections, etc. Numerous other instances may be found in the papers of Salant, 1911, and Wallace, 1912.

Pathologic conditions which modify *absorption* and *excretion* are of particular practical importance: Suppression of urine, as by nephritis, may lead to toxic symptoms from drugs or doses which are ordinarily harmless. The general reduction of vitality, the "*lowered resisting power*," which is so common in many diseases is similarly impor-

tant. As an instance of such modifications, the investigations of Lusini and Sebastiani, 1906, may be quoted. They found the absorptions of poisons hastened immediately after hemorrhage but not later. The toxic symptoms were not modified. The resistance was found lowered to a varying degree for different poisons: Most for strychnine, less for veratrine, and not at all for physostigmine. Wiggers, 1910, found that severe hemorrhage paralyzes the vagus center and thus alters the response of the heart-rate to epinephrine, digitalis and nitrite.

Inflamed Vessels.—These react abnormally. Eskin, 1914, found constrictor drugs generally less and dilator drugs more effective. Epinephrine often produced dilation, whilst caffeine, which normally dilates, constricted the inflamed vessels of rabbit's ear.

Diseased intestines allow a much more rapid diffusion of proteins, toxins and ferments than healthy intestine (Mayerhofer and Pribram, 1909).

The distribution of the drugs in the body may be different in disease and health. This is best illustrated by fluorescein (see Index).

Iodide and many dyes tend to accumulate in the necrotic areas of tuberculosis, tumors, etc. (Weil, 1916; Cecil and Weil, 1917).

Cumulative Action.—This is said to exist when the continuation of a given dose of a drug produces greater effects than the first doses. It may be due to an actual accumulation of the drug, absorption being greater than the capacity for excretion; or it may be due to the summation of effects, when the changes brought about by the first doses persist; the drug may use up some substance required for its disintoxication (phenol); or there may be general decrease of resistance.

Inconstant absorption is a frequent cause of apparent cumulative action. Successive doses of the drug may lie unabsorbed in the alimentary canal, to be finally taken into the system *in toto* when the conditions are favorable to absorption. This explains that the greatest individual variability to toxic doses exists precisely for those drugs which are absorbed with the greatest difficulty.

Irregularities of Excretion (nephritis, etc.) are also favorable to the development of cumulative effects.

"Education."—It is sometimes noted that effects are more easily reproduced after they have once been induced. This is seen particularly in drugs acting upon the central nervous system. It is claimed, *e.g.*, that the susceptibility to strychnine increases with its administration, and it would seem that this is caused by the central nervous system becoming educated to the stimulating actions and responding to them more readily.

Tolerance.—This may be due to non-absorption, to rapid elimination, to the neutralization or destruction of the poison, or to anatomic peculiarities. Many cases can not be explained in this manner, and must be assumed to be functional (the "histogenetic" immunity of Behring). The tolerance is rarely absolute, so that it is scarcely correct to speak of "immunity." (Critical review of the literature of tolerance, Heger and Zunz, 1914.)

Habituation.—Tolerance may be congenital, or it may be developed by the repeated administration of the poison. This habituation may be functional (alcohol, caffeine, nicotine); or it may be due to diminished absorption (arsenic) or increased elimination (atropine in cats); or to increased destruction of the poison (morphine); or to the production of antibodies (toxins). The tolerance is usually limited, not absolute.

In the case of the habit-producing drugs, the tolerance is largely psychic: The nervous centers learn to modify their reactions so as to adapt them to the drug-environment. When this environment is abruptly altered by the withdrawal of the drug, there is generally extreme discomfort, resulting in craving and great nervousness, constituting "abstinence symptoms." Functional habituation, when acquired for a particular drug, may hold also for other drugs having a similar action. A habitual drunkard, *e.g.*, is resistant to the general anesthetics; morphinists are said to be more tolerant to cocaine (Chouppe, 1889); etc.

Hausmann, 1907, and Santesson, 1912, give reviews of the data on habituation.

Antitoxin formation is a conspicuous instance of acquired tolerance. It was supposed to be confined to proteins, but seems to exist also toward certain glucosides (toad-stools, and poison ivy, Ford, 1909; snake venom, Faust, 1911). It does not occur with alkaloids or any of the simpler poisons.

Acquired Immunity in Protozoa.—This has a practical as well as theoretic bearing on chemotherapy, and has been investigated by Ehrlich, 1909, and Neuhaus, 1910. These organisms acquire immunity for several groups of poisons—metals and dyes—the tolerance induced by one drug applying to other chemically related drugs, but not to the other groups. The immunity when once induced, is transmitted unlimited from generation to generation. It is perhaps due to diminished affinity of the protoplasm for the poison; but the adaptation may consist merely in the selective propagation of the more resistant individuals; *i.e.* in the “survival of the fittest.” With alkaloids, Prowazek, 1910, found that different individuals, even in the progeny of a single parent, show varying resistance to the same alkaloid. He also found that lecithin protects against the alkaloids.

Idiosyncrasy.—This term (from *ἴδιος* one's own, and *σύνκρασις* a blending) is applied to peculiar, exceptional reactions to the effects of drugs. They may consist in quantitative hypersusceptibility to the ordinary actions of the drug. Such hypersusceptibility is especially conspicuous if it emphasizes a side-action that is ordinarily negligible. Neurotic individuals are subject to psychic exaggeration or modification of drug effects through fright, excitement, or suggestion.

Allergic hypersusceptibility is a special type of idiosyncrasy in which the patient reacts to special substances, foods or drugs by irritative edema and spasm of smooth muscle, urticaria, bronchial asthma and collapse. It is generally hereditary, but not congenital; *i.e.*, it may not manifest itself till later in life. It resides in the tissues, so that it cannot be transferred by the blood-serum. Allergic hypersusceptibility may be induced in excised tissues by treatment with colloidal precipitants (Thienes, 1926).

Impurities of Drugs.—Abnormal reactions may sometimes be due to the presence of impurities. It is rather doubtful, however, whether these impurities have the importance which is often assigned to them. Whilst it is desirable that drugs should be as pure as it is practical to make them, minimal amounts of foreign substances can not be said to be very objectionable, unless they are particularly poisonous. The pharmacopeias have taken a wise stand in this matter by permitting the presence of small amounts of such innocuous impurities which it would be very difficult and costly to remove.

Racial Idiosyncrasy in Animals.—Different species of animals often vary in their reaction (see Kirk, 1923). This can usually be explained by *differences in the physiologic functions*. For instance, the cerebral actions are usually the more pronounced, the more highly the central nervous system is developed; whereas spinal actions predominate in the lower vertebrates. Rodents are incapable of vomiting and therefore do not respond to emetics. Atropine quickens the heart of the dog, but not that of the rabbit, because it acts by paralyzing the vagus, which is not tonically active in the rabbit. The dog-fish, which is more or less resistant to nephrotoxic poisons, normally excretes urea and probably other metabolic products mainly by the intestines and bile (Denis, 1913).

Natural resistance is often due to the destruction of the poison, *f.i.*, that of atropine by the serum of rabbits, etc. The destructive mechanism may be greatly increased by habituation; *f.i.*, with morphine. Differences of absorption and excretion also come into play.

There are still a number of differences which *can not yet be explained on a physiologic basis*. These must be referred to our ignorance of the physiologic differences which are

involved. The *hedgehog* has a high unexplained resistance to many poisons; morphine, atropine, nicotine, cyanide, cantharides, arsenite, diphtheria and tetanus toxins; not for strychnine (Strubell, 1909; Willberg, 1913).

Even the same organs in different classes of animals may show unexplained differences. Thus, Gunn, 1909, claims that apocodeine, quinine, and yohimbine, which cause vasodilation in mammals constrict the blood vessels in frogs—both peripherally. Characteristic differences in epinephrine are well known; but the mechanism of these is explained by differences in innervation.

Individual Idiosyncrasy in Animals.—In animals, as well as in man, peculiarities exist in different individuals of the same species. *Qualitative differences* are seen particularly in the action of Cannabis on dogs.

Instances of *quantitative differences* are very numerous:

In a large series of experiments with toxic doses of drugs on animals the author has found that there is a fair degree of uniformity in the proportion of animals which die with a given dose. Thus, certain limits can be found inside of which, out of five animals three will always die. These limits vary from 0.5 per cent. (strychnine) to 25 per cent. (ergot), but are usually comprised within from 5 per cent. to 10 per cent.

On the other hand, the susceptibility of any one animal is subject to greater possible variations; *e.g.*, with a given preparation of digitalis, 0.6 mg. per gram will always kill three guinea pigs out of five. But in a large series of experiments, a number of animals will be found which will die of doses as small as 0.4 mg., while others will die only when 0.9 mg. is reached. Whether these comparatively immune animals always enjoy this immunity, or whether the condition is only temporary, as well as the influence of age, sex, etc., has not been determined.

These individual differences are still more striking if, instead of observing the toxic doses—*i.e.*, the sum total of the effects—we direct our attention upon some one particular action, *e.g.*, the amount of slowing of the heart or the variation of blood pressure. The differences in this respect are so great qualitatively that it is unsafe to draw conclusions from a single experiment, and it is difficult in these cases to establish any quantitative standard.

THE MANIFESTATIONS OF PHARMACOLOGIC ACTIONS

Modifications of Functions.—Since protoplasm is essentially identical in all cells, the action of pharmacologic agents must also be essentially the same in all situations; but just as quantitative differences exist in the cell, so does the pharmacologic action show quantitative differences and selective properties. As a general rule, the most conspicuous changes occur in the most conspicuous function of the cell—partly because these are the most readily appreciated, but partly also because specialized functions are the most complex and hence the most sensitive.

Pharmacologic agents do not create new functions in a cell or tissue; they can only modify existing functions, or at most make evident functions which have previously been latent. The functions of a cell may be increased or diminished, resulting in *stimulation* or *depression*. Since there are also structures the stimulation of which would lead to an inhibition of other structures, an actual increase of function is sometimes distinguished as *augmentation*. A very violent stimulation passes usually into injury; such injurious stimulation is called *irritation*. Moderate, but prolonged, stimulation also passes into depression, either by the disappearance of food substances (*exhaustion*), or by actual injury to the structure (*fatigue*). If the depression is so great that the given function has disappeared, the condition is called *paralysis*; if all the functions are abolished, there is *death*.

The greater number of pharmacologic agents produce at first a stimulation, which is followed in larger doses by a depression. In this respect the differences between the different poisons are again mainly quantitative.

The so-called “stimulants” produce a very strong and prolonged stimulation, the depression being produced only by relatively large doses.

The "depressants," on the other hand, cause only a slight stimulation, which passes readily into depression. Indeed, with some depressants, no stimulation whatever exists. It is very rare that a depression precedes a stimulation; when this occurs, the action is presumably on different structures.

Selective Action.—The actions of drugs are generally much greater on some tissues than on others; *i.e.*, they are selective. The difference may be almost or quite *absolute*, so that the drug acts specifically on one class of cells. This "monotrope" action is especially important in parasitocides, and was Ehrlich's ideal of modern "*chemo-therapy*," the treatment of infections by chemic agents. Antibodies also illustrate a strictly monotropic selective action. With most drugs the differences are merely quantitative or *relative*; a number of structures being affected with various degrees of predilection, which may sometimes shift with changing conditions. The actions on the central and peripheral nervous systems generally belong to this relative type.

Mechanisms of Selective Actions.—These may consist in differences of penetration; of the chemic affinities of the cell; or of sensitiveness of the functions. The details are known only in a few cases.

Selective Absorption.—A drug may act upon a cell without actually penetrating into it; for instance, by exciting the nerves supplying the cell, or more directly, by withdrawing water from the protoplasm; but as a general rule, the poison must be absorbed into the cell or cell-membrane, before it can produce any action. In order that this absorption may take place, the drug must be soluble in the cell contents, and particularly in the cell envelope. The solubility of a substance in protoplasm is not necessarily the same as in water. Indeed, it varies for each kind of cell, and consequently the penetrability of different cells for a given substance may vary greatly.

Whilst the renal cells, for instance, are very permeable for sulphates, the intestinal cells are but slightly permeable. It is in virtue of this peculiarity that cells are capable of preserving their own composition, notwithstanding considerable changes in the fluids in which they are bathed. This fact also explains why a given substance acts much more strongly upon one cell than upon another.

These differences are illustrated strikingly by the distribution of *dyes* in living and dead tissues; or indeed, in unorganized materials. Their behavior has been extensively studied, but as yet without leading to secure general conclusions.

The differences in absorption may be due partly to the cell envelope, partly to the cell contents. Lipoid solvents generally penetrate better than other agents, because of their affinity for the lipoid constituents of the cell membrane. Other agents probably form "solid solutions" with some of the cell constituents; others are attracted by chemic differences—*e.g.*, the basic stains by the acid character of the nuclear chromatin. Adsorption and surface forces probably play an important part.

Selective Absorption into Pathologic Tissues.—The distribution is often modified by conditions—reaction, oxygen, the presence of a second substance, etc. Important differences arise also in diseased conditions, *e.g.*, iodides are taken up in higher concentration by degenerating tissues.

Tuberculous caseous tissue particularly has this property of condensing iodides and dyes, especially those of the safranine and acridine groups (A. Lewis, 1917). Other inflamed tissues and inflammatory products also have a marked tendency to take up dyes (Cecil and Weil, 1917). This can be well demonstrated by the appearance of trypan-red in the aqueous humor, which occurs much more readily when the eye is inflamed, or when physostigmine is applied (P. A. Lewis, 1916).

The feeding of *madder-dye* stains bone and pathological calcareous tissue *in vivo*; probably by forming calcium alizarate (Macklin, 1917).

Effect of Concentration.—The amount of a drug absorbed into a cell varies generally with the concentration of the drug in the surrounding fluid.

This concentration is greatest at the place where the poison enters and leaves the body, *i.e.*, in the alimentary canal, liver, and kidneys. Differences of blood supply also come into play. The influence of concentration is most readily seen with locally acting drugs.

Chemic Differences.—The various cells differ in their chemic properties, and therefore in their reactions. This is seen most definitely with the antibodies, precipitins, cytolytins, antitoxins, etc., which are supposed to fit especially into certain cells, “as a key is fitted to a special lock.” Something of the same kind doubtless applies at least to some of the ordinary poisons, which can unite only to certain side-chains or certain constituents; but little is known of the details. Similar combining properties may make a poison innocuous to certain cells, by leading to its destruction, or binding it into a harmless form. On the other hand, the decomposition may serve to liberate or form an active substance—*f.i.*, formaldehyde from methenamine in acid urines.

Functional Differences.—The cause of selective action lies often in the cells themselves, *the more delicate functions being damaged more readily*. Hence a poison which acts indifferently on all tissues produces always the most conspicuous effect on the central nervous system.

The sensory nerve fibers are uniformly more susceptible than the motor fibers. The heart of the king-crab limulus furnishes a good illustration. Its structures fail in the same order (ganglion, motor nerve-plexus, muscle) in respect to all kinds of injurious agencies, alkaloids, anesthetics and other drugs; heat and cold, etc. (Meek, 1908).

Certain cells also accommodate themselves more readily to altered conditions.

CLASSIFICATION OF DRUGS ACCORDING TO SELECTIVE ACTION

Poisons which alter all tissues, and which therefore produce effects at the place where they are applied, are termed “*locally-acting*” drugs. They may produce similar chemic changes in dead tissues. These usually cause inflammation when applied to living tissues, and are then called *irritants* (including simple irritants, corrosives, and astringents). Others lessen inflammation mechanically (emollients and demulcents).

Others act chemically on all living structures, without changing dead tissues; these are termed “*protoplasmic poisons*.”

Poisons which act selectively on a few structures are called “*muscle-nerve poisons*.” They may affect end-organs (sensory endings, gland cells, or striped, smooth, or cardiac muscle); or the nerve-endings; or ganglia; or any part of the central nervous system.

Nerve trunks are so resistant that they are only affected when the poison is applied to them directly. The access of drugs to them is restricted, in intact animals, by their limited blood supply. The nerve fibers are also protected by the slight permeability of their sheath.

Pharmacologic Groups.—Various systems of classifying nerve-poisons have been devised. None is really satisfactory, because most drugs produce several effects which, by their interaction, complicate the subject so that no simple system will apply. With some drugs, one pharmacologic, chemic or physical feature predominates so greatly that they can be separated as fairly distinct groups. However, this is more or less arbitrary and artificial.

Variations in Symptoms.—The selective action of drugs is rarely absolute; even strychnine, a highly selective poison, acts as a general protoplasmic poison when it is directly applied in sufficient concentration.

Often, however, some one action is so predominant that it may be considered as characteristic for the drug. Even in this case, the poison as a rule acts selectively on several structures. This accounts for the great variability which is often seen in the action of the same drug under different conditions. Thus, atropine stimulates the vagus center, but paralyzes the endings: it may therefore cause either a quickening or a slowing of the pulse. Again, through the opposed action of small and large doses, strychnine, *e.g.*, may cause either a stimulation or a paralysis of the vasomotor center. Another frequent cause of variable actions lies in the indirect actions of a drug. A drug which causes convulsions will thereby tend to stimulate the vasomotor center, although its direct action of this center may be depressant.

These variable actions and interactions make the effects of many poisons appear very complicated, although they may prove quite simple on analysis. This analysis is important for a proper understanding of the action, but it is still more important to remember the complex effects which result, for it is with these that the practicing physician has to deal.

Often the pharmacologic action in this sense is not the therapeutic action. An important pharmacologic action of morphine, for instance, is a stimulation of the spinal cord; but no one would think of employing the drug therapeutically for this purpose, since this action is overshadowed by its other effects.

For this reason it would not be a good plan to classify the drugs strictly according to their pharmacologic actions. On the other hand, a *therapeutic classification*, although useful in some respects, is not favorable to a study of the underlying actions of the drugs, and tends to empiricism. The best principle of classification yet devised is that of Buchheim,¹ according to which drugs are grouped according to their principal pharmacologic characters, taking account of all the important actions, as well as of the chemic properties,² and in many cases also of the therapeutic uses of the drugs. This is the general plan adopted in this volume.

Definitions of Pharmacologic Terms.—Some rather loosely used pharmacologic terms may be defined in this place, in the sense in which they are generally employed in this volume:

Local actions: produced at the place where the drug is applied; *Remote actions*: occurring in distant parts of the body (may be either systemic or reflex); *Systemic effects* (sometimes called general action): produced after the absorption of the drug into the circulation; *Direct effects* (sometimes called primary): produced by the direct action of the drug on the tissue concerned; *Indirect effects* (sometimes called secondary), are not produced by the action of the drug on the tissue concerned, but by the intervention of some other structures on which the drug acts (*e.g.*, asphyxial convulsions are an indirect effect of asphyxiant poisons); *Reflex effects* are indirect actions arising from local irritation; *Immediate effects* (also sometimes called primary) are the effects resulting at once; *Late effects* are those occurring later; if they are preceded by other (immediate) actions, they are properly called *secondary actions*. *Side actions* are actions which are not desired in the therapeutic use of the drug.

Localization of Action.—The effects of drugs on patients, or in cases of poisoning, are by far too complex to furnish any real insight into the actions which are involved. To attain the object of pharmacology—the explanation of the action of drugs—it is indispensable to simplify

¹ Buchheim may be considered the founder of modern pharmacology, by the establishment of the first pharmacologic laboratory, at Dorpat in 1856.

² Drugs of very different chemic character often appear to have identical actions. Thus the action of strychnine resembles that of tetanus toxin, arsenic that of cholera, barium that of digitalis. In some cases the action may be supposed to be really identical, but in others the resemblance is merely superficial.

the conditions as much as possible, and to make the functions, which are to be studied, accessible to measurement, and if feasible, to graphic representation. The methods of experimental physiology are employed for this purpose.

The Study of Isolated Structures.—To eliminate the complications which arise from simultaneous actions on several structures or from indirect actions, the tissues to be studied are generally isolated. The most certain method is the actual anatomic isolation of the structure. Drugs of known antagonistic actions may also be utilized, but they are apt to lead to erroneous conclusions.

The anatomic isolation may be accomplished by employing unicellular organisms if the action on undifferentiated protoplasm is to be investigated; or by excising the tissue (as muscle, etc.) from the body; or by applying the drug to the exposed tissue (e.g., to a sympathetic ganglion); or by severing the connection with other tissues which might be affected (as by section of a nerve); or by restricting the action of a drug to a given part, by cutting off the circulation.

One or the other method of isolation may be employed, according to circumstances; that giving reliable results with *the least difficulty of technic* being naturally preferred. Complete isolation is in many cases superfluous. If the question is, for instance, whether an observed *stimulation* is of a central or of a peripheral structure, it suffices to divide the nerve: on an efferent chain, this will abolish the effects of a central stimulation, whilst those of a peripheral stimulation will persist. With an afferent chain the conditions would be reversed. By making sections at various levels of the chain, the location of the action may be accurately determined. When the structures to be investigated are inaccessible to the scalpel, one may substitute drugs which are known to paralyze these structures selectively (curare for the endings in striped muscle; nicotine for ganglia; atropine for endings of the vagi or parasympathetic, etc.). The *site of a paralysis* is similarly located by successive stimulation. The stimulation is accomplished by electricity or by appropriate drugs (epinephrine for sympathetic endings; muscarine for vagus endings; pilocarpine for glands; barium for smooth muscle, etc.).

A few examples will make this general method clear:

1. *Strychnine.*—It is noted that strychnine produces a tetanus. This implies a motor stimulation somewhere. The sciatic nerve is cut; it is found that the convulsions disappear in the leg but persist in the rest of the body. The action must therefore be central. The cerebrum and medulla are successively excised; the convulsions persist, and must, by exclusion, be located in the cord. This is confirmed by destroying the cord, which causes the complete disappearance of the tetanus.

2. *Curare.*—This produces a complete muscular paralysis. Stimulation of the sciatic elicits no response. The paralysis must therefore be peripheral. Direct stimulation of the muscle is effective. This excludes all the possible structures except the nerve trunk and endings. The nerve of another preparation is laid into the curare solution, and after a time, is stimulated; a contraction results, so that the nerve trunk is not paralyzed. The action must therefore be on the endings.

If a peripheral structure is stimulated or paralyzed, it is impossible to decide by this method whether there is not also a central action, for the peripheral effects would obscure the central. A stimulation of the cord, for instance, could cause no effect if the drug had paralyzed the motor endings. In these instances, it is necessary to confine the action of the drugs to the centers, which requires a more complicated technic.

The Study of the Effects of Drugs on Intact Normal Animals.—A complete conception of the actions of a drug can be obtained only by supplementing the study of its effects on isolated structures, by careful observation and analysis of the symptoms which it produces in intact mammals. The effects on metabolism, and the histologic lesions, etc., can only be studied in this manner. Indeed, these experiments are often undertaken before the more difficult investigations on isolated structures; for they furnish valuable hints of the direction which the latter should take. When circumstances permit, it is advisable to proceed from the lower to the higher classes of animals, and finally to man. Opportunities for observing *the effects of drugs on man* occur in cases of poisoning, and should not be neglected; but intentional experiments with drugs on man are to be undertaken only with the greatest caution, with doses which do not exceed the therapeutic maxima; and, as a rule, only after the effects have been thoroughly studied on animals.

The Effect of Drugs in Disease.—The action of drugs is not always the same in disease as in health. The differences are, however, as a rule quantitative rather than qualitative. Since the drugs are in practice employed most extensively in disease, their action in these conditions is of the greatest importance. As a general rule, it is possible to explain, and even to predict, the action of drugs in disease from their action on normal tissues. However, the actual test must always be made.

Animal experiments are as yet of limited value in this connection, and we are forced to rely mainly on observations on patients. To make these of value it is necessary that the observations be made accurately and that psychic factors be excluded; it is further necessary that the existing pathological condition be correctly known. These requirements are unfortunately not fulfilled in many cases, which accounts in part for the differences which are occasionally noted between the clinical and the experimental data. These exceptions will be discussed in the text.

In the case of the older drugs, clinical tests have been made so abundantly that further observations might seem superfluous. This is by no means the case. Accurate observations in the light of our advancing knowledge, and employing the improved methods of diagnosis and observation, are always needed.

It is also highly desirable that every physician should obtain his knowledge of the therapeutic action of drugs at first hand. He should utilize every case under his care for this purpose, and conduct his treatment as if it were a critical experiment, the interests of the patient being, of course, paramount. The conclusions will be greatly simplified if but one drug is used at a time.

Chemic Investigations.—Since the action of drugs depends so largely upon their *chemic constitution*, the latter is a legitimate subject of pharmacologic inquiry. The study of the *fate of the drug* in the body, of the *mechanism of its absorption, excretion, and storage*, is also indispensable. These involve the methods of quantitative chemic analysis.

Transfer of Results of Animal Experimentation to Man.—The utilitarian aim of pharmacology is to supply the science of medicine with a rational and scientific basis for the practice of therapeutics and for the study of toxicology. It was shown in the preceding section that these objects can be attained only by experimentation on lower animals. This brings up the fundamental question: *To what extent can results observed on animals be transferred to man?* The same question applies to all other fields of experimental medical research, and has been abundantly answered by their results. *A similar physiology implies a similar pathology and pharmacology.* In the great majority of cases, similar structures are affected in the same way by a given drug, no matter in what animal they are studied. Where differences exist, they can usually be explained by differences of physiologic function, as will be discussed under "Racial Idiosyncrasy." Those which are not yet explained must be referred to our ignorance. The differences in animals, physiologic and unexplained, are now generally recognized so that suitable species can be chosen for experimentation. They can furthermore be eliminated by using the drug on several species: *If a given poison affects all species alike, it may be concluded that its action on man is also the same.* If it produces different effects, but if these can be explained by differences in physiology, the effects on man will be similar to those produced on the species the physiology of which resembles most closely that of man.

Value of Limitations of Experimental Pharmacology.—It will be seen that great care must be used in applying the results of experimental pharmacology to man. The

neglect of this precaution, the drawing of far-reaching conclusions from a few limited experiments, threw discredit on pharmacology in its earlier days, and is still seen all too frequently. Pharmacology can not be held responsible for this misapplication of its data by half-trained enthusiasts. Its scope is limited primarily to its own results and not to their application, although it may legitimately suggest the latter. It should not be made to replace the science of therapeutics, but should only aim to place well-studied tools in the hands of the latter. If this limitation is realized; if the therapist will carefully study the results of pharmacology and will utilize and interpret them in the light of bedside experience, then pharmacology will be of very great value to medicine.

One very important service is rendered by pharmacology through the examination of new remedies. The development of synthetic chemistry especially has resulted in the discovery of a very large number of new substances of some therapeutic value. The number is indeed so large, that all could not be given a thorough trial on patients. Most of these substances possess some value, but many differ from each other by very insignificant details. In this case, pharmacology can select the most promising drugs of a type, and by their thorough study, indicate those which are worthy of trial by the clinician.

THE CHEMICAL AND PHYSICAL BASIS OF PHARMACOLOGY

Scope of Pharmacology.—The term *Pharmacology* in a general sense covers all scientific knowledge pertaining to drugs, *i.e.*, to substances which may be used in the treatment of disease. *Materia Medica*, *Pharmacognosy*, and *Pharmacographia* have the same meaning when they are used in a general sense.

More commonly, however, the term "pharmacology" is used in a more *restricted sense*, as a synonym for *pharmacodynamics*. It concerns itself with the actions of drugs on living structures; or with the reactions occurring between drugs and living structures. It is therefore a branch of physiology on the one hand, of chemistry on the other; and is essentially a division of biology. It has important practical relations with *toxicology* (the science of poisons); and with *therapeutics* (the treatment of disease).

The Nature of Pharmacologic Action.—The processes of life are essentially conditioned on chemical and physical changes in the constituents of the cells. Foreign chemic substances may enter into these reactions, and thus modify them more or less profoundly, with corresponding changes of function. These are termed *drugs* or *poisons*, according to whether they are useful or harmful in a given case. Some of the reactions are comparatively simple, analogous to those produced on isolated proteins. Others, however, occur only in living substances. Our limited knowledge of the chemical details of the living cell does not permit any deep insight into the nature of the action of these substances, except in a few directions. They suffice to show that the mechanism of the action of different drugs is not uniform, but is sometimes along chemical, and sometimes along physical lines. No sharp division can be drawn.

Physico-chemical Conditions of Life.—The living cell may be considered as a very complex laboratory, where chemic decompositions and syntheses, reductions and oxidations, etc., are constantly going on. These chemic changes lead to transformations of energy which find their final expression in the phenomena of life. The vital manifestations of the cell are, therefore, inseparably connected with physico-chemic transformations, which require for their occurrence the existence of certain chemic and physical conditions. The chemic essentials are: the presence of substances capable of liberating energy, and the conditions suitable for their reactions, such as a proper temperature, alkalinity, presence of ferments, etc. The physical conditions of life are: A viscid medium, containing colloid proteins, salts, fats, and water.

Ordinary Chemic Reactions.—In the simplest cases the actions occur on dead tissues, and resemble those produced on substances of known composition; this is the case with strong acids, alkalies, metals, etc.

Obscure Chemic Reactions.—In many cases, particularly with alkaloids, glucosides and toxins, the action is confined to the living cells; for most of these, no adequate explanation can be offered. It is very probable that many of these produce chemic changes in the protoplasm; but the evidence is suggestive rather than conclusive.

From the complicated structure of the protein molecules we conclude that it must be capable of a very great number of reactions, a conclusion which is confirmed by the large number of substances which are utilized by the cell. We find an expression of these chemic changes in the final excretory products of the cell; but we are very ignorant of the reactions by which these final changes are produced. When we find, therefore, that a chemic substance possesses actions for which there is no adequate physical explanation, we presume that it enters into chemic reactions with the protoplasm. This has been expanded especially in the *side-chain theory* of Ehrlich. This assumes that the poisons combine with certain groups (receptors) of the cell which are essential for its metabolism.

Evidences of Chemic Actions.—The theory of chemic combination is confirmed by the fact that most of the poisons (not all) are altered in the body; although it does not follow that the action is due to this particular change. The toxicity is often parallel to the chemical reactivity or lability of the poison. Other indications of chemic reaction are, that these poisons often accumulate in the cells; and that the effects generally increase with the dose. This would be expected with chemic reactions, but could also occur on physical grounds. In any case, the combination is often very loose and unstable, for the poison can often be removed by simple solvent (*f.i.*, antipyretics and fuchsin stain by alcohol, P. Ehrlich). Indeed, the organism recovers promptly from most poisons when these are washed out, unless secondary changes have occurred. In some cases, the action seems to be produced only whilst the poison is passing into or out of the cell (Straub; Kuyser and Wijsenbeck, 1913). The action is then probably on the plasma membrane. The relation between the action and chemic constitution of poisons also speaks for chemic reactions, but may in some cases be explained by corresponding alterations of the physical properties. Compounds between alkaloids and proteins have been described; but it is not certain whether these are real combinations, or merely adsorption products (Eddy and Gies, 1907).

Modifications of Ferments.—Catalytic reactions, which are so important to the cell, may be modified by chemic reagents, without as well as within the cell. This explains the asphyxiant action of cyanides.

Changes in the Cell Membrane.—Since most cells are in contact with surrounding fluids, they must be protected against changes of composition by a limited permeability of their surface layer, the cell wall or plasma membrane. This apparently contains lipid and protein constituents. It may, therefore, be altered by fat-solvents, or by agents which either precipitate or liquefy proteins. This explains, at least partly, the effects of *lipolytic narcotics*; hemolysis by these, by *alkalies* and *saponins*; the actions of various *ions*, especially Ca, etc.

Osmotic Changes.—Cells are generally much more permeable to water than to dissolved substances. This leads to osmotic phenomena—the withdrawal or absorption of water—when the cells come into contact with solutions of higher or lower salt concentration. This explains the actions of many otherwise nearly indifferent salts, *e.g.*, *saline catharsis* and *diuresis*.

Surface Forces.—The physical structure of protoplasm is such as to present large surfaces, and therefore gives peculiar opportunity for the development of the surface forces, which are very important for various vital functions. These are greatly modified by a variety of substances, including the *lipoid solvents*, *salts*, etc.

Colloid Phenomena.—Many chemical and physical conditions depend on the colloid character of protoplasm. The state of aggregation of colloids, and hence their reactions, are easily modified, especially by salts, acting both by their chemic properties and electric charges. This is an important element in *salt-action*.

Dependence of the Pharmacologic Action on the Chemic Constitution.

As a general rule, drugs having a similar constitution, possess similar actions; and definite changes in the molecule—as in homologous series, or the introduction of new groups—often produce definite modifications in the pharmacologic effects. This should be expected, since the physical as well as chemical properties change with the constitution. This relation has a wide general application; but its application to details has been rather disappointing, because we have not sufficient knowledge of the

chemic constitution and reactions to take account of the numerous variables.

It must be remembered, for instance, that the action is not so much determined by the elementary composition of the substance, but rather by the manner in which the elements are combined. Isomeric compounds have often very different actions. Apparent exceptions result also from the different penetrability of cells to substances which, could they be introduced into the cell, would cause similar effects. Other manifestations of selective action also come into play.

Attempts to construct a general theory of pharmacologic action on chemical lines have merely shown that this is as yet impossible. The data which we possess had therefore to be gathered empirically without much guidance.

The Importance of the Chemic Radicals or "Side-chains."—A substance, to produce chemical pharmacologic actions, must be capable of combining with protoplasm and then of altering its properties. These two functions—combination and action (analogous to amboceptor and complement, P. Ehrlich)—may be united in the same group; but they may be distinct ("haptophore" and "toxophore" groups), so that one may be modified without the other. Often several groups are present which may enter different combinations under different conditions. It is evident that these may introduce great variations in the actions.

Morphine, *f.i.*, produces its hypnotic action by "anchoring" or combining with its phenyl-hydroxyl. When this group is closed, *f.i.*, by the methyl radical, as in codeine, it anchors in a different way, to different cells; and the convulsant action becomes more prominent. The introduction of acid radicals into the amido-group renders this more stable and less toxic; but the same acid radicals when introduced in the OH group (*f.i.*, as in heroine) increases the toxicity, by providing a new combining group. In these cases, the new groups act only by altering the combining properties of the active group. In other cases, the new group may itself be active.

Striking instances of the insufficiency of a narrow side-chain theory are furnished by the toxicity of diazo-dyes (Cecil and Weil, 1917).

The Construction of Synthetic Compounds.—The recognition of the general modifications produced by the different radicals is of practical importance. It permits the prediction, with considerable probability, of the effects of new drugs; and it points the way to modifications which will emphasize desirable quantities and eliminate those which are undesirable. This has led to the introduction and improvement of many new remedies. Really new properties can not, of course, be predicted by known properties. Their discovery is generally accidental. Accordingly, synthetic chemistry has introduced relatively few new principles, but endless modifications; some useful in the ways indicated; many others needless and detrimental. It is easy to devise minor changes in composition which do not alter the actions of the original drug materially, but which are commercially profitable by evading the patent and trade mark laws. This needless multiplication is confusing and, therefore, undesirable.

PLANS OF TREATMENT

Vis Medicatrix Naturæ.—It is most important to the rational treatment of disease that the physician should understand that he cannot directly make a patient well. That is nature's task. Physiologic functions tend to run their normal course, or to return to it if they have been disturbed. "Nature," therefore, tends very strongly to bring the organism back to its normal conditions, or life would long since have disappeared from the globe. The task of the physician consists in directing his treatment in such a manner as to remove obstacles from nature's path.

Just as the surgeon can not cause the union of a broken bone, but can only put it in the most favorable condition for nature to perform this union—*i.e.*, set it—so the physician cannot cure heart disease. He may either remove the condition which causes it, if still present, or remove by digitalis, etc., the factors which retard the cure; but in any case he must rely upon nature to perform the last, the really important act: *viz.*, the permanent return to normal.

That nature not only puts the final touch upon every reparative process, but that she may take every step as well—*i.e.*, that a patient may get well without any medical interference—is too well known to require further discussion. The ways in which these processes of repair take place constitute one of the departments of pathology and medicine.

The Field of Therapeutics.—In the light of the above, it might well be asked: If nature is thus able to effect cures; if the greater number of diseases tend to spontaneous recovery, what is the function of the physician? Can he do anything but harm if he attempts to meddle with the processes of nature? If he undertakes to aid, does he not really meddle? We must, in examining this question, lay the emphasis in the above sentence on “nature *tends* to effect a spontaneous cure.” But nature is essentially blind in her workings. She works by general laws, which often do not take account of individual cases. Though we must recognize that her processes are generally in the right direction, they may be greatly at fault quantitatively. Nature may do too much or too little. It is now conceded that fever, pain, inflammation, etc., are protective mechanisms; but when the fever becomes so high as to be in itself dangerous to life; when the pain is intolerable and constant, and persists after it is no longer needed; when inflammation spreads; then it is evident that the originally salutary process is becoming the reverse. That the processes of nature are often insufficient is evident from the fact that they do not in all cases effect a cure. Nature may sometimes be absolutely wrong; *e.g.*, in the desire for solid food in typhoid.

It is, then, the duty of the physician judiciously to modify the natural tendency, if he possesses the means of doing so. But he must do so wisely, or it were better not at all. He must understand the diseased condition; he must understand nature's way of meeting the difficulty; he must judge in what ways nature may be supported; and, finally, he must thoroughly understand the means at his command for the purpose—*i.e.*, pharmacology. As long as he is not clear in regard to these factors, he is merely groping in the dark, as likely at least to do harm as good. In this case expectant treatment is alone justifiable.¹

Services of Pharmacology.—This has made possible a much more exact knowledge of the action of drugs, without which their employment would be a matter of mere chance. It is also made available much more accurate methods of observation, and furnished standards by which therapeutic trials must be conducted. It led to the introduction of the great number of synthetic drugs, some of great usefulness, because it pointed out the directions in which new drugs could be sought with most success. It furnished the means of trying their actions and probable usefulness on animals, when their use on man would not be justified without these preliminary trials. It has also contributed to the development of experimental pathology, and thus laid the foundation of *experimental therapeutics*—the experimental investigation of the action of drugs in disease.

Preventive or Prophylactic Treatment.—This aims to protect the body from disease. It comprises individual and community hygiene.

Etiologic, Causal or Curative Treatment.—The cure of disease is scarcely possible while the original cause persists. The physician must therefore always aim to discover and remove that cause. If this can be done, the conditions will generally return to the healthy normal unless anatomic lesions have already occurred. The chances for complete recovery are therefore the better, the earlier effective treatment is instituted. However, even considerable anatomic deficiencies can be compensated by the fact that the organism has large “factors of safety” (Meltzer).

Symptomatic, Functional or Alleviative Treatment.—When the cause of the diseased condition cannot be attacked, it is often possible to remove its functional manifestation or symptoms. This may be useful in some cases, objectionable in others.

¹ In this connection see S. J. Meltzer's essay on the Therapeutics of Self-repair; *Am. J. Med. Sc.*, July, 1908.

In striking the symptoms one very often also strikes the disease. The symptoms in themselves may be so objectionable or lead to such secondary results as to make their removal desirable. Pain, cough, and fever are all purely symptoms, and yet no one would refuse to treat them simply because unable to remove the root of the disorder. The derangement of function may be immediately threatening to life, *f.i.*, cardiac dilation; or it may add to the tax on the diseased organs, *f.i.*, the edemas of valvular disease. The faulty functionation may also be relieved by increasing other compensating functions, *f.i.*, diaphoresis in renal disease.

On the other hand, the symptoms may be very deceptive—a chill will not require external heat; a referred pain will not be relieved by local application of iodine to the place where it is felt. In removing the symptoms the physician also deprives himself of the only index to the treatment of the underlying disorder. He must constantly be on his guard against believing himself successful when he has succeeded in removing one or several of the symptoms of the disease. In many cases the symptom may itself be salutary; in which case it would not do to remove it (*e.g.*, cough when there is hypersecretion of mucus; a certain amount of pain when rest is indicated in fracture).

It need scarcely be added that it is not ethical to persuade a patient that he is being cured when he is in fact only being relieved of the symptoms.

Restorative or Roborant (Strengthening or Tonic) Treatment.—

Disease generally impairs the vitality and resistance of the organs directly involved, and of the body at large. This is corrected by rest and efficient nutrition of the diseased organs and of the entire patient; and by correcting any other abnormal conditions (digestive disturbances, suppurations, etc.) which may be present, and which are added drains on the vitality of the patient.

Expectant Treatment.—This is the absence of any real attempt at treatment beyond hygiene, rest, diet, and other similar general measures; with the object of leaving the powers of nature free play. This should be employed in all cases where no better treatment is known; but, as has been said, it is usually within the province and power of the physician to support nature in her endeavor.

The expectant treatment must also be used when it is desired to let the disease progress to a certain point, if this is necessary for diagnosis.

Empiric and Rational Therapeutics.—The treatment of disease has developed by two different methods, or perhaps more accurately, attitudes of mind. The *Empiric* method follows merely the dictates of apparent experience, without concerning itself about the reasons of these. It is typified by the patent medicine slogan; “it has cured others and will cure you.”

While in the present state of medical science it is still necessary to employ empiricism only too often, it requires only a thought to see how often it may be not only useless, but even injurious. Conditions which resemble each other very closely superficially may really be diametrically opposite, and may require very different treatment. The objection to the empiric method is not that it rests upon experience, which is the basis of all science, but that it does not endeavor sufficiently to distinguish whether the experience is real or deceptive. It is, of course, an equally grave error to go to the opposite extreme, and to base treatment on theories and deductions inadequately supported by observation.

Rational or scientific therapeutics should employ observation, experiment and scientific reasoning, checking each against the others.

A real science of therapeutics, by which it would be possible to foretell the exact results is still largely a vision. The numerous physiologic and pathologic variables render predictions uncertain. The personal factor plays a large rôle; and the due appreciation of this—“the art of therapeutics”—is therefore very important. However, the best results can only be secured by the critical application of all the known scientific facts.

Pharmaceutical and Non-pharmaceutical Therapeutics.—A distinction is sometimes made between “drugs” and “physiological agents,” including under the latter physical measures, such as heat or cold, bathing or climate, rest, exercise and massage, diet, etc. The distinction is convenient, but not fundamental. The use of drugs is no more “unphysiological” than the use of abnormal heat or cold, or of special diets, etc. The mechanisms of their action are not essentially dissimilar. Each is intended to produce definite changes of functions. One or the other may be better adapted to secure this end; and the physician should not hesitate to employ whichever is best suited.

Physiologic Processes Normally Controlled by Pharmacologic Agents.—The body normally produces a variety of pharmacologically active substances, as direct or by-products of its metabolism, and uses them as aids in regulating its own activity. The CO₂ control of the respiration and the various other hormones and internal secretions are familiar examples in mammalian physiology (Starling, 1908). The use of drugs is therefore not an unphysiologic proceeding.

THE PHILOSOPHIES OF THERAPEUTICS

Development of Therapeutics.—A glance at the history of therapeutics, the treatment of disease, will serve to explain errors which have long adhered to and which still adhere to the subject.

We may imagine one of our remotest ancestors brought face to face with disease. How mysterious must have seemed to him the phenomenon that yesterday he was strong, active, and full of life, and to-day, without any cause apparent to him, he is weak, listless, and about to die. What strong hold it must have taken upon his imagination, and how earnestly he must have sought for means to remedy it! Here he happened at once upon two apparently very different methods: a spiritual and a material. On the one hand, overpowered by the mysteriousness of the process, he lost himself in superstition. He deemed the disease due to malevolent spirits which could be appeased by prayers and incantations. This formed the principal materia medica of prehistoric ages, as it does of the modern savage. It still survives in a modified form in “Christian Science.”

On the other hand, chance and the observation of animals revealed to him that certain material products were also efficient. As long as he limited himself to actual observation, the results were usually good. However, he soon began to search for more of these remedial agents. In his ignorance as to the nature of the action—both of the disease and remedy, he was only too glad to be guided by any ray of light, without having the means to examine whether the light came from a beacon or was only an ignis fatuus. With the fantastic, half logical incongruity so characteristic of the untutored mind he assumed the most extraordinary relations.

It is interesting to observe a little closer the principles which guided the savage in his search for remedies. Having found that most active medicines had a bitter or disagreeable taste, he came to regard any such substance as beneficial. Thus arose a host of simples most of which might now be disregarded were it not that some zealot occasionally disturbs their repose and attempts to launch them as something new.

At a later period of the middle ages it was tried to combine the spiritual and the material treatment. It was thought that the Deity alone could cure disease, but that He had given man material remedies, and in His wisdom He had put a seal upon them by which man might know them. Thus arose in due time what is called the doctrine of “signatures.” According to this, the use of a remedy was suggested by a fanciful resemblance in shape or color to some organ; e.g., the liverwort, the lungwort, blood-root, etc. Even a name was sufficient. Silver was used in lunacy because it was dedicated to Luna.

On the other hand, alchemists had arisen with their pertinacious search for the philosopher’s stone, which was to convert all metals into gold, and cure all diseases. In this search they gave their *nostra* extensive trial on sick and well.

The school of spagirists was founded toward the end of the fourteenth century and reached its zenith with Paracelsus. They insisted upon the mystical virtues of antimony, arsenic and silver and chemicals in general, and stood opposed to the old Galen-

ists, who used only organic drugs. Notwithstanding their mysticism, which savors of quackery, we must thank them for the discovery of some valuable medicines.

Thus, a mass of materials, rubbish and otherwise, was added to the various simples, etc. Having so well-stocked an armory, the physician of that day felt that he was not doing his duty unless he gave his patient the benefit of it all, and the "shot-gun" prescription flourished at its best.

The Homeopathic Doctrine.—A natural reaction against this excessive drugging set in, and had for one of its first results the establishment of homeopathy by Hahnemann, near the end of the eighteenth century. The Hahnemann system was by no means new. For the most part it had its roots much further back. It was the natural result of the then existing theory of "vitalism."

Hahnemann believed that disease depends upon a perversion of the purely spiritual vital powers and is entirely immaterial in its nature. Logically, a thing spiritual could not be combated by material remedies, and hence, Hahnemann turned to a spiritual power which he believed to be bound up in plants and liberated by dilution. The activity would therefore increase with the dilution, and be the greater, the smaller the dose (doctrine of potency). This liberation of the principles exactly turned their action around, so that the action of his dilutions was, he stated, exactly the opposite of that of the concentrated drug, and could be used for the relief of such symptoms as the latter produced: *Similia similibus curantur*. This was the first tenet of Hahnemann. The second was that the nature of the disease being unseizable, it was not subject to treatment, but that only its symptoms could be treated. Hence, homeopathy, in so far as it follows the principles of its founder, has no place for the medical sciences, such as physiology, anatomy, pathology, or chemistry. Any one with an indexed book of symptoms and their remedies would be able to practice it without an elaborate study or preparation.

In marked contrast to the above is the third dictum: that the medicinal treatment must be supported by dietetic and hygienic measures.

The claims of homeopathy as a rational system hinge on the proof of the *similia imilibus* theory and of the doctrine of potentiation by dilution. Most of its advocates seem to deny altogether the relevance of scientific testimony, and to base themselves purely on the slippery ground of empirical experience. Others, while they neglect the great body of scientific experience which disproves their theory, avail themselves of the few experimental facts, which, through a variety of sophistications, can be twisted into a specious support. Hahnemann himself seems to have started from the observation that large doses of drugs produce the opposite effects from moderate doses. The correctness of this principle may be granted, for many cases. But it is a very unwarranted feat of logic to assume that infinitesimal doses must again cause effects opposite to those of moderate doses!

The more recent discovery of the effect of dilution on electrolytic dissociation, on ionization, has also been seized upon as illustrating homeopathy—quite disregarding the fact that the action depends on the number of ions rather than on the degree of ionization; and the further fact, that the majority of the substances employed in homeopathy are not electrolytes at all! These few examples of inconsistencies may suffice.

In his time, Hahnemann accomplished considerable for medical science. He called attention to the importance of diet, etc., when this was only too much neglected; but perhaps the principal use of homeopathy has been to show to rational medicine the fact that disease tends to recovery without any medical interference.

Therapeutic Nihilism.—This was, indeed, the next step which medicine took—total emancipation from all drugs. This dates from the establishment of the Vienna school by van Swieten, in 1745. The strongest advocate of nihilism was Skoda (1805-1881), the founder of the methods of percussion and auscultation. Such nihilism was absolutely necessary at that time, just as periods of skepticism are necessary in philosophy, and mark steps in progress. The accumulated refuse was so great as to bury the good. The only way was to empty out the whole and begin anew. This was a necessity then, but now consistent nihilism is as inconsistent as the "Shot-gun" prescription.

The Rise of Rational Therapeutics.—The reestablishment of therapeutics, founded now upon reason, was thus aided by the very man who had attempted to destroy it. For he established physical methods of diagnosis, and demonstrated the effects of disease as they had never been demonstrated before, making it possible also to demonstrate the effect of remedies.

Then followed the isolation of active principles (led by the discovery of morphine in 1817), thus substituting the definite for the indefinite drugs. Finally followed animal experimentation, by means of which modern pharmacology has developed.

Psychotherapy.—Rational therapeutics is now on a firm basis. But, at the same time, the mystic has also been further developed, not only in homeopathy, but also

in the many forms of suggestion. The value of suggestive therapeutics proper cannot be denied. It is a strictly scientific method of treatment, and is employed in its milder forms by every physician as "the personal influence" and the "faith in doctor and medicine." It often constitutes all there is of merit in those medical fads which have accompanied medical science since the oldest time.

DIGESTIVE FERMENTS

Nature of Ferments.—The digestion of food in the alimentary canal is accomplished mainly by the secretion of organic ferments or enzymes; colloid substances of unknown composition, whose presence accelerates chemical changes. Commercial ferments consist of the dried gland, or more or less purified extracts, rich in protein, and dried or preserved by glycerin.

Our knowledge of the nature of ferments is very incomplete. Like colloids, they possess electric charges (Michaelis, 1909). Emil Fischer found their action on sugars to depend on their optic activity. Several workers have shown that the cleavage ferments may, under proper conditions, produce syntheses (Taylor, 1904). The term "fermentation" is derived from fermentum, leaven; and this probably from *fervere*, to boil. It was originally applied to all effervescence.

The principal ferment preparations are: pepsin, papain, the diastases (malt) and pancreas. The purified pancreatic extract, insulin, will also be discussed in this connection.

Conditions of Action and Deterioration.—The digestive ferments are specifically adapted to the hydrolytic cleavage of the various food products (amylolytic, proteolytic, lipolytic, etc.). Their activity is greatly influenced by various conditions, especially by temperature (40° to 45°C . being optimal for mammalian ferments); by acid or alkaline reaction; by salts, etc. Solutions are quite unstable. They are destroyed rapidly about 50°C ., immediately by boiling and more gradually by any excessive conditions, and by putrefaction. Pepsin is much more resistant to destruction than trypsin, but both deteriorate even in neutral solutions, trypsin often in a few days. Dilute watery solutions deteriorate quickly even at ordinary temperature; and even dry "pancreatin" is unstable (Long and Muhleman, 1914). Pepsin can be completely destroyed by shaking (Shaklee and Meltzer, 1909).

Incompatibilities.—Solutions of ferments are incompatible with excess of acid and alkali (Long and Muhleman, 1914) or salts; with many antiseptics; with excess of alcohol; and with all protein-precipitants. Pepsin in neutral or alkaline solution is destroyed by sodium chloride (W. H. Hamburger, 1915).

Mixtures of ferments digest each other more or less rapidly according to their reaction. Pepsin, in the presence of weak acids, destroys trypsin and amylopsin completely; but trypsin has little effect on pepsin under ordinary conditions (Long and Muhleman). "Compound Digestive Elixirs," supposed to contain pepsin with pancreatin, etc., are practically worthless (J.A.M.A., 1907, v. 48, p. 434).

Administration of Ferments in Digestive Disorders.—This has not realized the early expectations (Bastedo report, 1925) one reason being that digestive disturbances are rarely due to deficiency of ferments. It is also difficult to administer ferments so that they could develop their actions. Apparently favorable results may often be explained by the other treatment with which they are usually combined.

Persistence of Ferments in the Stomach.—The reaction of the stomach is best suited to pepsin, and is more or less inimical to diastase and trypsin. However, when these ferments are thoroughly mixed with food, they may act in the fundus of the stomach for an hour or so (Cannon), before the mass becomes acid (Gruetznier, 1905); and since the acid is largely bound by the proteins, some of the trypsin may pass the stomach unchanged (Long and Hull, 1917). The actual quantity is generally too small for any practical use. However, there are some data which suggest that the administration of fresh pancreas by mouth improves the absorption of fat and proteins in dogs deprived of natural pancreatic secretion (Sandmeyer, 1895; Pratt 1909). The action of papain is too feeble at body temperature to deserve consideration.

Other Uses.—A more rational field for ferments is in the preparation of predigested foods, especially for rectal alimentation. Rennin and Pepsin are used for curdling milk. Pepsin has been employed to dissolve diphtheritic membranes.

PREPARATIONS—FERMENTS

Diastasum; Diastase.—A mixture containing amylolytic enzymes obtained from an infusion of malt. It converts not less than fifty times its weight of potato starch into sugars. A yellowish-white, amorphous powder or in translucent scales; odorless and tasteless. Diastase gradually loses its amylolytic power on keeping; its activity is diminished by the presence of acids or alkalis. Sol. in water; almost insol. in alc. *Dose*, 0.5 Gm., 8 gr.

Diastatic ferments are also obtained from other sources, animal and vegetable; takadiastase, for instance, from a Japanese mould. Their diastatic action is weak and unreliable (J.A.M.A., July 6, 1912, p. 50).

Maltum, U.S.P.; Malt.—The grain of barley, *Hordeum vulgare*, partially germinated artificially, and then dried at a temperature not exceeding 55°C. It is capable of converting not less than five times its weight of starch into sugars.

Extractum Malti (Ext. Malt.), U.S.P.; Extract of Malt.—Obtained by infusing malt with water at 60°C., concentrating the expressed liquid at a temperature not exceeding 60°C. and adding 10 per cent. by weight, of glycerin. Contains dextrin, maltose, a small amount of glucose, and an amylolytic enzyme. Extract of Malt is capable of converting not less than five times its weight of starch into water-soluble sugars. The extract is therefore a nutrient rather than a digestant. *Dose*, 15 Gm., 4 drachms, U.S.P.

Pancreatinum (*Pancreat.*), U.S.P.; Pancreatin.—A mixture containing enzymes, consisting principally of amylpsin, trypsin and steapsin, obtained from the fresh pancreas of the hog or of the beef. It converts not less than 25 times its own weight of starch into sugars and not less than 25 times its weight of casein into proteoses. Lipase is often absent, since it is destroyed by trypsin. The amylpsin acts best in a faintly alkaline (0.025 per cent. NaHCO_3) or neutral medium, and is destroyed by very weak acidity (0.006 per cent. HCl) (Long and Muhleman, 1914). Trypsin also acts best when alkaline (0.2 to 1 per cent. Na_2CO_3) but is somewhat active with very weak acidity.

The optimal reaction varies for different proteins (Long and Hull, 1917).

Excess in either direction is detrimental. It acts best on fibrin or casein, feebly on cooked albumen, and scarcely at all on raw albumen (Long and Muhleman; Sugimoto, 1913). Pancreatin occurs as a cream-colored, amorphous powder, having a faint, peculiar odor. Slowly sol. in water; insol. in alc. *Dose*, 0.5 Gm., 8 gr., U.S.P.

Hypodermic Trypsin Injections against Cancer.—These were advocated by J. Beard, 1905; and Shaw-Mackenzie, 1906, but proved disappointing. They produce local lesions and toxic effects resembling peptone-poisoning (Kirchheim, 1911, Wago, 1919). Intravenous injections are very toxic (Hildebrandt, 1890). Papain and takadiastase act similarly (Kirchheim, 1913).

Liq. Pancreat., B.P.—An alcohol-glycerin extract. *Dose* 4 to 8 c.c., 1 to 2 drachms, B.P.

Pulv. Pancreat. Co., N.F., B.P.C.—Pancreatin mixed with 4 parts of sodium bicarbonate; is used for the *artificial digestion of milk* (1.5 to 500, 38°C., 100°F., for half an hour).

Papain.—The dried milk-juice of the unripe fruit of *Carica Papaya*. Extracts are marketed under proprietary names. It is supposed to digest proteins in acid, alkaline and neutral media; its activity, however, is variable, and always much less than pepsin (Proc. A. Pharm. Assoc., 35, 740). The digestion is more rapid at 80° to 50°C (Pogerski, 1909; some of its peculiarities were studied by Mendel and Blood, 1910.) *Dose*, 0.1 to 1 Gm.

Pepsinum (Pepsin), U.S.P., B.P.—A proteolytic extract obtained from the mucous membrane of the stomach of the pig (or sheep or calf, B.P.). Capable of digesting not less than 3,000 parts of coagulated egg-albumen (U.S.P.), (2,500 parts, B.P.), when the test is made according to the official directions. Various processes are used in its manufacture. White or yellowish scales or powder, slight odor and taste; acid reaction. Freely Sol. in water; nearly insol. in alc. Solutions are *incompatible* with alkalies, salts, metals, and tannin.

All acid solutions deteriorate gradually in proportion to their acidity (C. F. Ramsay, 1917).

The *optimal reaction* for pepsin is $[H] = 4 \times 10^{-2}$; but there is practically little difference between 5.8 and 1.7×10^{-2} (Okada).

Dose, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 0.6 Gm., 5 to 10 gr., B.P. Numberless proprietary preparations are advertised, but are without material advantage.

Glycer. Pepsin., B.P.—10 per cent. of pepsin; 1.15 per cent. of hydrochloric acid. *Dose*, 4 to 8 c.c., 1 to 2 drachms, B.P.

Pepsin. Sacch.—1:10 of milk-sugar.

Liq. Seriparus, N.F., B.P.C.; Liquid Rennet.—Extracts of the fourth stomach of calves; used to coagulate unboiled milk (1:100 to 300, 38°C., 100°F.) for the preparation of junket and whey.

INSULIN

Insulin is a purified extract of the pancreas, containing, in an active form, the principle of the islands of Langerhans that appears to be essential for the metabolism of sugar. It is used in the treatment of diabetes mellitus.

Effects on Sugar Metabolism.—The hypodermic injection of insulin results in increased combustion of sugar and at the same time in increased deposition of glycogen. Both actions combine to lower the level of the blood sugar, and therefore to suppress all forms of glycosuria. The restored combustion of sugar also makes possible the proper combustion of fats and thus corrects the faulty fat-metabolism, the lipemia, and the ketosis and acidosis that are responsible for diabetic coma. The administration of appropriate doses of insulin therefore relieves all the phenomena of diabetes mellitus, from the minor symptoms to the coma. It is used as an adjunct to the dietetic treatment, permitting a more liberal diet; it is especially important for meeting acute emergencies, such as coma; and to increase the resistance of the patient against surgical operations, gangrene, infections, or any other heavy demands.

Insulin Action on Carbohydrate Metabolism.—The administration of Insulin lowers the blood-sugar level under all conditions, and therefore abolishes all the glycosurias that are due to hyperglycemia, such as pancreatic, puncture, epinephrine, asphyxia, carbon monoxide, ether, morphine, etc.; and it diminishes phlorrhizin glycosuria. The principal share in the acute fall of the blood-sugar level is the passage of the sugar into the liver and tissues, where it is stored in part as glycogen (McCormick, Macleod et al., 1923; A.C.F. Cori et al., 1923). At the same time, the oxidation of sugar is increased, as shown by a rise of the respiratory quotient and by increased heat-production (R. S. Lyman et al., 1923). The increased sugar consumption can be demonstrated even on the isolated mammalian heart; although the combustion and the glycogen deposition are naturally most marked when the insulin is administered together with carbohydrates to diabetic individuals. In clinical diabetes as well as in the experimental diabetes of animals, insulin restores the lost ability to oxidize carbohydrates and to store glycogen in the liver.

Inter-relations.—*Excision of the liver* does not prevent the insulin hypoglycemia, but hinders the subsequent restoration of the blood-sugar level (F. C. Mann and Magath, 1923). *The adrenals* are apparently not concerned in the insulin action; for neither does adrenalectomy modify the nature of the blood-sugar response, nor does insulin affect the epinephrine output of the adrenal glands; nor does *morphine glycosuria*, which appears to require the presence of the adrenal glands, differ from other glycosurias

in its response to insulin (Stewart and Rogoff, 1923). *Phlorrhizin* also does not modify the depressant action of insulin on the blood-sugar; insulin therefore diminishes the glycosuria, though it may not suppress it entirely. The indirect effects on the nitrogen excretion have not been sufficiently cleared up (F. P. Nash, 1923; M. Ringer, 1923; C. T. Cori, 1923). In *vitamine-deficient pigeons*, insulin administration restores the ability to store glycogen, and therefore improves the assimilation of the polished rice; but it does not remove the polyneuritis (Bickel and Collazo, 1923).

Mechanism of Insulin Action.—Insulin appears to be necessary for the metabolism of the sugar in the body, both for its decomposition (combustion) and for its polymerization (glycogen formation). Since it occurs in all vertebrates and in invertebrates such as shellfish, and since an analogous although perhaps not identical substance, *glucokinin* occurs in yeast and in the higher plants (Collip, 1923; effects on plants, M. M. Ellis and Eyster, 1923), it may be assumed that protoplasm in general cannot properly assimilate sugar except by the aid of this substance. It has been suggested that it converts the ordinary alpha and beta isomers of dextrose into a somewhat hypothetical, more labile gamma isomer (Winter and Smith, 1922; W. D. Forrest et al., 1923); but this remains to be established.

Clinical Efficiency in Diabetes Mellitus.—The properly dosed and spaced administration of insulin abolishes the glycosuria and the excessive glycemia, diminishes the thirst and polyuria, removes the emaciation, the edema, and the mental inertia, controls the acidosis, lowers the non-protein nitrogen and the creatinine of the blood to the normal level, and restores patients from complete coma (C. B. F. Gibbs and Sutter, 1923). The effects usually last only during the continuance of the insulin administration; although in the relatively lighter cases a partial restoration of the functions of the pancreas seems sometimes to occur, presumably as an indirect result of the improved health of the patient.

Hypoglycemia.—If the dosage of insulin is such as to reduce the blood-sugar too much below the normal level, both in diabetic and in normal individuals, symptoms of "nervousness" appear, which increase in proportion to the descent of the blood-sugar level, and culminate in convulsions, coma and death. They may, however, be promptly and completely removed by restoring the normal blood-sugar level, by the administration of sugar.

Hypoglycemia Symptoms.—The clinical symptoms of overdosage progress through weakness and fatigue, nervousness and tremor to profuse sweating (the most characteristic feature), palpitation, and sometimes pallor and flushing. More severe cases suffer from acute distress, mental disturbances, unconsciousness; and with still further lowering of blood sugar (in animals), prolonged irregular convulsions and death.

The phenomena are proportional to the lowering of the level of the blood sugar; but the critical level varies somewhat for different species, individuals and conditions. In man, symptoms begin usually at the blood sugar level of about 0.07 per cent., and coma at about 0.035 per cent. (Banting, Campbell and Fletcher, 1923); but these levels are raised if the blood-sugar has been persistently high, and if the reduction is abrupt. Rabbits become convulsive between 0.047 and 0.037 per cent.; dogs are very resistant (0.018 per cent., Banting). Pigeons, which have normally a rather high sugar-level (0.150 to 0.185 per cent.) do not show any noticeable symptoms at 0.080 per cent., but their ovulation is decreased (O. Riddle, 1923).

Relief of Hypoglycemia.—This may be secured by the oral administration of sugar (candy) or any other carbohydrates that form dextrose.

If the patient is comatose, glucose is administered intravenously, 5 to 20 grams in 5 to 50 per cent. solution. The sterilized solution should be kept on hand for emergency. If it is not available, epinephrine may be injected hypodermically (0.5 to 0.5 c.c. of 1:1,000), always followed by sugar by mouth. Epinephrine is effective only by mobilizing stored glycogen, and is therefore likely to fail in diabetes (R. S. Lyman et al., 1923).

Other sugars than dextrose and mannose are not effective antidotes. Alkalies and sodium lactate have no effect (E. C. Noble and Macleod, 1923). Glycerol is effective in rats (Voegtlin, Dunn and Thompson, 1925); its mechanism is obscure.

Mechanism of the Hypoglycemic Convulsions.—These are accompanied by marked venosity of the blood; they are of the same asymmetric type as asphyxial convulsions and

originate in the same region; *i.e.* they occur after decerebration, but not after transection below the medulla. The asphyxia, however, is not explainable by interference with the respiratory movements. It has been suggested that the lowered sugar-level interfered with the oxidative processes in the nervous centers (J. M. D. Olmstead and Logan, 1923). Raising the temperature of the room hastens markedly the onset of the convulsions in rats (Voegtlin and Dunn, 1922).

Circulation.—Dogs show a slight decrease of cardiac efficiency during the hypoglycemia (D. J. Edwards et al., 1924).

Dosage.—The action of the insulin is exerted only as long as it is present in the body, although it improves the course of the disease indirectly. It must therefore be administered continuously, two or three times a day, in proper dosage, which must be adjusted to the individual case, and carefully controlled. Inadequate dosage fails to secure the full benefits, and excessive doses produce the very serious phenomena of hypoglycemia.

The dosage of insulin is expressed in "units," the preparations being standardized experimentally by their effect in lowering the blood-sugar level of rabbits. Under ordinary clinical conditions, the "unit" of insulin disposes of about two grams of dextrose; and the dosage is adjusted to metabolize the amount of dextrose that appears in the urine of the patient with the prescribed diet. Patients whose glycosuria can be suppressed by an adequate diet do not require insulin. Cases of moderate severity require 5 to 60 units per day. In coma or acidosis, 30 to 60 units may be given intravenously, followed every 3 to 4 hours by 20 or more units subcutaneously; but rarely exceeding 120 units in 12 hours, and guarding against hypoglycemia by administering a gram of glucose for every unit of insulin. The quantity of glucose must be increased if necessary, so as to produce some glycosuria (the urine should be examined every hour). Sterilized glucose solution, 50 to 100 c.c. of 10 per cent. solution, for intravenous injection, should be in readiness against emergency.

Adjustment of Dosage.—For patients that are being well observed, it is advised to adjust the dosage as: Units per day equals
$$\frac{\text{average grams of glucose in urine, per day.}}{1.5}$$

This dose is therefor somewhat higher than the equivalence of two grams of glucose per unit. In patients who cannot be so well observed, it is recommended to start with half of the estimated dose, and to increase this gradually until therapeutic results are obtained.

The daily dosage is usually distributed equally between two injections, given 0 to 30 minutes after breakfast and supper; if the daily dose exceeds 40 units, a third injection is made before the noon meal. The carbohydrates should be fairly evenly distributed between the three meals.

Insulin is not indicated as a routine so long as the patient metabolizes enough glucose to permit a diet sufficient for light work; but it may be used in such cases for unusual demands and emergencies.

Administration.—Insulin is most effective hypodermically. The injection is somewhat irritant, (D. J. Bowie and Robinson, 1923), but not sufficiently to constitute a serious objection; the irritation is said to become less noticeable with continued use (M. Sturtevant, 1924). The intravenous injection acts most rapidly and may therefor be preferred for the first dose in coma; but the excretion is so rapid that it must be supplemented by the hypodermic injection. Oral administration has only a slight and uncertain effect, because the insulin is in large part destroyed in the digestive tract, and that which is not so destroyed is absorbed abruptly and therefor too rapidly excreted. Pill-coatings do not materially obviate these

difficulties. Other channels of administration, such as the rectum, also give only uncertain results and do not permit the precision of doses that is indispensable.

Channels of Administration.—In depancreatized dogs, Banting et al., 1923, found peritoneal injection practically equal to the intravenous in the degree and rapidity of response. Oral and rectal administration produced some effect, but much less than hypodermic (see also Peskind et al., 1924). Spraying in the nostrils was ineffective. Some absorption has also been observed from a Thiry fistula, from the scrotal sac, and from the vagina (N. F. Fisher 1923). Specially coated tablets, by mouth (Murlin, 1925) gave uncertain results. Telfer, 1925, claimed good absorption from inunction with a lanolin-lard mixture.

Fate and Excretion.—The action of insulin is fairly prolonged. With the hypodermic injection of ordinary doses, the maximal effect on the blood sugar is reached in about $1\frac{1}{2}$ hours, and then declines gradually; but with larger doses, convulsions may persist as long as 24 hours, so that it is not very rapidly destroyed or excreted (G. W. Pucher, Cori and Bowen, 1923). This is perhaps partly due to relatively slow absorption from the skin. When it is injected into the blood, almost the entire amount can be recovered from the urine; with oral administration, about 25 per cent.; less after hypodermic injection (N. F. Fisher and Noble, 1923). Perhaps a part of the superiority of hypodermic administration may be due to the relatively slower absorption and therefor more persistent action.

Preparation of Insulin.—This requires the prompt arrest of proteolysis, and separation from irritant and toxic proteins. This is secured through the method of Collip, 1923, by extraction of the fresh pancreas of cattle, with cold acidized alcohol, and purification of the alcoholic extract by precipitation at the isoelectric point. The precipitate is dissolved in slightly acidulated water, filtered through Berkefeld filters, and standardized by its effect on the blood-sugar level of rabbits. Insulin itself has not been isolated, and its chemical nature is therefor unknown; it is perhaps a protein cleavage-product.

Further details are given in N.N.R. Insulin may also be prepared by other methods; for instance adsorption on freshly prepared benzoic acid (Maloney and Findlay, 1923).

Chemical Properties.—Highly purified insulin does not respond or but faintly to the color reactions of protein; but the precipitation reactions of its solutions resemble those of albumoses. It is freely soluble in water, except between pH 5 and 6. It is also soluble in alcohol, except at the isoelectric point. It is precipitated by half-saturation with ammonium sulphate. It is not demonstrably dialyzable. It is readily adsorbed on charcoal, etc. (E. A. Doisy et al., 1923), and its potency is greatly reduced by passing through a Berkefeld filter (Bert and Macleod, 1923). It is not injured by moderate heating with decinormal acid, but dilute alkalis destroy it at blood-heat, though rather slowly (Dudley, 1923). Its activity is proportional to the loosely combined sulphur (Abel and Geiling, 1925). Its activity is completely destroyed by the proteolytic ferments, pepsin, trypsin and papain (E. J. Witzemann and Lioshis, 1923). Abel, 1926, has obtained a crystalline insulin preparation.

Standardization.—The clinical "*Insulin Unit*" is one third of the amount required to lower the blood sugar of fasting 2 Kg. rabbits (from the normal of 0.1 to 0.12 per cent.) to an average of 0.045 per cent. over a period of 5 hours; the insulin solution being injected hypodermically. The details are described in N.N.R. and discussed by Macleod, 1924. Greater accuracy may be secured by the use of standardized rabbits (Macleod and Orr, 1924), for rabbits differ somewhat in susceptibility. The previous conditions of feeding also influence the results; rabbits fed on acid-forming diet (oats and bread) giving a smaller blood-sugar response than those fed on the alkali producing diet of hay, carrots or cabbage (I. H. Page, 1923). Other methods of standardizing have also been suggested; for instance the degree of interference with the blood-sugar rise after the injection of dextrose or of epinephrine (G. S. Eadie and Macleod, 1923). The occurrence of convulsions for instance in white mice (D. T. Fraser, 1923) forms a less trustworthy, though perhaps more convenient index of the hypoglycemia.

Bibliography.—The scientific literature to 1925, is discussed in a book of Grevenstuck and Laqueur, "*Insulin*," Munich, 1925. This contains 304 titles, which means the publication of a paper for practically every day that insulin has been before the public!

Historical.—Prompted by the dependence of diabetes on injury of the islands of Langerhans, many investigators had sought for a sugar-metabolizing hormone in the pancreas; and some rather suggestive data had been obtained, for instance by Zuelzer and by Murlin. However the results were considered essentially negative. It may now be seen that the failure of the older workers is to be attributed to several causes:

(1) The want of sufficiently delicate methods of blood analysis to give definite indications of successful results.

(2) Partial destruction of the hormone in the course of isolation, by tryptic digestion.

(3) The high toxicity and local irritation of the insufficiently purified extracts, which complicated and obscured the antidiabetic effects.

O. P. Banting, 1920, conceived he thought of avoiding the tryptic digestion by destroying the ferment secreting cells by previous ligation of the pancreatic duct. Under the direction of J. J. R. Macleod, and with the aid of Best, (Banting and Best, 1922), he put this to trial, and by the modern tests succeeded in demonstrating that the extract of the ligated pancreas lowered the blood-sugar level of depancreatized dogs. The practical preparation of the purification of insulin from ordinary pancreas was then worked out by Collip, 1923; and the large-sale production by the firm of Eli Lilly and Company. Insulin is now also marketed by a number of other firms.

PREPARATIONS

* *Insulin, N.N.R.*—Marketed as a somewhat acid (pH 2.5) watery solution, in some brands with the addition of 0.1 per cent. of Cresol. Put up in ampules of 5 and 10 c.c., with 10 to 80 units per c.c. Eli Lilly and Company use the protected name "Iletin."

LACTIC ACID-PRODUCING ORGANISMS

These were introduced by Metchnikoff, with the idea of acidifying the intestines, and thereby preventing intestinal putrefaction, which he held responsible for premature senility.

This theory of old age was without scientific support; nor does the administration of the organisms advocated by him (*Bac. bulgaricus*) or of milk soured by them, check intestinal putrefaction. On the contrary, they succumb promptly to the ordinary putrefactive bacteria of the intestines. Apparently, however, the growth of *Bac. acidophilus*, which is normally present in the intestines, can be increased by the administration of its culture.

On the other hand, sour milk is sometimes distinctly beneficial, especially in pediatrics, against vomiting, acute and chronic diarrhea, etc. (see *N.N.R.*), and there are advantages in souring the milk by known organisms. *Bacillus bulgaricus* is used, alone or in combination with *Streptococcus lacticus*. The reliable commercial preparations are listed in *N.N.R.*

PHLORHIZIN

General Statement.—This glucoside produces a unique glycosuria by forcing the kidneys to the excretion of dextrose, with polyuria and acetoneuria, leading to loss of sugar, and thus to the production of sugar from proteins, greatly increased excretion of nitrogen, etc. The phenomena are of great scientific but of no therapeutic importance (Critical Review, G. Lusk, 1912).

Phlorhizin was isolated by Koninck, 1835, from the root-bark of apple, pear and similar trees. Stas, 1839, showed it to be a glucoside decomposed by acid hydrolysis into dextrose and phloretin; and the latter again into phloretinic acid and phloroglucin. The characteristic glycosuria was discovered by Mering, 1886. It has been produced in all vertebrates tried: mammals, birds, frogs and reptiles. The phlorhizin is excreted for the most part unchanged (Pietkiewicz) within two days (Prausnitz). The glycosuria outlasts the excretion.

The amount of glucose in the urine may be very high, above 12 per cent. It persists for several hours after a single injection, but may be prolonged indefinitely at its highest degree, by administering 1 Gm. of the glucoside per kilo of body-weight, by mouth, three times a day. Larger doses do not increase the glycosuria.

The Glycosuria is Not Pancreatic.—The symptoms after phlorhizin resemble those of pancreatic diabetes, but their mechanism is in fact totally unrelated. The most striking difference is the absence of hyperglycemia. With phlorhizin, the sugar of the blood is diminished (Mering); if the kidneys are excised, or the ureters tied, the blood-sugar remains normal (Minkowski; Schabad, 1892. According to Underhill, 1912, it may rise, indicating overproduction of sugar, but this plays at most a minor part).

The Action is Renal.—It is evident from these experiments that the glycosuria is due essentially to more ready elimination of sugar by the kidneys. The effect is peripheral, for it occurs after destruction of the medulla and cord, and after section of all renal nerves (Frey). It the phlorhizin is injected into one renal artery, glycosuria occurs in this kidney and not in the other (Zuntz). Mosberg deduced by the Nussbaum arrangement that the sugar excretion occurs in the *tubules*, but the evidence is not conclusive. Nishi found that the cortex contains more sugar than the medulla, whilst the reverse holds normally. Histologic changes have also been described in the renal epithelium. Carmine and methylene blue, which are also excreted by the tubules, may suppress the glycosuria.

The excretion of sugar is proportional to the activity of the kidneys; it is diminished, for instance, when one kidney is excised, and increases again as the remaining kidney hypertrophies (Schilling, 1904). The glycosuria is suppressed in severe nephritis, and the injection of phlorhizin (phlorhizin test, 5 mg. in warm water, hypodermically) has been proposed as a means of diagnosis. The result, however, is not decisive in either sense.

Other Renal Functions.—Diuresis occurs (Frey, 1906; Lowei and Neubauer, 1908), presumably as a result of the glycosuria, but is relatively small. The excretion of the other solid constituents, salts, protein, etc., shows no constant abnormalities. The oxygen consumption of the kidneys is largely increased. The *milk* after phlorhizin contains the normal amount of lactose, and no dextrose. Traces of sugar appear also in the saliva and gastric and pancreatic juice (R. G. Pearce, 1916).

Nature of the Action.—The evidence is unsatisfactory and contradictory. Cushny, 1917, considers that it tends to prove that the glycosuria is due to inability of the tubules to absorb sugar from the glomerular filtrate.

The glomerular membrane of perfused frog kidneys is normally impermeable to certain concentrations of glucose (Hamburger). This impermeability is destroyed by phlorhizin (Brickman, 1919). This is in line with Mering's original assumption that the phlorhizin action consists in increased permeability of the kidneys. It appears, however, that this is not the whole explanation for living animals. Levene, *f.i.*, found more sugar in the blood of the renal vein than in that of the renal artery. Minkowski suggested that the phlorhizin acts as a glucosidal vehicle, splitting off its sugar in the kidneys, and again taking up sugar from the tissues; but the quantity of sugar excreted when phlorhizin is injected into the renal artery speaks against this view.

Pavy, Brodie, and Siau (1903) have shown that the quantity of sugar which is excreted when the other abdominal viscera are excised exceeds the quantity of sugar which disappears from the blood, and that which could be derived from the limited glycogen depots of the muscle.

This indicates that phlorhizin causes the kidneys to assume the function of forming sugar from the proteins of the blood, and of secreting this into the urine, *i.e.*, a function analogous to that of the mammary glands. They supposed that the sugar of the blood exists in loose and firm combination with the blood proteins; the phlorhizin causes the kidney to secrete first the loosely combined sugar; and when the supply of this fails, the firmer combination is attacked. The stock of carbohydrates in the body therefore disappears first, although some glycogen is retained very persistently (Mering), even in fasting (Sansum and Woodyatt, 1915). With persistent administration, the sugar is derived from the carbohydrates of the food; and if these are excluded, from the proteins. Exclusion of the liver (Eck's fistula) does not influence the glycosuria (Foster, 1912).

In complete phlorhizin poisoning the ability to oxidize sugar is also impaired, so that dextrose, when injected hypodermically, is completely excreted (Stiles and Lusk).

Liver-glycogen.—Phlorhizin does not mobilize the glycogen directly, but only as a result of the hypoglycemia. On the contrary, when the kidneys are excluded, phlorhizin leads to a re-accumulation of hepatic glycogen. Since there is no hyperglycemia, it appears that phlorhizin stimulates directly the synthesis of glycogen. When the kidneys are intact, this action is overcome by the glycosuria (Eptein and Baehr, 1916).

D ÷ N Ratio.—In the urines of depancreatized dogs, fasting or fed on meat or fat, Minkowski found that the weight of dextrose divided by the weight of nitrogen gave a constant ratio of 2.8. This signifies that 45 per cent. of the protein molecule is excreted as dextrose. A ratio greater than this shows that some of the sugar ("extra-sugar") is derived from other sources. Phlorhizin produces the 2.8 ratio in fasting rabbits, cats

and goats, after the "extra-sugar" has been flushed out. In dogs, the ratio is 3.67, so that 58.7 per cent. of the protein is excreted as dextrose. This ratio is also found in acute human diabetes.

Sources of the Sugar.—Feeding with meat or gelatin increases the dextrose excretion, but leaves the ratio unchanged, showing that their conversion into sugar takes the ordinary course. Glycocoll, alanine, leucine, asparaginic acid and glutaminic acid are more or less completely converted into dextrose. The following are also converted and excreted as dextrose, and therefore raise the $D \div N$ quotient: levulose, lacose, d-lactic acid, glycerin, glycinic acid, propyl alcohol. Feeding with fat, ethyl or butyl alcohol and tyrosin have no influence, so that no dextrose can be formed from these sources.

Total Metabolism.—The calories lost by the glycosuria are compensated by increased nitrogen metabolism, the fat metabolism remaining unchanged. In fasting animals the N excretion may be increased to four or five times above hunger alone (Reilly, Nolan and Lusk).

Acidosis.—In starving animals phlorhizin produces fatty changes in the liver, with increased excretion of ammonia, beta-oxybutyric acid and acetone substances (Mering). This is prevented if plenty of carbohydrates is given (Moritz and Prausnitz). It is increased by the ingestion of butyric acid or butter-fat. These changes are analogous to those caused by other agents producing inordinate protein metabolism.

Phlorhizin Test of Renal Function.—This is described in N.N.R. It has not maintained itself, although it is still recommended by some (for instance, Krotoszyner and Stevens, 1917. These authors use 0.01 Gm. in 2 c.c. of saline intravenously). Carnio, 1916, has also suggested glycosuria after lumbar subdural injection as an indication of meningitis. Normal meninges being impermeable to it, no sugar appears in health.

MEDICINAL FOODS

Limitations.—The administration of food in the guise of medicine is sometimes advantageous; but medicinal foods are subject to the ordinary law of dietetics, and therefore can not accomplish the wonders which are often claimed for them. The proprietary foods have been enormously overestimated, and therefore have probably done more harm than good. The ultimate value of any food depends mainly on the amount of calories which it can yield, and on its supplying at least a minimum of proteins, of the essential amino-acids and of vitamins. In these respects, the medicinal foods are all inferior, for they can not be administered practically in sufficient quantity to supply the needs of the body. They have a place as adjuvants to other foods, permitting the introduction of more food than the patient could otherwise be induced to take. This may be needed for superalimentation; when digestion is low, as in fevers or convalescence; or to tide the patient over some temporary crisis. Aside from the special diabetes foods and cod liver oil, their value is largely psychic. The better medicinal foods, it is true, are free from indigestible portions, and are pleasantly flavored; those which contain meat extractives would stimulate the flow of gastric juice; but all these properties are possessed by milk, eggs, cereals and soups. A few are more concentrated; but this has no advantage in feeding the sick, since water must be supplied in one form or another.

Rectal Feeding.—This would be desirable when food by mouth is inadmissible. Its practical possibilities are, however, limited mainly to dextrose and water. It therefore suffices only for short periods, depending on the previous condition of the patient, especially the adipose tissue.

The rectum and large intestine have practically no digestive power, except to a limited extent for carbohydrates. Water, dextrose and sodium chloride are absorbed effectively from nutrient enemas. Dextrin is easily digested and then absorbed. Amino-acids are absorbable, but proteins are not; not even peptones unless they are first broken down by

bacterial putrefaction. Fats are practically unabsorbed (a good discussion of the subject is given by van Noorden, 1920).

Water.—Its absorption is a normal function of the colon, for this resorbs $\frac{1}{2}$ to $\frac{2}{3}$ of the water of the colon-contents. The entire water-needs of the organism can be supplied by this channel; provided that the injections do not contain irritant substances, and are not too strongly anisotonic.

Salts.—Many are absorbed perfectly, including NaCl. The colon expels hypo- and especially hypertonic solutions. 0.8 to 0.9 per cent. NaCl is osmotically indifferent, but may cause thirst. 0.6 to 0.75 per cent. is the best concentration.

Alcohol.—This is readily absorbed. 3 per cent. solutions are non-irritant; higher concentrations may be expelled.

Carbohydrates.—The most useful are dextrose (Bergmark, 1915) and dextrin, which are both absorbed.

Dextrose.—May be used as 6 to 7 per cent. for single injection, or 5 per cent. for continuous irrigation. If salt is added, the dextrose must be reduced (for instance 2.2 per cent. of dextrose and 0.45 per cent. NaCl).

Dextrin.—This is non-irritant in any concentration, and is easily digested. It may be used as 10 to 15 per cent. for continuous irrigation; or 20 to 25 per cent. for single enemas. This higher concentration makes it possible to introduce more calories than with dextrose.

Levulose and Maltose.—Excite peristalsis. *Lactose* is not easily absorbed, and *Galactose* is poorly utilized. *Saccharose* is absorbed poorly. *Starch*, boiled or raw, is non-irritant, and is somewhat digested, but only in limited quantity.

Proteins.—These must be broken down to amino-acids and polypeptids before they can be utilized. The colon readily absorbs these cleavage products; but its peptolytic power is insignificant. However, bacterial putrefactive processes are active, and through them a fair amount of protein becomes absorbable. One of the most accessible sources is *Witte's peptone*. This may be given as 15 to 20 per cent. in single enemas, or 5 to 10 per cent. for continuous irrigation. About 75 per cent. of its nitrogen is absorbed.

Amino-acid mixtures (erepton, etc.), would theoretically be preferable, but have no apparent advantage.

Absorbable protein cleavage products can also be secured by pancreatin-digestion of milk carried on for 24 hours (Reach, 1901). This may be used as the vehicle for the dextrose (Bywaters and Short, 1913). Practically no protein is absorbed from milk or eggs, unless they are predigested to the amino-acid state (Bergmark, 1915; Adler, 1915).

The value of the proteins to an enema-nourished patient requires investigation. They increase the energy metabolism to such a degree that their calorific value is probably negative.

Fats.—Only small quantities are absorbable from the colon; (Makashima, 1914; Ornstein, 1918); at most 10 grams per day. Ordinary oils, for instance olive oil, are least absorbable; milk and cream are somewhat better. Egg-yolk is absorbed most efficiently but is liable to putrefaction.

Technic of Nutrient Enemas.—These may be given as "single enemas," or as "continuous drop enemas."

Single Enemas.—Two of these should be administered daily, each of 300 c.c. They are warmed and injected very slowly through a funnel and soft rectal tube, inserted about 3 inches. The patient remains recumbent for at least 2 hours, and the anus may be compressed with a warm towel for 10 minutes. Tr. opii, $\frac{1}{2}$ c.c., may be added to the injection or better be injected 20 or 30 minutes in advance. Small enemas are carried by antiperistalsis to the cecum, but not into the ileum; with larger injections, some of the material passes into the small intestine (Cannon).

With nutrient enemas containing albumen, peptone or fat, two cleansing enemas should be given daily; if only carbohydrate and albumen are used, one cleansing enema suffices.

Continuous Drop-irrigation is Preferable.—The usual daily dosage is 1,200 to 1,500 c.c. and not over 2 liters.

Nitrogenous and carbohydrate injections are best given separately.

Parenteral Alimentation.—Dextrose may be injected subcutaneously or intravenously when absorption from the alimentary tract is defective; *i.e.*, in acute fevers or shock. Proteins are unsuitable for parenteral administration, since they provoke toxic reactions. Homologous serum may be an exception, but is not available practically in adequate quantity.

The injection of amino-acids is still experimental and not very promising. Oil is but little absorbed from subcutaneous injection (only about 1 Gm. per day); and it is doubtful whether this is in suitable form for metabolism (van Noorden, 1920).

Subcutaneous Feeding.—The hypodermic injection of nutrient solutions has been tried with limited success. *Dextrose* has given the most promising results. Even large doses are well utilized and have no detrimental effects on nitrogen metabolism (Underhill and Closson, 1906; Berendes, 1911); but are capable of diminishing acetoneuria (Bergmark, 1915). Only a small proportion is excreted into the alimentary tract (Kleiner, 1911). A 5 per cent. solution may be given under the skin, or 10 per cent. intravenously, up to 1,000 c.c. per day (Kausch, 1911).

Saccharose is partly utilized (Mendel and Mitchell, 1905; about one-third, Japelli and d'Errico); but mainly excreted unchanged (Mendel and Kleiner, 1910; Heilner, 1911). It is not available for feeding (Mendel, 1914). Roehmann, 1915, claims that the blood, after intravenous saccharose injections, sometimes develops ferments that invert it to dextrose and levulose, and even convert these into lactose. Abderhalden and Brohm suggest that the utilization may be explained by partial excretion into the alimentary canal, where it is converted, and reabsorbed in usable form.

Kuriyama, 1917, with rapid intravenous injection of sucrose into dogs, found about 20 to 30 per cent. destroyed. The remainder is rapidly eliminated by the kidneys, and a minute amount also by the liver and intestinal mucosa. Lactose, dextrin and glycogen are also not available. In normal animals, lactose injected into the blood disappears rapidly into the tissues and urine; after nephritis or in nephrectomized animals, it is retained in the blood (O. Schwarz and Pulay, 1915).

Oil can be utilized hypodermically; 10 to 100 Gm. per day of olive oil being slowly injected with the same technic as is used for the injection of antitoxic serums. The absorption, however, is so slow that these injections are almost worthless (Winternitz, 1903; Henderson and Crofutt, 1905).

Intravenous Alimentation.—*Dextrose* has been used in this manner clinically, for instance in pneumonia (250 c.c. of 8 per cent., 2 or 3 times daily).

Animals have been successfully nourished exclusively by intravenous injections of a mixture of protein-cleavage products, dextrose, sodium acetate and salts (Henriquez and Anderson, 1913). Serum protein is well utilized (Austin and Eisenbrey, 1912), but the dangers (anaphylaxis, etc.) preclude its clinical use as nutrient.

Fat introduced in emulsion intravenously is also burned (Murlin and Riche, 1915).

Predigested Foods.—The value of these is doubtful, even if they are well utilized; for digestive disturbances involve the motor functions and absorption more commonly than the chemical function. The continued use of predigested foods often produces irritation.

Utilization of the Products of Artificial Digestion.—It has been questioned whether this is as effective as that of the products of natural digestion. However, the work of Abderhalden and others has shown that nitrogen equilibrium can be maintained in animals on a diet of the products of acid-hydrolysis of proteins, if these are sufficiently varied to secure a proper balance of the various amino-acids, etc.

Animals with their digestive canal excised can be kept alive by intravenous injection of amino-acid mixtures, but not by peptones, proteoses, ammonium or urea (Henriquez and Anderson, 1914).

Deficiency of Amino-acids.—Osborne and Mendel, 1912 et seq., found that the animal organism is apparently unable to synthesize certain amino-acids that are essential groups to the animal proteins, and that these must therefore be supplied in the food. For instance, animals placed on diets that do not contain the lysin or tryptophane groups cease to grow. When food-stuffs containing these are added to the food, growth may be resumed. When the food is partly deficient in a constituent, this is not compensated by increased food-consumption; for the appetite is regulated by the energy-requirements, and not by the growth requirements. However, this phase of food-deficiency probably does not occur easily under the practical conditions of civilized life.

A few amino-acids are synthesized freely in the animal body; especially glycin or glycocoll, which unites with benzoic acid to form hippuric acid.

Dry "Peptones."—The dried product of the artificial digestion of meats, usually consisting mainly of albumoses. Their taste is disagreeable and they often cause irri-

tation. Intravenously they are toxic, lowering the blood pressure and rendering the blood non-coagulable (see Index).

Liquid Predigested Foods.—As found on the market, these are flavored solutions containing small amounts of predigested proteins ($\frac{1}{2}$ to 6 per cent.) and of sugars and other carbohydrates ($\frac{1}{2}$ to 15 per cent.), with 12 to 19 per cent. of alcohol, and often with large quantities (up to 30 per cent.) of glycerin (details in Rep. C.P.C., J.A.M.A., May 11, 1907). Their protein content averages less than that of milk (3.5 per cent.), and in energy value, on the basis of calories, they are vastly inferior. Their daily dose (50 to 150 c.c.) yields but 55 to 300 calories, including their alcohol; and this is only one-thirtieth to one-fifth of the minimum daily requirement, even of resting patients (1,500 calories, yielded by two quarts of milk). To increase their dose to that required to maintain nutrition would mean the ingestion of an amount of alcohol equivalent to about a pint of whisky per day.

No liquid food should be given consideration unless it contains, exclusive of alcohol and glycerin, at least as much food value as milk; and at least one-fourth of this should be in the form of nitrogenous constituents. Even these can only be considered as adjuvants and vehicles.

Meat and Beef Juices.—When prepared extemporaneously by expression of fresh or slightly broiled meat, these contain from 2.5 to 9 per cent. of coagulable proteins, and 2 to 4 per cent. of other proteins and nitrogenous extractives. They have therefore a moderate value as sources of nitrogen. The commercial preparations are supposed to be concentrated; in fact, however, they are very inferior, containing but 0.2 to 3 per cent. of coagulable proteins; others are reinforced by the addition of defibrinated blood, sugar, glycerin, etc., which are of doubtful utility (Rep. C.P.C., J.A.M.A., Nov. 20, 1909).

Bouillon and Meat Extracts.—Bouillon (beef-tea) is prepared by boiling meat with water; the extracts by evaporating the solution to a semisolid consistency. The coagulable proteins are removed by this process, the extract containing the salts of the meat, the flavoring substances and meat bases (xanthine and creatine products) and a certain amount of non-coagulable protein, in the form of gelatin, albumoses, etc. In the small amounts in which they are used, these preparations contain a *very insignificant quantity of nutriment*. They are, however, *valuable as stimulants*. They owe their action largely to the odoriferous principles which they contain, and which are excellent stomachics (Wolff, 1912).

The potassium salts have also been invoked to explain the action, it being claimed that they stimulate the heart in moderate doses and paralyze it in large doses. But the dose required to produce the former effect is very much larger than would be administered in beef-tea.

Composition of Meat-extract.—American brands of the Liebig-type (pasty consistence contain, on the average: flesh-bases, 26.4 per cent.; gelatin and albumose, 16.5 per cent.; N-free extractives, 14.6 per cent.; inorganic salts, 22.5 per cent.; water, 20 per cent. (N.N.R. 1920).

Insoluble Meat Powders.—These have been employed to thicken soups. Their usefulness is very limited.

Casein.—This is used to enrich the protein content of the diet in infantile diarrhea, and in the diet-therapy of diabetes. It has also been advertised to the public with most extravagant claims as a tonic (Sanatogen, J.A.M.A., May 6, 1911), but for this purpose it has no serious advantage over cottage-cheese. For infant-feeding, it is employed as the partly soluble calcium caseinate. The commercial brands are listed in N.N.R.

Carbohydrate Foods.—These are used therapeutically for rectal and parenteral alimentation (dextrose); for modifying infant food (lactose, maltose and dextrin); in forced alimentation (lactose); and in the diet-therapy of diabetes.

Food for Diabetics.—These are intended to reduce the intake of sugar-forming carbohydrates. They fall into two groups: sugars and carbohydrates that do not yield dextrose; and flours for diabetics.

Non-dextrose Sugars.—*Levulose, inulin and lactose* are sometimes tolerated better than other sugars. (v. Noorden, 1910; Goudberg, 1913); but the difference is usually not important. In pancreatic diabetes and phosphorus glycosuria the levulose is deposited as glycogen, whilst dextrose is not (E. Neubauer, 1900). H. B. Lewis and Frankel, 1914, conclude that inulin is quite useless. It is not digested, although some is burned by the intestinal bacteria. None is converted into utilizable carbohydrate, even in phlorhizin animals.

Rapidity of Oxidation of Sugars.—In man, the respiratory quotient shows that saccharose, lactose, and levulose begin to be oxidized within five or ten minutes after their ingestion. With glucose and maltose, oxidation begins only after 20 to 35 minutes (Higgins, 1916).

Inosite.—This carbohydrate, $C_6H_6(OH)_6$ occurs in several plants and in muscle. Kulz, 1874, found that on feeding, only insignificant amounts appear in the urine; and that diabetic glycosuria is not increased. From this he thought it might serve as a sugar substitute in diabetes. However, it soon appeared that it is not burned. (R. J. Anderson, 1916); the greater part being eliminated unchanged by feces.

However, Greenwald and Weiss, 1917, claim that it is slowly, but completely converted into sugar in phlorhizin-diabetic animals.

In man, daily doses of 0.5 Gm. per Kg. cause diarrhea (J.A.M.A. 1916, 67:900).

Grafe, 1914, finds promising results with *caramelized sugar*. It is all absorbed and completely tolerated even in severe diabetes. It does not increase the blood-sugar, and the respiratory quotient shows that it is utilized in the diabetic as well as normal organism.

Mannite is also employed as sweetener, being assimilated without causing glycosuria; doses above 20 to 30 Gm. are laxative. (For normal assimilation limits of various carbohydrates, see Macleod, 1913 and 1914; Jacobson, 1913.)

Hediosite.—An artificial sugar, the lactone of α glucoheptonic acid; was introduced by Rosenfeld, 1911, as sweetening agent and food, but has failed to realize the original expectation. When administered by mouth, 25 to 85 per cent. is excreted unchanged by the urine and feces. The fate of the remainder has not been established. Large doses produce diarrhea and other digestive disturbances. Its excretion is diminished in nephritis, resulting in retention (Kohshi, 1912; Kramer, 1912; Lenel, 1914).

Flour for Diabetics.—These are intended to form a substitute for bread, as a vehicle for butter, etc. High food value is not desirable. Gluten flours should not contain more than 10 per cent. of carbohydrates. The reliable are listed in N.N.R. Other flours (in N.N.R.) consist of soy-bean meal or casein.

Jambul.—The fruit, leaf, or bark of *Syzygium Jambulana*, Eastern Asia. It contains an essential oil, tannin, and probably a glucoside. (The constituents are discussed by Hart and Heyl, 1917.) It has been recommended in diabetes mellitus in doses of 0.3 to 0.5 Gm. of the fruit (5 to 8 grains). Its efficiency is very doubtful.

Sugar Substitutes.—In cases where sweetening is desired and sugar is excluded, particularly in cases of diabetes, the artificial synthetic product *gluside* (*saccharin*) may be substituted. It is about 300 times as sweet as sugar, but the taste is not exactly the same. The dose for a cup of coffee or tea is about $\frac{1}{2}$ to 1 gr. *Glycerin* is another sweetening substance which does not contain sugar, and is sometimes employed in place of saccharin.

PREPARATIONS—CARBOHYDRATE FOODS

* *Dextrosium* (Dextros.), U.S.P.; Dextrose, d-Glucose.—A sugar ($C_6H_{12}O_6 \cdot H_2O$) usually obtained by the hydrolysis of starch. White, crystalline powder, or white granules. Odorless; sweet taste. Sol. in water (1:1), alc. (1:59). As a nutrient, be mouth, to 180 Gm., 6 ounces, daily. Intravenously, 250 to 300 c.c. of a 5 per cent. (isotonic) solution to 15 per cent. solution, two or 3 times daily; by enema, 5 to 12 per cent. solution.

Glucosum (Glucos.), B.P., Glucose (Syrupy).—The product obtained by the hydrolysis of starch, consisting chiefly of dextrose, maltose and dextrins. Colorless, or slightly colored, thick, syrupy liquid. Very sol. in water, sparingly sol. in alc.

Its use as a food is apparently not deleterious. White rats have consumed commercial glucose in quantities equivalent to 200 grams per man, daily for six months, without bad effects (Carlson et al. 1916).

Syr. Glucos, B.P.—Glucose 1, syrup 2.

* *Lactosum* (Lactos.) U.S.P.; *Saccharum Lactis*, B.P., Lactose, Milk-sugar. $C_{12}H_{22}O_{11} \cdot H_2O$.—White, hard, crystalline masses, or white powder, feeling gritty on the tongue; odorless; faintly sweet taste. Freely sol. in water (1:4.9); almost insol. in alc.

This also produces osmotic effects. Nine to 15 Gm. (2 to 4 drams), in warm milk an hour before breakfast, causes a soft stool. Smaller doses (pure or as milk) are efficient for diuresis (the effective dose would be 100 to 200 Gm. per day). Milk-sugar is also used to facilitate the comminution of powders, on account of its hardness. It is further employed as sweetening agent, especially for powders; and as a carbohydrate food, especially for infants.

Fats as Foods.—These are usually employed as the ordinary food-fats. A peculiar position is occupied by cod-liver-oil, because of its vitamin content.

Intarvin (N.N.R.) is an artificial fat, consisting mainly of the glyceryl ester of margaric acid, small quantities of other fats, and 12 per cent. of liquid petrolatum. The margaric acid contains an odd number of carbons, and therefore its oxidation does not give rise to oxybutyric acid, even in the absence of sugar-oxidation; and it produces very little or no glucose even in diabetic individuals. It seems to be well utilized, and

no deleterious effects have been demonstrated in rats to whom it was fed for seven generations (Heft, Kahn and Gies, 1925; M. Kahn, 1923).

Intarvin is employed as an addition to the diabetic diet, in quantity sufficient to make up the energy requirement, generally about 100 Gm. per day; 1 Gm. of intarvin yielding 8.1 calories; or about 120 calories for a heaped tablespoon. Its rather rancid taste is a distinct disadvantage. It may be taken before meals by adding two table-spoons to a cup of hot coffee, so that the melted fat is swallowed with the coffee.

VITAMINES

Importance of Special Food-factors.—It has long been recognized that the diet must not only represent a certain amount of calories, but that it must include certain foodstuffs. The special importance of proteins was naturally the first to be recognized. It also became known quite early that one-sided diets are likely to result in general malnutrition, and in special diseases, such as scurvy. The advance of knowledge has shown that the subject of special food factors has a wider application than was formerly suspected; and it has also thrown considerable light on the nature of the factors that are concerned.

So far, two distinct types of deficiency factors may be recognized, viz.:

(1) Deficiency in constituents that are used directly as food, notably the various amino-acids. This was discussed in the preceding section.

(2) Deficiency of substances that are needed only in minute quantities, and which therefore presumably do not act as foods directly. These "vitamines" (Casimir Funk, 1911) or "accessory food factors" (Gowland Hopkins, 1912) occur in a great variety of foods, but appear to be formed mainly if not solely in plants. They are rather unstable and for the most part are stored only for short periods. According to their actions and solubility characters they may be arranged into a few groups; but as the pure vitamins have not been isolated it is not known whether each group includes one, several or many individual substances. Inadequate supply of the vitamins results in impairment of appetite, nutrition, growth, fertility, general health and of resistance to infective and other unfavorable agencies. Excess income tends to increase growth, resistance and fertility (Sherman and Campbell, 1924). Certain of the vitamins also have a specific corrective action in certain diseases, such as rickets, scurvy, beri-beri, polyneuritis and pellagra. These conditions may be conceived as "deficiency-diseases," i.e. as due to deficiency of the vitamin by which they are corrected. However, they usually also involve other factors, and the vitamin may act as a non-specific corrective, for instance, as a regulator of appetite or peristalsis or as a pharmacologic agent, much as bitters or alcohol correct anorexia, and mineral oil or cascara may correct the constipation of a non-residue dirt. It would be absurd to describe such a constipation as a "cascara-deficiency disease." These questions cannot be decided with our present knowledge.

Specific Growth Substances.—Rats kept on artificial diets that contain all the essential amino-acids and energy units, nevertheless soon cease to grow, unless substances are added that contain small quantities of some special ingredients, that may be isolated in more or less purified form (Osborne and Mendel, 1913 and 1914; McCollum and Davis, 1913; Mendel, 1915).

There are two groups of these substances, one being fat-soluble (A) and the other water-soluble (B). McCollum, 1917, believes that there are only these two substances (A and B) concerned in the dietary protection. Some investigators assume a large number of specific "vitamines."

Importance in Diet.—Vitamines in general are present in most natural food, both animal and vegetable; particularly in glandular organs and products, including milk and eggs, and in green vegetables (spinach, cabbage, lettuce) and in the embryo and hulls of cereals. They may also be prepared from yeast.

They are relatively deficient in meats, potatoes, flour, most oils and sugar products (Osborne and Mendel, 1918).

Mechanism of Action.—This is practically unknown. Vitamine deficiency is always associated with loss of appetite; and the "cure" or resumption of growth on vitamine administration is accompanied by increase of appetite. The increased food-consumption is undoubtedly an essential factor in the growth but it is not known whether it is merely a result of the growth needs.

A. B. Macallum believes that the action is directly on tissue metabolism; and on the whole this seems the most probable view; because sometimes changes of growth may occur without change in food-consumption.

The effects on nutrition are not of the type of catalyzer reactions (T. B. Robertson).

McCarrison, 1919 (Brit. Med. J. 1:177) believes that deficiency of polyneuritic vitamine causes "nuclear starvation" of all cells, and that the neuritis is merely incidental.

Starvation Factor.—The effects of vitamine deficiency resemble closely those of simple starvation; and it is difficult to say what part of the "deficiency phenomena" results from the loss of appetite. Growing animals, because of their relatively greater need of food, suffer more than adults; and proliferating tissues suffer more than those that are stationary. The weight changes in different organs, however, are complex and probably inconstant (Randoin, 1923).

Intestinal Change.—McCarrison also found, in pigeons and guinea pigs suffering from experimental vitamine deficiencies, that the intestines showed marked changes, *i.e.*, atrophy of the coats, lesions of the neuro-muscular system, and impaired digestion and absorption. There is commonly persistent constipation, and the administration of the vitamins is usually followed by diarrhea. The rice-hull extract stimulates the contractions even in excised intestine.

These observations suggest that a direct action of the vitamine may possibly be that of regulating the peristalsis, and thus the intestinal bacteria; and that this may at least have a part in the result.

Parasympathetic Stimulation.—Uhlmann, 1918, claims that antineuritic vitamine when injected intravenously, produces a typical pilocarpine action, *i.e.*, stimulation of the parasympathetic receptive mechanism in glands and unstriated muscle; the stimulation being removable by atropine. He attributes the dietary effect to stimulation of the digestive glands. However, as pointed out by Clark, the autonomic effects might be caused by impurities.

Secretin-effect.—Voegtlin and Myers find that intravenous injection of yeast-extract increases the flow of pancreatic juice and of bile. They also find that secretin relieves experimental polyneuritis. There is a similarity in the chemical and physical properties of the two substances; but as they have not been isolated, their identity can not be affirmed.

Sugar Metabolism.—Pigeons on a vitamine-free diet develop hyperglycemia and decrease of liver glycogen. These are restored to normal by vitamine treatment (quoted from Macallum).

"A" SUBSTANCE, FAT-SOLUBLE OR GROWTH VITAMINE

This is essential for growth and reproduction, its deficiency causing suspended growth; or in advanced cases, a type of xerophthalmia. These are curable by the administration of the substance (McCollum, 1918). In nature the A vitamine is always associated with antirachitic vitamine, but it does not follow that they are identical. The antirachitic factor has been called "vitamine D."

Occurrence.—Vitamine A is most abundant in the intracellular fat of glandular organs, and therefor in butter fat, beef-fat, egg-yolk, and cod-

liver oil; it is absent from lard, or olive or almond oils. It is also widely distributed in plants, especially the leaves (McCollum, Simmonds and Pitz, 1916). The ether extract of dried spinach or clover evaporated on starch, is a very effective growth substance (Osborne and Mendel, 1919).

The A vitamine apparently is synthesized only by the chlorophyll of plants in the presence of light. Animals derive their supply of vitamine A from the green plants, directly or indirectly, and store any excess especially in their lipochromes (carotin). The carnivorous animals depend upon this source. The amount stored varies with the diet. The liver of marine fish, which feed on green sea plants, is especially rich in vitamine A. In milk this vitamine is almost entirely in the butter-fat, *i.e.* in the cream.

Properties.—The “A” substance is soluble in oil and fat-solvent, and also fairly soluble in water.

The growth promoting action of butter fat is not due to contamination with nitrogen or phosphorus compounds (Osborne and Wakeman, 1915). It is confined to the portion of the fat with low melting point; is not destroyed by steam (Osborne and Mendel, 1915) and as it exists in butter, is very stable under ordinary conditions of storage (Mendel and Osborne, 1916). In the more concentrated butter oil, it deteriorates almost completely within a year (Osborne and Mendel, 1916).

Macallum, by similar experiments, arrived at different conclusions as to the fat-vitamine: He found that butter fat purified according to Osborne and Mendel still contains N components. He also claims that the growth-vitamine of butter fat is unable alone to bring about normal growth increment in young animals. In short experiments it is not superior to lard and only quantitatively superior in long experiments.

Deficiency Phenomena.—Young animals respond promptly to vitamine A deficiency by arrested growth and xerophthalmia. In young rats, this may develop in two or three weeks. Deficient bone formation is manifested by delayed dentition and by rickets. In adults, the results may not be notable for several months; partly because they usually start with a larger store of the vitamine, and partly because there is less need for a growth vitamine. However, the body weight gradually decreases, and the resistance to infections is lowered. Sterility develops; indeed a diet adequate for growth may not contain enough A for reproduction. Starvation-edema may be connected with vitamine A deficiency.

Xerophthalmia.—This occurs in man as well as in rats and rabbits (V. E. Nelson and Lamb, 1920). It consists in an irritative condition of the conjunctiva, with keratinization of the epithelium. There is doubt as to whether the lowered general resistance leads to the infection of the epithelium and this to keratinization (Mellanby and Fox, 1919); or whether keratinization, which is also produced in other epithelia, such as the salivary glands, pancreas, kidneys, etc., lowers the resistance and leads to infection (Wolbach and Stowe, 1925). Lack of both A and B vitamins does not impair the capacity to produce antibodies (Wakeman, 1923).

COD LIVER OIL AND ANTI-RACHITIC VITAMINES

The oils expressed from the liver of cod and other marine fish are very rich in vitamine A, containing sometimes 250 times as much as butter fat (Zilva and Miura); so that a teaspoonful of cod liver oil would contain as much vitamine A as three pounds of butter or five gallons of milk. These oils are especially effective for the cure and prevention of rachitis, clinical and experimental (Hess, 1917). They are also useful in phthisis and other wasting diseases. The activity resides in the unsaponifiable lipoids (Zucker, 1922). Similar actions may be conferred on cholesterol and on phytosterol by exposure to the ultra-violet rays (A. F. Hess, 1924, H. Steenbock, 1924). Cod liver oil also has a direct nutritive value, as an easily emulsifiable, digestible and metabolizable fat. The oil has a disagreeably fishy taste, which can be minimized by careful preparation of the oil, and by cooling it on ice, before administration. It may produce eructations and diarrhea. These are often avoided by starting with

small doses, gradually increased. It is generally administered two hours after meals. Indigestion and fever contraindicate its use. "Fat-free" extracts of cod liver oil, which have been widely advertised, contain neither the fat nor the vitamine (Street, 1915) and are apparently without value.

Historical.—Cod liver oil was adopted into medicine in the early decades of last century from the Norwegian fishermen, who prepared it by very crude methods, involving putrefaction. These oils, therefore, contained free fatty acids (Buchheim, 1874), bile constituents (Naumann, 1865), cholesterin, putrefactive alkaloids (aselline, morrhaine, etc.; Gautier and Mourgues, 1888); traces of iodine (about as much as oysters), and other impurities. All of these have been credited with the effects; but these substances are eliminated in the modern sanitary processes, without decreasing the usefulness of the oil; whilst "oil-free," "tasteless" extracts, wines, etc., are useless (Rep. C.P.C., J.A.M.A., Oct. 9, 1909).

The easier emulsification of the oil is probably a peculiarity of its characteristic fats, which are largely glycerides of jeoleic and therapeutic acids. Lipanin was a mixture of olive oil with 6 per cent. of oleic acid, based on Buchheim's suggestion that free acids aid emulsification. It has not established itself clinically. The digestibility of different animal fats is discussed by Langworthy and Holmes, 1915. Mottram, 1915, attributed the superiority to the high percentage of unsaturated fatty acids, which approaches more closely the form in which fat is supposed to be utilized in metabolism.

Antirachitic Action.—This consists in a better or more economical utilization of calcium and phosphate for bone formation. The credit for the conclusive proof of the value of cod liver oil belongs largely to A. F. Hess. With Unger, he showed statistically a definite and striking inverse relation between the incidence of rickets and the administration of the oil; the effect being proportional to the total dosage and to the time of continuance of the administration. In a series of New York infants who did not receive the oil, only six per cent. were non-rachitic; of those who had received 21 ounces of oil during four months, 58 per cent. were non-rachitic; of those with the same amount of oil, but spread over six months, 80 per cent. were non-rachitic; and of those who were given 54 ounces during six months, 93 per cent. escaped rickets. Similar data were obtained in Vienna. The cure of developed rachitis requires about 10 c.c. of the oil per day, but 8 c.c. produces improvement. The vitamine is transmitted to the breast-milk, so that the administration of the oil to the mother tends to prevent rickets in the breast-fed child.

Subcutaneous injection of the oil is said to promote growth, but to be ineffective against rickets (Lesne and Vagliano, 1923). This supports the opinion that the two qualities are due to different vitamins. Hess has also observed that cod liver oil is effective when rickets develop on diets with adequate vitamine A. The U. S. Pharmacopeia authorizes a test for minimum content of vitamine A and it may be assumed that oils deficient in this are probably also deficient in antirachitic properties.

The Antirachitic Activation by Ultra-violet Irradiation.—Rachitis is benefited by exposure of the patient (or experimental animals, Sheets and Funk, 1923) to the ultra-violet rays of sun light, of the quartz vapor lamp or of the carbon arc. Exposure to these rays also endows cholesterol and phytosterol with antirachitic properties, and as cholesterol is contained in almost all animal cells, and phytosterol in almost all vegetable cells, practically all food may be activated in this manner (A. F. Hess, 1924, 1925; H. Steenbock, 1924, 1925). Green vegetables, even when grown in the sun are not antirachitic, but become so on exposure to the more powerful artificial radiation. It is doubtful, however, whether irradiation of food would have sufficient practical advantage over ordinary cod liver oil, or over direct irradiation of the patient (Hess, 1925). The skin contains considerable cholesterol and is rendered antirachitic by irradiation, so that it is likely that heliotherapy acts through this chemical mechanism (Hess, Weinstock and Helman, 1925). The irradiation of the cholesterol changes its spectrum so as to render it more transparent to the ultra-violet rays; but excessive exposure renders it opaque and inactive

(Hess and Weinstock, 1925). If a similar change occurs in the skin, over-energetic heliotherapy would be detrimental (Hess). Ultraviolet rays do not prevent the xerophthalmia of vitamine A deficiency (Sheets and Funk, 1923; G. F. Powers, Park and Simmonds, 1923).

PREPARATIONS—COD LIVER OIL

**Oleum Morrhuae* (Ol. Morrh.), U.S.P., B.P.; Cod Liver Oil (Ol. Jecoris Aselli).—A fixed oil from the fresh livers of *Gadus Morrhua* and other species. Occurs as a pale yellow thin oil, having a peculiar fishy, but not rancid odor, and a bland fishy taste. It thickens on exposure to air. *Dose*, 10 c.c., 2½ drachms, U.S.P.; 4 to 15 c.c., 1 to 4 drachms, B.P., three times daily, after meals; for infants ½ to 1 teaspoonful. If assayed for vitamine A, it should contain at least 50 "units" per Gm., U.S.P.

**Emulum Olei Morrhuae* (Emuls. Ol. Morrh.), U.S.P.—A 50 per cent. emulsion, made with acacia, sweetened with syrup and flavored with wintergreen. *Dose*, 15 c.c., 4 drachms, U.S.P.

Sodium Morrhuate.—This has been tried hypodermically, similarly to sodium gyno-cardate, against tuberculosis and leprosy. B. Rogers, 1918, claims good results; but these would require strict and extensive confirmation.

CHOLESTEROL

Cholesterol is familiar especially as a constituent of gall-stones, but it occurs in all animal cells. It is a difficultly soluble lipid and a chemically inactive monatomic alcohol. Its role in the economy of life has been puzzling. It forms chemical compounds with saponins and therefore protects against hemolysis by these poisons, but this of course is not a natural function. The cholesterol content of the blood changes with its other lipoids, but this might be a secondary phenomenon. The growth-promoting effects of cholesterol irradiated by ultraviolet light suggests that it may be an important factor in nutrition, and in the response of the organism to sun light.

The protective action of cholesterol against saponin hemolysis has led to therapeutic trials in hemolytic diseases. The results have not been decisive.

Characters.—Cholesterol is a mon-atomic alcohol, $C_{27}H_{45}OH$, with the solubility characters of fats. It is therefore but poorly absorbed (Stadelmann, 1898; Klein, 1910). Its oxidation products produce effects (digitalis and saponin) resembling those of bile acids and of the poisons of toads and snakes. Indeed all these are probably derivatives of cholesterol (Faust, 1911; Flury, 1911). Cholesterol itself is somewhat stimulating to the heart-muscle, (Danilewsky, 1907). Cholesterol and its fatty esters lessen phagocytosis; lecithin removes this effect for cholesterol, but not with the esters (Steuber, 1913).

Occurrence.—Cholesterol is an essential constituent of all animal cells, and therefore occurs in most foods. Egg-yolk is especially rich, one yolk containing about 0.25 Gm. (Klein, 1910). It is generally prepared from gall-stones. Its esters and homologs constitute wool-fat (see Index).

Cholesterol is present, partly free and partly as esters of the higher fatty acids, in the blood plasma, red corpuscles, and especially in the leucocytes, in fairly constant quantity under normal conditions. Cholesterol plates may be found in any tissue when the cells have undergone slow destruction and where absorption is poor.

Formation of Gall-stones.—According to Schade the cholesterol that exists in the bile as a colloidal solution, is protected by the cholates, soaps and other constituents. Acidification would precipitate the cholesterol by disrupting the protecting salts. Bacteria that produce acid, such as typhosus, pyocyaneus and proteus would therefore tend to precipitate the cholesterol, whilst infections with non-acid forming bacteria, such as staphylococcus aureus would not have this tendency (Lichtwitz).

Cholesterol Income.—The cholesterol content of the body is increased by feeding cholesterol (Lehmann, 1914; Wacker and Hueck, 1913). Mice can synthesize cholesterol when it is absent from their food (Degani, 1914); but it is now believed that it is not

ordinarily formed in higher animals, but depends upon the food and therefore eventually on plants. Ordinary food contains adequate amounts; but when the diet is restricted, or when there are extraordinary demands, as in growing children, it may conceivably be deficient (Mendel, 1914).

Fate.—Cholesterol is absorbed from the alimentary tract into the lymph, being demonstrable in the thoracic duct.

During absorption from the intestines, free cholesterol is partly esterified, and the esters are partly hydrolyzed (J. H. Mueller, 1915). A part is converted into esters before absorption (Mueller, 1915). The excretion in man, with various diets, was studied by Ellis and Gardner, 1912. It is first oxidized into oxycholesterin, and a part probably into the cholic acid of the bile (Liefschuetz, 1914).

Hypodermic injection into rabbits produces marked inflammation and necrosis of the subcutaneous tissue. This gradually subsides with the disappearance of the cholesterol, which is effected mainly through the leucocytes (Basten, 1915).

With intravenous injection, it leaves the blood rapidly, being deposited in various organs, and partly excreted by the bile and urine. The kidneys show degenerative changes and focal infiltration with cholesterol (K. Dewey, 1916).

Relation to Fat-metabolism.—Cholesterol probably plays some rôle, but this is not understood (Bloor, 1917).

Lipoid Balance of the Blood.—In normal blood the ratio of true fat, lecithin, cholesterol and its esters, varies within narrow limits for the individual, and somewhat wider limits for the species. It can be temporarily altered, for instance, by the ingestion of fat, but usually returns rapidly to the normal. In lipemia, therefore, all lipoids tend to increase in the blood, but with a certain amount of lag, the true fat increasing first, then the lecithin and last the cholesterol (Bloor, 1920). The normal cholesterol content of the human serum ranges between 1.5 and 1.8 Gm. per liter; mean; 1.6 (Chauffard et al., 1920).

Cholesterol Content of Blood in Disease.—This has been studied by Klitkert, 1913; Buerger and Beumer, 1913; Gorham and Myers, 1917; Chauffard et al., 1920; etc. Increase of the cholesterol content of the plasma was reported for diabetes mellitus, icterus and some other diseases; decrease in infective diseases.

It is also increased by partial or complete excision of the suprarenals; at the same time, increased quantities are excreted by the bile (Rothschild, 1914).

Lipemia.—The increase of lipoids concerns first the true fat, then the lecithin and lastly the cholesterol. In restoration the fat is also the first to return toward normal, and the cholesterol the last, so that the cholesterol:lecithin ratio becomes high (Bloor, 1921).

Blood-cholesterol in Hepatic Disorders.—In obstructive icterus by gall-stones, the cholesterol content of the blood is markedly elevated, apparently proportional to the intensity of the icterus, but not to the amount of bile pigments in the blood. In other hepatic disorders the blood-cholesterol is not increased, but usually diminished. It has been suggested that the liver regulates the cholesterol content of the body through this biliary excretion (Rothschild and Felsen, 1919).

Blood Cholesterol after Ether and Chloroform.—With dogs, ether anesthesia of 60 to 90 minutes, on successive days, increases materially the serum-cholesterol, persisting for several days after the inhalations have been discontinued. Chloroform produces a smaller increase for 2 or 3 days, and then decreases the serum cholesterol (Ducceschi, 1919).

Blood-lipoids in Anemia.—These appear to retain approximately their normal ratio, if the reduction of corpuscles does not exceed half of the normal. Beyond this point, abnormalities occur, in the following order of magnitude and frequency: (most marked) high fat in plasma; low cholesterol in plasma and sometimes in corpuscles; low lecithin in plasma (least marked). These changes have been attributed to deficient fat-assimilation; conversion of fat into lecithin being one of the functions of the corpuscles (Bloor and MacPherson, 1917).

Effects on Growth.—The continued administration of cholesterol to white mice causes marked retardation of growth in early life, acceleration in later life (T. B. Robertson, 1916, 1919). Its administration to mother-mice markedly retards the growth of the sucklings (Robertson and Cutler, 1916). The division rate of paramecium is greatly increased (Browder, 1915).

Robertson and Burnett, 1918 believe that the growth accelerating action of cholesterol and of tethelin are conditioned on their OH group.

Effects on Cancer.—The injection of cholesterol emulsions is said markedly to accelerate the growth of experimental cancer (Burnett, 1913) and to promote the formation of metastases, but it does not originate cancers, nor increase the rate of natural incidence. T. B. Robertson points out that the cholesterol content of the tissues increases with age, and that this would increase their susceptibility to cancer invasion.

Phagocytosis and Antibodies.—In rabbits and guinea pigs, cholesterol injections lower phagocytosis by direct action on the leucocytes. They also delay antibody formation (Dewey and Nuzum, 1914).

Atheroma.—Feeding or injections of cholesterol produce arterial lesions in rabbits (Walker and Hueck, 1913; Ignatowski and Chalатов; Adler, 1914; Denny and Frothingham, 1914); also degenerative changes in the suprarenal cortex (Knack, 1915). Less marked arterial changes are produced in guinea pigs (Bailey, 1915).

By intravenous injection over long periods, Adler, 1917, produced arterial lesions resembling closely those of human arteriosclerosis. They were most marked in the pulmonary artery. Adler is inclined to attribute them to the intermittent but very extensive blocking of the vessels by the injected oil, and therefore not to the chemical properties of cholesterol.

Protection against Poisons.—Free cholesterol neutralizes a number of poisons, especially hemolytic (saponin, tetanolyisin). It is also said to protect against strychnine, but only if the two substances are mixed (Fizzeni and Perucci, 1910).

Therapeutic Use.—In paroxysmal hemoglobinuria, Pringheim, 1912 and 1913, reports partial success from six intramuscular injections, on alternate days, each of 5 c.c. of 10 per cent. cholesterol emulsion. The action did not outlast the administration. Reicher, 1908, in pernicious anemia, administered it by mouth, 3 Gm. in 100 c.c. of olive oil, daily, in tablespoon doses. The preparation of a watery emulsion for intravenous injection is described by Dewey, 1916.

LECITHINS

These constitute a group of peculiar lipoids, of wide distribution in animal cells and therefore in food, which may also have complex effects on nutrition and growth. Lecithin has been acclaimed as a remarkable tonic, but it has not achieved a secure place in therapeutics. The ordinary diet furnishes a liberal supply of lecithins, and it is difficult to see how the small quantities that may be added in the form of rather expensive medicines could have any other than imaginary effects.

An extensive review of the rôle of phosphorus compounds in nutrition is given by Forbes and Keith, 1914.

Structure and Occurrence of Lecithins.—These are esters of fatty acids, glycerophosphoric acid, and a nitrogenous base (mainly choline). Their structure will be understood by the following formula, in which *R* represents fatty acid—oleic, stearic, palmitic or other. The part to the right of the dotted line represents choline.

Glycerophosphoric acid.

Lecithin.

The various lecithins differ according to the fatty acid, etc. They occur in animal (not in vegetable) cells, generally combined with proteins. Their place may be taken by related compounds or "phosphatids" which are but little understood.

Lecithins are conveniently isolated from brain substance or egg-yolk ("vitellin"). The commercial products are quite impure. They contain 3.84 to 4.12 per cent. of phosphorus. The purest are those obtained by Erlandsen's method. (Bibliography of Lecithins, Merck's Report, 26: 50). H. MacLean, 1915, states that ordinary lecithin is really a mixture of kephalin (which tends to become insoluble in alcohol), and true lecithin (which remains alcohol-soluble).

Barbieri, 1910 and 1917, threw doubt on the existence of lecithin; contending that this is merely a mixture of fats, phosphates and dializable nitrogen without any choline. However, this has been disproven by Levene and West, 1917, 1918. They isolated pure lecithin, from egg, brain and other tissues, and established its composition as conforming to that generally accepted.

The lecithin content of different tissues was studied by Cruikshank, 1913.

Properties.—Lecithin is a white to orange-colored substance, usually amorphous and waxy when dry. It is very hygroscopic, softening to a semifluid mass in the air. It

also oxidizes readily, becoming darker. It dissolves in alcohol or most fat-solvents (not in acetone). It is insoluble in water, but readily takes up water, swelling to a gelatinous mass and finally to a colloidal solution, from which it is precipitated by certain acids and salts; while other salts prevent the precipitation (W. Koch). It is decomposed by prolonged contact with water; alkalies saponify it readily into choline, fatty acid, and glycerophosphoric acid. Further cleavage results in ordinary phosphoric acid. The cleavage with dilute acids is quite slow.

Lecithin Content of Food.—The ordinary mixed diet contains at least 5 Gm. of lecithin daily; and this can be doubled by adding a couple of eggs (egg-yolk contains 6.8 per cent. of lecithin); or by liver or sweetbreads, which are also rich in phosphorus. In comparison with this, the phosphorus content of medicines is ridiculously small; for instance, the daily dose of lecithin amounts to only 0.2 Gm. Milk, however, is rather poor in lecithin (1 pint contains 0.3 to 0.4 Gm.) (W. Koch, 1905); but the organism is able to synthesize its lecithin from inorganic phosphates.

Fate of Lecithin.—Modern investigators agree that little, if any, lecithin is absorbed as such (contrary to the opinion of Bunge); but that the fat-splitting enzymes of the intestines split off the glycerophosphoric acid, which is further decomposed into phosphoric acid before it is absorbed (Bokay, 1877; Pasqualis, 1893; Plimmer, 1913). Possibly a fraction of the glycerophosphoric acid, and even of undecomposed lecithin, is absorbed before the cleavage is completed. In this case, or if the lecithin is introduced parenterally, the cleavage occurs in the tissues; the excretion being entirely as inorganic phosphates.

Synthesis of Lecithin.—Miescher, 1896, deduced that the production of roe and milt in the fasting salmon must involve the synthesis of large amounts of phosphorized fats from inorganic phosphorus compounds. Roehmann, 1908, showed that mice can be maintained for two generations on lecithin-free food; and Fingerling, 1912, and McCollum, Halpin and Drescher, 1912, demonstrated that the organic phosphorus of egg-yolk can be formed from inorganic phosphorus compounds, since it is not diminished if birds are kept on a diet free from organic phosphorus. Plimmer, 1913, came to the same conclusion.

Effects on Growth.—Danilewsky, 1895, and 1896, believed that feeding isolated lecithin stimulates the processes of growth, producing increase of red corpuscles and accelerated physical development as compared with control animals. The growth of plants was also increased.

Since the experimental quantities were too small to have much food value, they would have acted as true stimulants. However, a critical attitude toward these statements appears justified. It is rather remarkable that the addition of these small doses of isolated lecithin should have effects which are not produced by the much larger quantities in the ordinary diet. Moreover, several recent investigators (Goldfarb, 1907; Yoshimoto, 1910) were unable to confirm the experimental data. They obtained negative results even with long-continued administration. It is quite conceivable that the positive results were due to contamination with vitamine A.

T. B. Robertson states that lecithin tends to retard the multiplication of infusoria, the development of sea-urchin ova, the growth of experimental cancer (on direct application), and the growth of mice, and that it accelerates development of tadpoles; but that the results are inconstant.

Phosphorus in Nerve Tissue.—Phosphatides, especially lecithin, are contained in glands, cell membranes (especially of the red corpuscles), and nerve tissue, where they subserve important physical and chemical functions. Nervous tissue is rich in phosphorus ($\frac{1}{3}$ per cent. of moist; $1\frac{1}{2}$ per cent. of dry); but not more so than glandular organs. Its phosphatide content (27 per cent. of dry), however, is three times or more that of glands. Its importance therefore can not be doubted; but the percentage of phosphorus is not decreased even in severe nervous diseases (dementia precox). Nervous diseases are therefore not due to deficiency of lecithin (W. Koch, 1909).

Even in growth, when the nervous tissue, and therefore its lecithin, increases rapidly, an abundance of phosphorus compounds is supplied by the food. Moreover, Hart, 1908, showed that even in extreme phosphorus starvation the tissues keep up their phosphorus content by drawing on the phosphates of the bones. The effects of withholding or adding inorganic and organic phosphorus compounds to the food of growing dogs was studied by Durlach, 1913.

Effects on Metabolism.—The statements are contradictory. Tunnicliffe, 1906, and Slowtsoff, 1906, described retention of nitrogen and phosphoric acid.

The Clinical Data.—These are even more unsatisfactory than the experimental, although apparently successful tonic and hematonic effects have been described (e.g., Serono, 1897; Cronheim and Mueller, 1903, etc.).

Carcinoma.—Hypodermic injection retards the growth of rat-carcinoma; oral administration is not effective, presumably because the lecithin is decomposed before absorption (Robertson and Burnett, 1916).

Action on Circulation.—Danilewsky, 1906, Michailowsky, 1910; and Katznelson, 1910, state that the heart of frogs and rabbits is stimulated by dilute, depressed by concentrated solutions. Lifschitz, 1910, describes rise of blood pressure and cardiac stimulation. Lawrow and Woronzow, 1912, produced a marked antagonistic effect to cardiac poisons (chloral and other lipolytic narcotics) in mammals, by the intravenous injection of 0.1 Gm. per kilogram, as 5 per cent. emulsion. Much larger doses were harmless. The results were still more marked in excised hearts. They attribute the effects partly to direct cardiac stimulation, partly to disintoxication of the lipolytic poisons. Hauschmidt, 1913, confirms that intravenous injection is harmless and lessens the toxicity of the lipolytic narcotics and also of curare, strychnine and morphine; but that it increases the toxicity of ricin.

Rôle in Fat-assimilation.—Bloor, 1915 et seq., found that the *lecithin content* of *by the blood* increases 10 to 35 per cent. during the absorption of fats, generally parallel to the increase of blood fat. The accumulation of lecithin is greatest in the corpuscles, which contain about twice as much as the plasma. The cholesterol content (which is about equal in the corpuscles and plasma) is not increased by feeding fats.

These data indicate an important rôle of lecithin in fat assimilation. Bloor believes that lecithin is a regular stage in fat metabolism, through which all fats must pass before they are assimilated. The formation of lecithin probably occurs in the liver.

Lecithin on Cutaneous Absorption.—Borshim, 1912, claimed that small amounts, rubbed into the skin before the application of a potassium iodide solution increases its absorption; while large amounts have the reverse effect. Glucose, salicylic acid and tetanus toxin were not absorbed.

Administration.—Commercial lecithin may be administered as pills, 0.1 to 0.5 Gm., 1½ to 8 gr. per day; for infants, one-third of this dosage. It has also been given hypodermically, 1 c.c. of 5 per cent. in oil; but in view of the impurities, this is not advisable. It is incompatible with alkalis (Details of administration; Merck's Reports, 26:40).

Kephalin.—This is a highly unsaturated monamino-monophosphatide. Its nitrogenous base is probably not choline (W. Koch, 1902); otherwise it is closely related to lecithin.

Koch and Woods, 1915, believed that it is distributed as widely as lecithin.

Other Phosphatides.—The number of these is probably very limited; the various phosphorized fats prepared from different tissues being probably mixtures of lecithin and kephalin, with closely related homologous fragments (Levene and Komatsu, 1919).

Plant Phosphatides.—These were formerly considered identical with lecithin, but are now known to be quite distinct. They usually contain a sugar molecule.

Phytin.—This consists of the salts (usually calcium) of an organic phosphoric acid, probably containing inosite (presumably inosite-hexaphosphoric acid). It is widely distributed in plants (bibliography, A. R. Rose, 1912). It is prepared from plant seeds, and has been proposed as a substitute for lecithin. It is absorbed and metabolized, but must be decomposed before it can be used by the tissues. Abundant amounts are contained in ordinary food; and there is no clear evidence that it is superior to inorganic phosphates.

WATER-SOLUBLE GROWTH VITAMINE B: ANTINEURITIC VITAMINE

Plants of all kinds contain water soluble substances that promote nutrition. Diets that are deficient in these, lead to arrest of growth, loss of weight, and death by starvation. The phenomena are promptly corrected when food or extracts containing the B vitamine are added to the diet. These also cure promptly the polyneuritis (beri-beri) that results from an exclusive or nearly exclusive diet of polished rice. The growth and anti-neuritic effects are always associated in the extracts, but they may be due to different constituents.

Beri-beri.—This disease appeared and spread rapidly in the Orient about the middle of the 19th century, when shelled rice was introduced. It may be defined as an endemic polyneuritis, with nutritional disturbances. Most patients are extremely emaciated but with some this is obscured by edema. Eykmann, 1890-1897, and Casimir Funk, 1911-1913, proved its causation by producing identical wasting and polyneuritis in

fowl, through feeding polished rice, and its relief by extracts of the hulls. Human beri-beri develops after about 90 days of the hulled rice diet. The patients are improved by diets rich in vitamine B, and rendered worse by B-deficient diets (Oho-mura et al., 1922).

Experimental Rice Disease.—This is most typical in fowl, especially in pigeons. When fed exclusively on shelled rice, these promptly lose their appetite, become emaciated and die when they have lost more than half their weight, in three to five weeks. A portion of the birds develop paralytic phenomena in 1 to 5 weeks, usually in 3 weeks, but this polyneuritis depends on the individual predisposition of the birds, and the majority die without this symptom (Pilcher and Sollmann, 1925). Typical beri-beri polyneuritis has been produced in cats and dogs by an exclusive diet of lean meat, heated for 3 hours at 120°C. with sodium carbonate solution. Different animals required different periods to develop the disease. The pathology and the response to treatment are the same as for beri-beri (Voegtlin and Lake, 1919).

There is also considerable quantitative variation in the malnutrition of the pigeons. The previous diet plays a rather minor part, if it was rich in vitamine, the malnutrition is delayed by about a week, corresponding to the limit of vitamine storage, if the diet was so poor in vitamine that the animals start with subnormal weight, the starvation proceeds more rapidly (Pilcher and Sollmann, 1925). Young animals are more susceptible than the full grown; with young rats, growth is arrested in 2 to 3 weeks. Pregnant and diseased animals are also more susceptible.

Excess income of vitamine B results in a moderate increase of growth (Funk and Macallum, 1911; Pilcher and Sollmann, 1925).

Relation of Antineuritic and "B" Growth-vitamine.—Although these occur together they do not appear to be identical. Excessive heat destroys the antineuritic value of whole rice for fowls; but does not destroy the growth factor for rats (Emmet, A. D. and Luros, 1919). Conversely, yeast-fuller's earth adsorbate (L. Seidell) contains the antineuritic, but not the growth properties (Emmet and McKim, 1917).

Mechanism of Action.—The classification of beri-beri as a "deficiency disease" is perhaps misleading. Simple starvation would represent an even more complete deficiency of B vitamine, but its phenomena are apparently less severe and less rapid than with rice diet. There is, however, a general similarity in the phenomena, and the share of the different factors cannot yet be assigned. Deficiency of the B vitamine appears to inhibit the normal activity of the digestive tract, but this could be either the effect or the cause of the other symptoms. B vitamine does not affect the secretion of pancreatic juice, secretin, bile or saliva in the dog (Cowgill and Mandel, 1921); but the polished-rice diet diminishes the quantity, acidity and pepsin content of the gastric juice, and is accompanied by increase of the intestinal flora. These effects are antagonized by histamine (Danyasz-Michel and Koskowski, 1922); while atropine, epinephrine and pilocarpine accelerate the starvation (Arloing and Dufourt, 1923). Adsorbents (kaolin, charcoal, etc.) diminish the effect of the vitamine (Masserli, 1922).

McCarrison claims that partial vitamine B deficiency produces loss of appetite, diarrhea, atrophy of the lymphoid tissue of the intestines, especially of Peyer's patches, and sterility.

W. R., Hess, 1921, pointed out some similarities of cyanide poisoning and attributed the phenomena of rice-disease to depletion of the respiration enzymes.

Storage.—Animals appear to be unable to manufacture vitamine B, and can only store it for a short time; even when a large excess has been fed to pigeons, this delays the weight-loss only by about a week (Pilcher and Sollmann, 1925).

Occurrence.—The "B" substance is also of wide occurrence in animals and especially in vegetable food, particularly in green vegetables (McCollum et al., 1916). It is present in milk, eggs, liver and pancreas, but deficient in meat (muscle); (Osborne and Mendel, 1917).

Traces have been isolated from ox-bile and from human urine (Muckenfuss, 1919).

Fruit and fruit-juices protect against B-deficiency although rather large quantities must be taken (Osborne and Mendel).

Ordinary baker's and brewer's yeast is rich in B vitamins and the vitamine preparations on the market are prepared from this material (see under Yeast).

Potency of Commercial Vitamine Preparations.—This is generally low (McCollum and Simmonds, 1922). A method of assaying is described by Seidell, 1922.

Chemical Structure of Antineuritic Vitamines.—Funk, 1911 and 1912, isolated from defatted rice-hulls a crystalline substance, of which 4 mg. effect the cure of a polyneuritic bird. Similar substances have been isolated from yeast and from ox-brain; but they all lose their activity on further purification, and therefore are probably merely contaminations. Funk considered his substance as probably a pyrimidine derivative, but did not establish its chemical nature; and since it is not the active principle, this is not important. R. R. Williams, 1917, considers that the betaine-ring is essential, betaine itself being weakly protective. The antineuritic vitamin prepared from egg-yolk is not adenine (Steenbock, 1917) and adenine is not antineuritic (Voegtlin and White, 1916).

Solubility Characters of Antineuritic Vitamine.—This is water-soluble and dialyzable (Eykmán, 1897). It is insoluble in ether or absolute alcohol, but dissolves in ordinary alcohol (Fraser and Stanton, 1910), especially if this is acidulated.

When extracted from various sources by alcohol, it becomes soluble in organic solvents especially benzol (McCollum and Simmonds, 1918). This may have led to confusion with the "A" substance.

Resistance to Reagents.—The vitamin is highly resistant toward acids, remaining unaltered on boiling for 24 hours with 20 per cent. mineral acids (Funk and Cooper, 1911). Alkalies do not destroy it at room temperature; but they sometimes destroy it during its isolation.

Heat Stability of B Vitamine.—It tolerates heating to 100°C. for several hours, in neutral or acid solution, and therefore persists in canned vegetables. However, it is quickly destroyed in neutral solution at 120°C., and in alkaline solutions also at lower temperatures (Chick and Hume, 1917, Proc. Roy. Soc. 90 B: 60; McCollum, 1918, Am. J. Publ. Health, 8: 191).

It remains active when yeast is autolyzed at 35°C. for 24 hours (Cooper, 1914).

It tends to disappear gradually from stored foods.

Culture-activating Substance; "Bios."—The multiplication of yeasts, infusoria, bacteria and other organisms is more rapid in media on which the organisms have already been grown (within certain limits), than it is in fresh culture media. Wildiers, 1901, and F. B. Robertson ("Chemical Basis of Growth and Senescence," 1923) attribute this to the formation of an autocatalytic agent, "bios." Robertson conceives that this bios is formed in the nucleus, and suggests interesting theories as to its relation to the life-cycle of the cell.

It is not known whether the yeast "bios" is identical with the antineuritic or growth vitamin.

YEAST

The ordinary bakers' and brewers' yeast consists of the cells of *Saccharomyces cerevisiae*, filtered from their cultures, generally in extracts of malted grain; they are often mixed with starch to the proper consistence. The living cells have long been used as a bactericidal dressing for ulcers, boils, etc., but had become nearly obsolete. The discovery of vitamin B in yeast (McCollum et al., 1916) aroused fresh interest. The administration of living, dried and autolyzed yeast or extracts is effective against human beri-beri, (although less active than rice-hull extract, Saleeby, 1919), and against the polyneuritis and malnutrition of polished-rice disease. This led to their trial against other forms of malnutrition and against infantile scurvy, but without beneficial results (Hess, 1916). It should be recalled that the yeast vitamin could only be useful if the diet is deficient in vitamin B; but this vitamin is so widely distributed that the ordinary American and European diets automatically assure an adequate supply. The only possibility of deficiency would be in special and unusual dietaries. The "tonic action" that is so widely advertised in the public press is apparently mainly attributable to psychic suggestion. Living and perhaps also dead yeast cells are laxative, but it is questionable whether they should be preferred to the medicinal laxatives that are better understood. The administration of yeast is sometimes followed by the relief of acne, furunculosis, herpes, etc.; but the results are so inconstant, that it is not possible to judge how far the results are due to

coincidence or to other factors, such as the catharsis, the high content of nucleic acid, etc. (see Tsuru, 1909; Abraham, 1910). Its use by physicians has already greatly decreased. The dosage is from 1 to 20 Gm. of the "compressed yeast" per day. Yeast extracts resemble "meat extracts" and may be used to flavor soups and bouillons.

Yeast as Nitrogenous Food.—Yeast has been proposed as a nitrogenous food; but its protein value is not high, a large part escaping by the feces. Its high purine content tends to raise the uric acid of the blood (Funk, Lyle and McCaskey, 1916).

Degeneration of Testicles.—Caution should be observed in administering yeast continuously for Osborne and Mendel, 1919, observed that the testes of rats on a yeast containing diet often undergo degeneration, with consequent sterility.

Active Principle.—This adheres to fuller's earth, and can be concentrated by treating autolyzed yeast with this absorbent. Its extraction from yeast is further described by T. B. Osborne and Wakeman, 1919.

NUCLEOPROTEINS, NUCLEINS, AND NUCLEIC ACIDS

Chemistry.—These terms are often applied so loosely and incorrectly to the commercial products, that it may not be amiss to review briefly their meaning. *Nucleoproteins*—which occur mainly in nuclear material—are natural compounds of nucleic acids and proteins. By peptic digestion or dilute acids, a fraction of the protein may be split off, resulting in modified nucleo-proteins, correspondingly richer in nucleic acid. These are termed *nucleins*. They contain about 5 per cent. of organic phosphorus. The remainder of the protein component can be removed by tryptic digestion or alkalis, yielding the true *nucleic acids*. These are definite chemic substances, their composition varying according to the tissues from which they have been obtained (as does also the protein constituent; so that the different products are not identical). Their composition approximates: $C_{40} H_{52} N_{14} O_{25} P_4$; the atomic ratio of P:N lying between 4:14 to 20. *Commercial nucleic acids* are often contaminated with more or less nuclein, as may be readily shown by the biuret or Millon's reactions. They are usually prepared from yeast, but also from thymus, pancreas, spleen, the sperm of certain fishes, and the embryo of grain. Nucleins and nucleic acids have fairly strongly acid characters. They are insoluble in water, but form soluble salts with dilute alkalis.

Actions and Uses.—On hypodermic injection, they increase the number of all varieties of circulating leucocytes; and it is now claimed that they also raise the opsonic index.

In dogs, the injection produces a primary leucopenia followed in 24 hours by a marked increase of leucocytes, often to double; the changes involving mainly the polymorphous cells (Fox and Lynch, 1917).

Because of the leucocytosis, nuclein preparations have been used in tuberculosis and other infectious diseases (Chantemesse, 1907), but their value is very doubtful. The leucocytosis is of short duration, requires increasing doses, and causes other disturbances (Neymann, 1917).

Favorable results have been reported for oral administration. The absurdity of these claims may be appreciated from the fact that 100 Gm. of ordinary moist meat contains about 0.02 Gm. of phosphorus (Kossel, 1882) corresponding to 0.2 Gm. of pure nucleic acid; the same quantity of moist liver, spleen, or pancreas corresponds to about 2 Gm. of the pure acid; whilst the oral dose of the impure nucleins is stated at only 0.06 to 0.3 Gm. (Bibliography, Merck's Rep., 1914, 27: 1).

Fats.—Nucleic acid passes the stomach unchanged. It is partly split in the intestines, with the liberation of phosphoric acid, but not of purines. A further part is presumably split during absorption (bibliography, Forbes and Keith, 1914).

The nucleins are excreted as purine bases and uric acid; so that they are contraindicated in gouty and rheumatic conditions, etc. The phosphate elimination is also increased. The acceptable commercial preparations are listed in N.N.R.

ANTISCORBUTIC VITAMINE C

Green vegetables, fruits, potatoes, onions and germinating grain contain an unstable vitamine that protects against scurvy; and deficiency of this vitamine leads to the development of the disease, *i.e.* hemorrhages from the gums and in other situations and suspension of growth. The

latter is perhaps a secondary manifestation. Changes in the digestive tract and in the lymphatic system are also described. The condition is not infrequent in improperly fed infants, and was very common in sailors in the days of long sailing voyages. It is now rare in adults, because with these the disease develops only after a deprivation of some 4 months, for which there is not often occasion. Guinea pigs develop typical scurvy after weeks of a diet without green food; *i.e.* grain and water, with or without hay (Holst and Froehlich, 1912). They are cured by the same agents that are effective in human scurvy. Rats and mice appear to be immune.

Wolbach, 1925, ascribes scurvy to an inability of the cells to form and to maintain their characteristics intercellular substance. The cells continue to manufacture an imperfect and often liquid substance; and the antiscorbutic vitamine rapidly converts this liquid into the normal intercellular jelly.

Occurrence and Stability.—The antiscorbutic vitamine is especially abundant in the juice and rind of citrus fruits and in tomato juice, and in these it is fairly stable, even on cooking. This is perhaps due to a protective action by the acid. Otherwise it is very unstable and disappears on cooking or drying. It is therefore absent from preserved fruit or vegetables, except tomatoes. It is not abundant in fresh milk, and diminishes by pasteurization and by drying (Johnson and Hooper, 1922). It is almost absent from dried grain, but is formed in germination. Proprietary vitamine preparations are generally not antiscorbutic (J. H. Hess et al., 1922).

The storage in the body is probably very slight.

Chemical Nature.—This is not known. The vitamine is water soluble and dialyzable. The antiscorbutic activity of orange and lemon juice is not due to the citric acid; for citric acid itself is ineffective (Chick and Hume, 1917; Hess, 1918); whereas scurvy is cured by decoctions of orange peel (Hess, 1918) which are practically devoid of citric acid, or by orange juice from which the citric acid has been removed (Harden and Zilva, 1918).

CHAULMOOGRA OIL

This fat, which is expressed from the seeds of East Indian trees of the genus *Taraktogenos* and *Hydnocarpus*, consists of the glyceryl esters of a unique series of cyclic fatty acids. These possess a specific toxicity for acid-fast bacteria.

When properly administered, these acids arrest the progress of clinical leprosy, producing recession of the nodular, macular and anesthetic lesions, and the degeneration and disappearance of the bacilli. The arrest is so complete, that a very considerable proportion of the cases (in one series about 50 per cent.) can be paroled as apparently cured. The amenability decreases with the duration of the disease.

The oil has been used in India against leprosy since antiquity; but the nauseating taste and the gastro-intestinal irritation render effective and intensive medication by mouth difficult. Vastly better results are being secured by the weekly intramuscular injection of the ethyl-esters of the fatty acids, which are better tolerated. The treatment, however, must be continued for a considerable time.

Chaulmoogra oil has also been suggested for the treatment of tuberculosis, but there is no convincing evidence of its clinical value, and the results of animal experiments were negative.

Composition.—F. B. Power et al., 1904-1907, confirmed by A. L. Dean and Wrenshall, 1920, showed that chaulmoogra oil consists principally (90 per cent.) of the glycerides of a series of unsaturated fatty acids which are unique in that they contain a closed 5-carbon ring, are optically active, and have not been found in any other oils.

The most abundant of these acids are *chaulmoogric acid*,

and *hydnocarpic acid*, which contains 10 CH₂ in the side chain, instead of 12. Their actions on the leprosy bacillus are qualitatively similar, but the hydrocarpic is somewhat more active. There are also small quantities of other homologues. McDonald and Dean 1920, suggest that more effective lower homologues might be synthesized.

The oil contains also small quantities of ordinary fats, which do not participate in the action. The oil of *Gynocardia odorata*, which has been confused with chaulmoogra oil, does not contain the cyclic fats, and is inactive (Schoebl, 1924).

Historical.—The first attempts to obviate the oral administration utilized the hypodermic or intramuscular injection of the oil, generally thinned by the addition of olive oil, (for instance V. G. Heiser, 1913). This gave better response, but produced severe local irritation. Leonard Rogers, 1916, used the sodium salt (soap), subcutaneously and intravenously; this also gave good response, but often led to obliteration of the vein. The ethyl esters were prepared by Hollmann and Dean, 1919, and applied by McDonald and Dean, 1920, at Honolulu. Further references can be consulted in Walker and Sweeney, 1920.

Clinical Improvement.—Details may be found in the papers of J. T. McDonald, 1920; McDonald and Dean, 1920; and van Gaasbeek, 1923. According to the latter, the disease can generally be arrested if it has lasted less than 5 years; if between 5 and 10 years, it can be improved; if over 10 years, the improvement is relatively slight and may be practically nil.

Febrile Reaction.—With the modern intensive administration, about 10 per cent. of the patients develop skin eruptions and fever, beginning 1 to 3 days after the injection, and disappearing in 2 to 3 weeks. The reaction is not serious but may require interruption and slowing of the treatment, (McDonald, 1920). It is probably due to the liberation of toxins by the reaction of the bacteria and tissues.

Bactericidal Action in Vitro.—E. L. Walker and Sweeney, 1920, showed that the sodium salts of these fatty acids arrest the growth of acid-fast bacteria in dilution of 1:1,000,000, and kills them in 1:100,000; that is, they are about a hundred times more active than phenol. This high toxicity does not extend to other bacteria. It is evidently connected in some way with the fatty and waxy nature of the acid-fast envelope, which is presumably altered in some way by these acids. This again is connected with their cyclic structure and not with their unsaturated characters; for the soaps of linoleic acid and the cod-liver oil lack the specific toxicity.

Choice of Method of Administration.—Although chaulmoogra oil is not toxic to animals or man, it produces considerable local irritation. The relative inefficiency of the oral administration indicates that it is imperfectly absorbed. The method of choice, therefore, is intramuscular injection of the relatively non-irritant ethyl esters. This has been combined with oral administration but the latter appears superfluous (McDonald and Dean); so also is iodization of the esters; but it may be that this diminishes the local reaction, as claimed by Wade, 1925.

Dosage of the "Ethyl Chaulmoograte."—This consists really of the esters of the mixed acids. McDonald uses it in weekly injections, made into the upper and outer quadrant of the gluteal region, alternating the sides weekly. The first injection is of 1 c.c., increased by 1 c.c. every 2nd and 3rd injection, until the maximum of 3 to 5 c.c. is reached. Resistant lesions may also be injected directly with the ester.

The injection produces some pain and irritation, and sometimes necrosis, but much less than with the oil (Voegtlin et al., 1921). Abscess is exceptional. There is generally no digestive disturbance.

Oral Administration of Ethyl Chaulmoograte.—The dose is increased gradually from 1 to 5 c.c. per day, after meals, in warm milk or hot tea. It is tolerated much better than the oil, and over longer periods, since its taste and odor are not disagreeable and it does not disturb digestion.

Oral Administration of Chaulmoogra Oil.—The dosage begins with 0.3 c.c. three times daily, and is increased to the point of tolerance. Various methods are described by B. E. Read, 1925.

Intramuscular Administration of Chaulmoogra Oil.—This is quite painful and very seriously irritant, and easily produces necrosis at the site of injection (Voegtlin et al.,

1924; Cadbury, 1920). The oil must be thinned by the addition of olive oil, and analgesics are usually added; for instance, equal parts of chaulmoogra and olive oil, with 5 per cent. of camphor and 10 per cent. of guaiacol; or the "Heiser Mixture," equal parts of chaulmoogra and camphor oil, with 3.6 per cent. of resorcin. Either mixture is injected weekly, increasing from 2 to 10 c.c. *Intravenous injection of the esters* is dangerous, as it may result in pulmonary embolism (Walker *et al.*).

Sodium Soap.—The intravenous injection, according to Rogers, 1917, produces temporary giddiness, headache, and occasional occlusion of the vein, preventing its further use. According to Voegtlin *et al.*, 1921, this is due to the alkalinity of the soap, and is a serious objection. Rapid injection of the 2 per cent. solution also produced embolism.

Experiments with Tuberculosis.—The similarity of the bacilli suggested to Rogers, 1916, that chaulmoogra oil might be efficient in tuberculosis. He claimed the production of fever, reactions in the lesions, and changes in the bacteria; but his clinical results have not been adequately confirmed. The soaps are effective *in vitro*, (Walker and Sweeney, 1920; Shoeb, 1924); but they fail *in vivo*, partly because they do not penetrate the tubercles, (Walker *et al.*), and the experiments of Voegtlin *et al.*, 1920, with the ethyl-esters failed to reveal any effect on the weight, growth, lesions and mortality rate of a large series of tubercle infected guinea pigs.

PREPARATIONS

Oleum Chaulmoograe (Ol. Chaulmoog.), U.S.P., B.P., Chaulmoogra Oil, Gynocardia Oil.—The fixed oil expressed from the seeds of the East Indian tree, *Taraktogenos Kurzii* (B.P.) and also several species of the related genus *Hydnocarpus* (U.S.P.). A yellowish or brownish oil, congealing below 25°C. to a whitish soft solid. Characteristic odor and somewhat acid taste. *Dose*, 1 c.c., 15 minims, U.S.P.; (0.2 to 0.6 c.c., 5 to 10 minims, gradually increased to 2 to 4 c.c., $\frac{1}{2}$ -1 drachm, B.P.).

Aethylis Chaulmoogras, (Aethyl-Chaulmoog.), U.S.P. Ethyl Chaulmoograte, (Chaulmestrol).—The ethyl esters of the fatty acids of chaulmoogra oil. A clear, pale-yellow liquid of slight, fruity odor. Insoluble in water, miscible with alcohol, chloroform and ether. *Dose*, by mouth or by intramuscular injection, 1 c.c., 15 minims, U.S.P.

Unguentum Chaulmoograe, B.P.—10 per cent. in a mixture of hard and soft paraffin (petrolatum).

EMOLLIENTS, DEMULCENTS AND PROTECTIVES

These are chemically indifferent substances that are used to cover and thus to protect surfaces against irritation. Oils, fats and glycerin, when so applied to the skin, also tend to soften the epidermis, and are therefore termed emollients (emollire, to soften). When applied to mucous membranes or wounds, protectives are designated as demulcents (demulcere, to smooth down), since their main purpose is to soothe irritation. Viscid water-miscible solutions, for instance, of the gums, or glycerol, adhere to these moist surfaces better than does oil. This corresponds to the natural mechanisms for the protection of the body surfaces: Whilst the skin is normally covered with a thin layer of emollient oil, the membranes of the interior of the body are moistened with mucus, which is a typical gummy demulcent. Fine insoluble and adhesive powders, talcum, etc., are also used as demulcents on the skin, mucous membranes or wounds.

The protectives diminish the local action of chemic, mechanical or bacterial irritants; decreasing pain, reflexes, catarrh, spasm and other manifestations of irritation. They also delay and diminish absorption, particularly from the stomach, but also from the intestine, subcutaneous tissue, etc. In this way they diminish the systemic effects of absorbable poisons, whilst they prolong their local actions.

Mechanism of Action.—Colloids and fats are practically indifferent and inabsorbable for cells, so that they do not produce any direct effects on them; but through their adhesive character, they form an extra cover-

ing to the surfaces to which they are applied, and thus hinder the access of irritant agents. Oils prevent the penetration of water-soluble substances, gums that of fats and resins. Gums also lessen the effects of crystalloids, although they do not impede their diffusion. They produce this effect by increasing the viscosity of the solution, thereby interfering with its transportation (von Tappeiner, 1902). Adsorption probably also plays a part, for dissolved substances are condensed on the surfaces of fine powders and thus removed from the solution. All protectives prevent the irritation of drying, and the access of bacteria and mechanical irritants.

Emollient Drugs.—These comprise the true fats and oils (glycerides of fatty acids), woolfat, petrolatum, and glycerin. They are employed mainly on external surfaces, to soften and protect the skin, ulcers, burns, and other superficial wounds; as vehicles (salves) for the application of medicaments to the skin or, more rarely, for systemic effects (mercurial inunctions). Internally, the true fats serve as nutrients. Larger amounts than can be digested stimulate peristalsis and act as intestinal lubricants and laxatives. For external use, the liquid or soft fats, the oils, lard, etc., should be chosen for inunction, when the preparation is to be rubbed in the skin glands; whilst protection and prolonged contact is best secured by the harder and more adhesive ointments, woolfat and petrolatum mixtures, cerates and plasters. Petrolatum alone is not very adhesive, and exceptionally it is somewhat irritant. All the ointments and glycerol tend to soften the epidermis, by preventing drying. In this they aid the natural oil of the skin and prevent roughness and "cracks" from wind, cold weather, sunburn, skin diseases, etc.

Penetration of the Skin.—Oils when rubbed into the skin, enter the sebaceous glands and eventually can be demonstrated microscopically in the lymph channels. True fats are gradually oxidized and disappear; but the mineral fats remain for a long time in the subcutaneous tissue, and thus produce chronic irritation and fibrosis. The animal and vegetable fats therefore deserve preference when penetration is desired (Sobieranski; Juckuff; Meyer; see "Ointments" in Index).

Fats on Penetration.—Fats and oils protect the skin against the penetration of fat-soluble irritants, such as phenol, mustard oil, or "mustard gas" (Sollmann, 1918, 1919). On the other hand, oiling of the skin also hinders the access of watery solutions to the epithelium (Filehne and Biberfeld).

Rancidity.—Fats turn "rancid" on keeping, especially if they are exposed to air, light and heat, and if they contain protein impurities. The change consists in oxidation with the development of free volatile fatty acids. Rancid fats are disagreeable and irritating, and therefore unfit for medicinal use. Lanolin and the petroleum products are free from this objection, but rancidity may be avoided with other ointments by keeping and dispensing them in air tight "tin-tubes."

OLIVE OIL AND OTHER BLAND FATTY OILS (OLEA PINGUA)

Uses.—The expressed oils of olive, cottonseed, almond, sesame, etc., are essentially similar. For internal use, olive oil is preferred because of its more agreeable flavor. These oils are employed externally to soften the skin and crusts in eczema and psoriasis; as dressing for burns; as vehicles for liniments, etc.; and by rectal injection, to soften fecal concretions (150 to 500 c.c., 5 to 20 ounces, of the cheaper cottonseed oil, warmed. Hertz claims that oil is less effective than water for this purpose). Internally, olive oil is used as nutrient, laxative, and in hyperchlorhydria

(15 to 50 c.c., $\frac{1}{2}$ to 2 ounces before meals). Kennedy and others have claimed beneficial results in biliary colic, using large doses (150 to 500 c.c. in four to eight portions within three hours). Its effects, if any, have not been explained; it does not increase the flow of bile, and the concretions found in the feces when olive oil and epsom salt are given are not gallstones, but simply soap (magnesium oleate).

These oils are insoluble in water or glycerol, very sparingly in alcohol, freely in chloroform, ether, volatile oils, or fats.

Fats are useful antidotes in corrosive poisoning. The protective action of oils against irritation and absorption was known and used by the Greek physicians.

Influence on Digestion.—Neutral fats allay gastric peristalsis, diminish gastric secretion and acidity (Pawlow; Cowie and Munson, 1908; Chiari, 1915), and lessen the pyloric tone. They leave the stomach slowly and in small portions; a fatty meal requiring seven hours for complete passage into the duodenum. The digestibility of animal fats is discussed by Langworthy and Holmes, 1915. The length of gastric sojourn increases with the melting-point of the fat, Feyer, 1913. In the duodenum, fats check the gastric discharge and stimulate the flow of pancreatic juice and the evacuation of the gall-bladder (Klee and Knuepfel, 1914).

Subcutaneous injections of fats as nutrients were proposed by Leube, 1895. They can be administered indefinitely without irritation or other disturbance, and are gradually absorbed by the lymph. However, the absorption of plain fats is too slow to be of practical value (Winternitz, 1903; Y. Henderson and Crofutt, 1905). Somewhat better results were obtained with fats emulsified by lecithin (Mills and Congdon, 1911). The injection of free fatty acids would be toxic. Fats are also oxidized when emulsions are injected into a vein (Murlin and Riche, 1915).

Oleic Acid Anemia.—The continued administration of large doses of oleic acid, by mouth or hypodermically, to animals, produces hemolysis and severe anemia (Faust, 1906 and 1908; Polano, 1909; Adler, 1911). Similar effects produced by the injection of extracts of tapeworm (bothriocephalus) are also attributed to oleic acid-cholesterin esters (Faust).

However, Klotz and Spencer, 1917, did not observe any changes in the number or structure of the blood corpuscles, after two weeks of intravenous injection of suspensions of cholesterol in sodium oleate.

The saturated higher fatty acids are also hemolytic (Shimazono, 1911). The hemolysis of bacterium putidum is oxydimethyl thiol-crucic acid, a typical unsaturated fatty acid (Burckhardt, 1910).

Nephritis.—Salant and Bengis, 1917, claim that oral administration of fatty oils causes renal disturbances in rabbits on an oats diet; but not when they are fed on carrots. The effect does not occur when the oil is injected hypodermically; it is perhaps due to some secondary product arising from the presence of the oil in the intestines.

PREPARATIONS

Acid. Oleic, U.S.P., B.P.—Mixture of fatty acids consisting chiefly of $C_{17}H_{33}COOH$. Yellowish or brownish-yellow, oily liquid; peculiar lard-like odor and taste. Practically insoluble in water; completely miscible with about 85 per cent. alcohol; soluble in chloroform and in fixed and volatile oils. Used as solvent for metallic oxides and alkalis, intended to be absorbed from the skin.

Ol. Amygdala Expressum (Ol. Amygd. Exp.); Ol. Amygd., B.P. (Oil of Sweet Almond).—Fixed oil from bitter or sweet almond.

Ol. Arachis, B.P. (Peanut Oil.)

Oleum Gossypii Seminis (Ol. Gossyp. Sem.). U.S.P.; Cottonseed Oil.—Fixed oil, expressed from seeds of cultivated varieties of Gossypium. Slightly sol. in alc. On account of its cheapness, it is especially adapted for external use. It is inferior for internal administration; it can not be readily emulsified or saponified, since the free fatty acids have been removed in the process of purification.

Gossypol.—Feeding with "cottonseed meal" (not the oil) sometimes produces toxic effects. These are due to gossypol, a crystalline substance, first isolated by Marchlewski, 1890. This is insoluble in water, soluble in dilute alkali, in oils and in gasoline. It is tasteless; but the solutions act as a slow capillary poison, resulting in local inflammation and edema. It may be rendered harmless by steaming and various methods of oxidation, precipitation or extraction (Withers and Carruth, 1915).

Phenomena of Cotton-seed Poisoning.—As observed in the slow poisoning by feeding farm or experimental animals (dogs, rabbits, cats, less typical in rats), these consist in diarrhea, loss of appetite, emaciation, edema of the lungs and shortness of breath, edema of the ano-genital region, neuritis and paralyses. The disturbance of digestion and nutrition is due to enteritis, which is severe and may be hemorrhagic.

Injections of alkaline or oily solutions produce marked irritation and edema at the site of injection. Intravenous and intraperitoneal injections kill by pulmonary edema. Less characteristic direct effects on the heart and excised intestine have been described. Cottonroot bark, which also contains gossypol, has been used as abortifacient (see Index), but does not seem to be very effective (Alsberg and Schwartz, 1919; Schwartz and Alsberg, 1924; Macy and Outhouse, 1924).

Ol. Lini, U.S.P., B.P.; Linseed Oil.—Expressed from Linseed. Disagreeable odor. Employed mainly in veterinary practice and in liniments. "Boiled" oil must not be used. *Dose*, 30 c.c., 1 ounce, U.S.P.

**Oleum Olivæ* (Ol. Oliv.), U.S.P., B.P.; Olive oil (Sweet Oil).—A pale yellow or greenish-yellow fixed oil, expressed from the ripe fruit of *Olea europæa*. Slightly sol. in alc. *Dose*, 30 c.c., 1 ounce, U.S.P.

Ol. Sesami, B.P.; Oil of Sesame (Teel Oil, Benne Oil).—Expressed from seeds of *Sesamum indicum*.

**Ol. Theobromatis* (Ol. Theobrom.), U.S.P., B.P.; Oil of Theobroma (Cacao Butter). A yellowish-white solid fat from the roasted seeds of *Theobroma Cacao*. It melts at the temperature of the body. It is used mainly for making suppositories, and as a lubricant in massage. Not to be confused with:

Oleum Cocos; cocos-oil.—The expressed oil of the cocoanut, the fruit of the palm, *Cocos nucifera*. It is a whitish fat, soluble in alcohol, used especially in soap-making.

SOFT ANIMAL FATS

These are employed as soft ointment bases. They have the inconvenience of rapidly turning rancid. This is delayed by antiseptics, as in Benzoinated Lard.

PREPARATIONS

Adeps, U.S.P.; *Adeps Præp.*, B.P.; Lard.—The purified internal fat of the abdomen of the hog. Insol. in water; very slightly sol. in alc.; melts between 36° and 42°C.

**Adeps Benzoinatus* (*Adeps Benz.*), U.S.P., B.P.; Benzoinated Lard.—Lard digested with Benzoin. In this process it takes up a certain amount of the latter, and acquires the antiseptic and stimulant properties of balsams, besides increasing its own keeping qualities.

Butyrum, *Butter*, is sometimes used as an ointment basis. Since it can not be salted for this purpose, it keeps very poorly.

Sevum Benzoatum, B.P.; Benzoated Suet.

Sevum Præparatum (*Sev. Præp.*), U.S.P., B.P.; Suet.—The internal fat of the abdomen of the sheep, purified by melting and straining.

Other Animal Fats.—Other animals also yield fats which are popularly supposed to have special advantages—dog fat, goose grease, etc. There appears to be no established reason for preferring them to the more easily obtainable lard.

WOOLFAT-LANOLIN

This differs chemically from ordinary fats in that the fatty acids are not united to glycerol but to cholesterol and isocholesterol and smaller quantities of other alcohols.

Crude woolfat or suint was used by the ancients, but was too disagreeable, until a purified product was introduced by Liebreich as "lanolin." Even this has a rather unpleasant odor and disagreeable sticky consistence, but it does not readily turn rancid. Since its composition resembles that of the natural skin-fat, it was believed that it would be more readily absorbed; but this does not seem to be the case. Its chief advantage lies in the property of forming salve-like emulsions with up to two or three times its volume of water, so that watery solutions may be incorporated with it. In contrast to ordinary emulsions, the water is the

dispersed and the lipoid the continuous phase. Considerable quantities of true fats or petrolatum may be mixed with the woolfat without destroying this quality. Anhydrous woolfat is too "doughy" for ointments; it is employed after the admixture of 30 per cent. of water (Hydrous Woolfat), or better with the further addition of an equal weight of petrolatum or other fat. Ointments containing woolfat are more adhesive and coherent than ordinary fats, and are therefor more suitable for prolonged effects, and less so for inunction.

Composition.—Woolfat consists of a mixture of cholesterol esters and of alcohols of the fatty series, including ceryl alcohol. Its fatty acids are largely those of ordinary fats (E. Rohmann, 1916).

Lieftschütz and Unna (E. Unna, 1912) attributed the emulsifying action to traces of free ischolesterol and oxycholesterol; but Rohmann failed to confirm the presence of ischolesterol (also of carnaubic acid or alcohol).

Absorption.—Woolfat is not absorbed from the intestines (Bloor, 1913).

PREPARATIONS

Adeps Lan., U.S.P., B.P.; Woolfat.—The purified fat of the wool of sheep, freed from water. A light-yellow, tenacious, unctuous mass, not more than a slight odor. Miscible with about twice its weight of water. Sparingly sol. in alc., readily in chlorof., eth., acetone, etc. Melts between 38° and 42°C.

**Adeps Lanæ Hydrosus* (Adeps Lan. Hyd.), U.S.P., B.P.; Hydrous Woolfat (Lanolin).—Contains from 25 to 30 per cent. of water. A yellowish-white, or nearly white, ointment-like mass, having not more than a slight odor. Miscible with about twice its weight of water.

WAXES. WAX-LIKE FATS

These are used in pharmacy mainly to stiffen ointments (as in cerates).

PREPARATIONS

Acidum Stearicum (Acid. Stear.), U.S.P.—Mixture of fatty acids consisting chiefly of $C_{17}H_{35}COOH$ obtained from tallow or other fats. Hard, white, or yellowish-white, somewhat glossy, solid, odorless, or having a slight, tallow like odor, tasteless. Melts above 56°C. Sol. in alc. (1:21); almost insol. in water. Used in glycerin suppositories.

Cera Flava (Cer. Flav.), U.S.P., B.P.; Yellow Wax, Beeswax.—The purified product of the hive bee, *Apis mellifera*. Melts between 62° and 65°C. Sparingly sol. in alc.; sol. in eth., chlorof., and oils.

Cera Alba (Cer. Alb.), U.S.P., B.P.; White Wax.—Bleached beeswax.

Cetaceum (Cetac.), U.S.P., B.P.; Spermaceti.—A fatty substance, obtained from the head of the sperm whale, *Physeter macrocephalus*. Consists mainly of ester of cetyllic alcohol and palmitic acid.

Resina (Resin.), U.S.P., B.P.; Rosin (Colophony).—The residue left after distilling off the volatile oil from turpentine, the concrete oleoresin obtained from species of Pine.

COMPOUND OINTMENT BASES

Typical ointments melt at the temperature of the body.

PREPARATIONS

Unguentum (Ung.), U.S.P.; Ointment (Simple Ointment).—2 parts White Wax, 8 parts Benz. Lard.

Ung. Ag. Ros., U.S.P., B.P. (Cold Cream).—Expressed Almond Oil, thickened with Spermaceti and White Wax, flavored with Rose Water, and containing 5 per cent. of Sodium Borate, U.S.P. To be preserved in tin-tubes.

Ung. Cetæ, B.P.—Spermaceti, 20 per cent.; White Beeswax, 8 per cent.; Liq. Paraff., 72 per cent.

Ung. Lanæ Co., B.P.—Lard, 40 per cent.; Woolfat, 40 per cent.; Paraff. Oint., 20 per cent.

Ung. Paraff., B.P.—Hard Paraff., 27 per cent.; Soft Paraff., 70 per cent.; Beeswax, 3 per cent.

Ung. Res., B.P.—Resin, 26 per cent.; Yellow Beeswax, 26 per cent.; Olive Oil, 26 per cent.; Lard, 22 per cent.

CERATES

These are stiffer ointments, containing sufficient wax so that they do not melt at body temperature.

PREPARATIONS

Ceratum (Cerat.), U.S.P.; (Simple) Cerate.—Three parts of White Wax and 7 parts of Benz. Lard.

Cerat. Res., U.S.P.; Rosin Cerate (Basilicon Ointment).—Rosin, 35 per cent.; Yellow Wax, 15 per cent.; Lard, 50 per cent.

PETROLATUM AND OTHER PETROLEUM PRODUCTS

Properties.—These were introduced under the name of *vaseline* by Chesebrough, 1871. They are obtained from petroleum by fractional distillation, chilling, purification by filtration through bone-black, etc. They consist of hydrocarbons of the methane and related aliphatic series. According to the process of preparation, they occur of various consistencies, from the waxy “paraffin” (employed for hardening ointments), through the buttery “petrolatum” (a typical emollient), to the “liquid paraffin” (used especially for laxative and sprays). The color, from deep yellow to almost pure white, does not affect the action.

Notwithstanding the chemical difference, they resemble the fats in physical character and therapeutic application. They have the advantage that they are chemically indifferent, do not undergo deterioration, can not become rancid or irritant, and do not react with drugs, such as oxidizing or reducing agents. They are not so well adapted for inunction.

Liquid Petrolatum as Laxative.—Mineral oils are not absorbed (except perhaps doubtful traces; Bradley and Gasser, 1912); but are eliminated unchanged by the feces (Randolph, 1885; Hutchison, 1899; Bloor, 1913). They can not, therefore, act as nutrients. By softening the feces, they are mildly laxative, and are used as such in intestinal stasis (A. D. Schmidt, 1905; Lane, 1913). Sometimes they do not mix well with the feces, the oil leaking from the anus. Occasionally they are followed by nausea and regurgitation (Bastedo, 1914). Any of the “liquid paraffins” (Petrolatum Liquidum Album) may be employed—there being no therapeutic difference between the light or heavy Russian or American oils (Bastedo, 1915). Their composition is perhaps also similar. The usual dosage is from 10 to 30 c.c., one-half hour before meals; or a single dose of 30 to 60 c.c. before retiring. The “light” oil is preferred for sprays (Wilbert, 1914); the more viscid oils for laxatives.

Irritation.—N. Burns, 1917, claimed that erysipeloid skin eruptions have followed the use as wound dressing of liquid petrolatum, when insufficiently purified. This needs confirmation.

Composition of Liquid Petrolatums.—All crude petroleum oils are complex mixtures of hydrocarbons, the composition varying quantitatively according to their origin. These differences are eliminated in refining, so that the composition of the thoroughly refined, colorless products is probably similar, whether the product is derived from Russian or from American oils. The liquid petrolatums consist mainly of naphthenes (C_nH_{2n-2}) and polynaphthenes (C_nH_{2n-2} and C_nH_{2n-4}). They do not contain true paraffins (C_nH_{2n+2}); so that the term “Paraffin Oil” is a misnomer. The irritant olefin hydrocarbons and the benzenes of the crude oils are absent from the refined. Certain ingredients, which give the fluorescence and rancid taste, are more difficult to eliminate from some oils than from others (Brooks, 1916).

The history and composition is discussed in the J.A.M.A., 1914, 62:1740; and by Hilton, 1914.

Criteria of Availability.—Brooks considers the physical qualities, the color, odor, taste and viscosity or specific gravity as much superior to all chemic tests.

Paraffin Treatment of Burns.—Paraffin of proper plasticity forms an excellent dressing for burns. A thin film of melted or liquid paraffin is painted on the clean burn; this is covered by a thin layer of cotton, and this again by a heavier coat of melted paraffin; then cotton, bandages, etc. The treatment obtained notoriety in the form of a secret preparation ("Ambrine"), but simple "surgical" paraffin is fully as good. The addition of antiseptics is useless, since they are hermetically sealed in the solid paraffin (Sollmann, 1917).

Melted paraffin may also be used as a protective surface coating for ordinary dressings (Sollmann, 1917). Fisher, 1916, suggested the impregnation of bandages with paraffin mixtures to avoid adherence to wounds. Gauze impregnated with liquid petrolatum is not easily clogged by secretion, and therefore facilitates absorption by the dressings (Sollmann, 1917).

Sterilization.—H. Lyman, 1917, suggests paraffin for sterilization of instruments; 10 minutes at 150°C. kills even anthrax spores.

Paraffin Prothesis.—The persistence of the mineral fats in the subcutaneous tissue has been utilized for the *correction of deformities* (e.g., of the nose), by injecting subcutaneously a mixture of paraffins melting at about 40°C. There is some danger of embolism, and the results are not permanent, the paraffin being gradually replaced by scar-tissue (Heidingfeld, 1910), which may be a starting point for neoplasms.

Paraffin "Wax" Dermatitis and Cancer.—Continuous handling of unpurified paraffin may lead to dermatitis (Joseph, 1896), acne and other eruptions, and papillomas (see "Tar").

Petroleum (Coal oil).—When petroleum is swallowed, it produces narcotic effects similar to those of alcohol, with strong gastroenteritis. It is toxic in proportion to its content of the more volatile products. No fatal case has thus far been reported, although as much as a liter has been swallowed. Coal oil applied to the skin is a moderate irritant.

Gasoline (Petroleum Benzin).—The inhalation of the vapors causes headache, nausea, giddiness, inebriation, unconsciousness, muscular tremors, convulsions, dyspnea, cyanosis, and death (Buegi and Burgl; Wolf, 1911). Chronic poisoning results in dullness, pain in limbs, trembling, muscular weakness and other nervous disturbances (Rambousek), and pulmonary hemorrhages (Jaffe, 1914). The symptoms of acute and chronic poisoning, as they occur in the rubber industry, are described by Alice Hamilton, 1915.

Concentrated vapors cause purely paralytic symptoms in frogs, but in mammals they seem to have only a weak anesthetic action. If they are inhaled to the exclusion of air, they will cause an asphyxial anesthesia. Before this sets in there are very characteristic convulsions (Sollmann, 1904). The animal struggles violently, then falls on its side and claws the air with all fours, as if running. The pupils are widely dilated. Reflexes absent. The spasms are intermittent, and between them the dog is perfectly limp, except that the toes, tail and eyelids continue to twitch. The respiration is first stimulated, then weakened. There is paralysis of the vagus, then a depression of the cardiac muscle, and later of the vasomotor center. Either heart or respiration may stop first.

Gasoline is, therefore, unsuitable as an anesthetic even for animals; although it has been tried with man (Felix, 1888). It is said to be used as an intoxicant. Its oral administration does not produce gastroenteritis. It is absorbed slowly from the alimentary tract, and excreted mainly by the lungs (Jaffe, 1914).

PREPARATIONS

Benzinum Purificatum (Benzin. Purif.), U.S.P.; Purified Petroleum Benzin.—Used as a solvent. It distills completely between 35 and 80°C. Insol. in water, freely sol. in alc., miscible with ether, chloroform, etc.

Paraffinum (Paraff.), U.S.P.; *Paraff. Dur.*, B.P.; Paraffin, Hard Paraffin.—A purified mixture of solid hydrocarbons. Colorless, or white, more or less translucent mass, with out odor or taste; insol. in water or in alc. Melts at 50° to 57°C., U.S.P.; 50° to 60°C., B.P.

Paraffin for Films (Surgical Paraffin, Plastic Paraffin), N.N.R.—This is the variety used in the treatment of burns. It should melt at or below 50°C. and comply with prescribed criteria of plasticity.

* *Petrolatum* (Petrolat.), U.S.P.; *Paraffinum Molle* (Paraff. Moll.), B.P.; Petrolatum Soft Paraffin (Petroleum Jelly, Vaseline).—A purified mixture of semisolid hydrocarbons obtained from petroleum. An unctuous mass, varying in color from yellowish to light amber, having not more than a slight fluorescence; without odor or taste. Insol. in water; scarcely sol. in cold or hot alc.; freely sol. in fats and fat solvents. Melting-point, 38° to 54°C., U.S.P.; 40° to 46°C., B.P. The color may be specified by adding "*Album*" for white, "*Flavum*" for yellow.

* *Petrolatum Liquidum* (Petrolat. Liq.), U.S.P.; *Paraff. Liq.*, B.P.; Liquid Petrolatum, Liquid Paraffin.—A mixture of liquid hydrocarbons. A colorless, transparent, oily liquid free from fluorescence; odorless; and tasteless when cold; insol. in water or alc. *Dose*, 15 c.c., 4 drachms, U.S.P.; 4 to 16 c.c., 1 to 4 drachms, B.P. *Heavy Liquid Petrolatum* (Heavy Liquid Paraffin, Heavy Mineral Oil) is a very viscous liquid. *Light Liquid Petrolatum* (Light Liquid Paraffin, Light Mineral Oil) is almost free from viscosity.

GLYCERIN

Therapeutic Uses.—This acts both as emollient and demulcent. It is used to soften the skin, to prevent chapping, internally in coughs, etc. Concentrated glycerin abstracts water, so that the soothing action is preceded by smarting. It should therefore be diluted with two or three volumes of water (rose water for lotions). Roth has shown (with Cataplasma Kaolini), that glycerin does not abstract water from the intact skin, because of the impermeability of the stratum corneum.

Undiluted glycerin injected into the rectum causes evacuation in a few minutes, without pain if there are no abrasions (5 to 10 c.c., 1 to 2 ̄; of the official suppository). Similarly, it provokes uterine contractions if introduced into the cervical canal. Large doses (100 to 150 Gm. per day, in divided portions) have been employed to kill intestinal trichinæ.

Pharmaceutic Uses.—Glycerin has many uses in pharmacy, as a vehicle and solvent for salts; sweetening agent; to preserve ferments and vaccines; to keep pill masses or extracts moist, etc. As a sweetening agent in diabetes it has been displaced by saccharin.

Nutrient Value.—Glycerin has been tried as a substitute for cod liver oil. It is transformable into glycogen and sugar; but its nutrient value is rather doubtful, since larger quantities lessen gastric secretion (L. Kast, 1910) and provoke diarrhea. Like other intestinal irritants, it produces increased elimination of uric acid (Abl, 1913).

Toxic Effects.—None have been reported in man, but they occur in animals when large doses are given, by any channel. The symptoms are convulsant and paralytic, probably through a direct action of glycerin on the central nervous system. The blood corpuscles are laked, especially if the glycerin is injected hypodermically. This is probably an osmotic effect, the glycerin remaining for a time unabsorbed, and in high concentration at the place of injection; and the corpuscles being laked during their passage through this area (Filehne).

On muscle-nerve preparations, glycerin acts similarly to veratrine.

Germicidal Action.—Concentrations of 25 per cent. and higher are distinctly disinfectant, the efficiency increasing with the concentration. Undiluted glycerin destroys $\frac{1}{10}$ of the bacteria in 3 hours (Winslow and Holland, 1919).

On the other hand, glycerin hinders the antiseptic efficiency of substances for which it is a better solvent than is protoplasm; for instance thymol, phenol, mercuric chloride, or boric acid.

PREPARATIONS

* *Glycerinum* (Glycerin.), U.S.P.; (*Glycer.*), B.P.; Glycerin, $C_3H_5(OH)_3$.—A liquid obtained by the hydrolysis of vegetable or animal fats, purified by distillation. Clear, colorless liquid, of a thick, syrupy consistence, sweet to the taste. Miscible with water or alc.; insol. in eth., chlorof. or oils. *Dose*, 4 c.c., 1 drachm, U.S.P.; 4 to 8 c.c., 1 to 2 drachms, B.P.

Suppositoria Glycerini (Supp. Glycerin.), U.S.P.; *Supp. Glycer.*, B.P.; Glycerin Suppositories.—Each suppository contains 2.6 Gm. of glycerin, solidified by sodium stearate, U.S.P.; 70 per cent. of glycerin, solidified by gelatin, B.P.

Glycerites are solutions of medicinal substances in glycerin.

DEMULCENTS OR MUCILAGINOUS SUBSTANCES

These comprise gums and other colloid substances, which form viscid solutions with water, and are insoluble in alcohol. They are used to emulsify oils; to suspend insoluble powders; to mitigate the taste and local effects and to delay the absorption of other drugs; and to allay inflammations of mucous membranes, especially in bronchitis, gastritis, enteritis and diarrhea. The effects are strictly local, but in the respiratory passages they are said to extend into the bronchi. Gums and proteins (raw eggs, milk, flour) are employed for their protective action against irritant poisons. They are also precipitant chemic antidotes for metals.

Acacia or gelatin are added to saline injections, to prolong their sojourn in the circulation; see index, "Saline Transfusion."

Mucilages and similar drugs (salep, Irish and Iceland moss) were formerly considered efficient carbohydrate nutrients; but it has been shown that they are very imperfectly digested, and for the most part eliminated unchanged by the feces (Mendel, 1908; Swartz, 1911).

Demulcents as Flavors.—Gums and similar substances markedly diminish the characteristic taste of all substances, acid, salt, and sweet, as well as bitter. They act by enveloping the substance and forming a protective layer over the mucous membrane, and in this way preventing the access of the substance to the taste organs. This, of course, diminishes absorption as well as taste. One can readily convince himself of this "corrective" action by mixing a 1 per cent. solution of citric acid with water and with a thin starch paste. The latter will taste much less sour. Colloid substances of this kind are present in fruits as pectin bodies, and have a marked influence upon their taste. The raspberry, for instance, actually contains more acid than the currant and but little more sugar, its less sour taste being due to the greater amount of these pectin substances present in it.

Anaphylactoid Phenomena on Intravenous Injection.—These are described under Anaphylaxis—see index.

PREPARATIONS

* *Acacia* (Acac.), U.S.P.; *Acaciæ Gummi* (Acac. Gum.), B.P.; (Gum) Acacia (Gum Arabic, Gum Senegal).—The dried, gummy exudation of *Acacia* Senegal, and of other African species of *Acacia*. More or less spheroidal tears, or angular fragments; whitish to light amber colored; translucent; very brittle; nearly inodorous; taste insipid, mucilaginous. Insoluble in alc.; slowly soluble in twice its weight of water, forming a mucilaginous liquid, which is acid to litmus. *Incompatible* with alc., borax or metallic salts.

Mucilago Acaciæ (Mucil. Acac.), U.S.P., B.P.; Mucilage of Acacia.—35 per cent., U.S.P., 40 per cent., B.P., dissolved in cold water, with 0.1 per cent. of sod. benzoate, U.S.P. *Dose*, 15 c.c., 4 drachms, U.S.P., usually diluted with 3 parts of syrup (Syr. Acac. U.S.P. IX contained 10 per cent. of acacia).

Agar, U.S.P.—See index.

Gum. Ind., B.P.—A gummy exudation from the stem of *Anogeissus latifolia*.

Mucil. Gum. Ind., B.P.—25 per cent.

Tragacantha (Trag.), U.S.P., B.P.; Tragacanth.—The dried gummy exudation from the stems of *Astragalus* species. Swells in water to a gelatinous mass, without dissolving. Used in pill excipients, emulsions, etc.

Mucil. Trag., U.S.P., B.P.—6 per cent. in diluted glycerin, U.S.P.; 1.25 per cent. in water, B.P.

Glycer. Trag., B.P.—20 per cent.

Pulv. Trag. Co., B.P.—Tragacanth, Acacia, Starch and Sugar. *Dose*, 0.6 to 4 Gm., 10 to 60 gr., B.P.

DEMULCENT TEAS

Drugs containing mucilages are used as decoctions, ad libitum, mainly in folk medicine.

PREPARATIONS

Agropyron (*Agopyr.*), B.P.; *Triticum*, Couch Grass.—The dried rhizome and roots of *Agropyron repens*.

Ext. Agopyr. Liq., B.P.—*Dose*, 4 to 8 c.c., 1 to 2 drachms, B.P.

Dec. Agopyr., B.P.—5 per cent. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 2 ounces, B.P.

Althæa, U.S.P.; Marsh Mallow Root.—The root of *Althæa officinalis*, deprived of the brown, corky layer and small roots.

Amygdala Dulcis (*Amygd. Dulc.*), B.P.; Sweet Almond.—The ripe seeds of *Prunus Amygdalus dulcis*.

Emul. Amygd., (Milk of Almond).—An emulsion made by rubbing 6 parts of blanched sweet almonds with 1 part of acacia, 3 parts of sugar, and enough water to make 100 parts.

Mist. Amygd., B.P.—12.5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Pulv. Amygd. Co., B.P.—Sweet Almond, Sugar and Gum Acacia.

Cetraria; Iceland Moss, a Lichen.—A gelatinous decoction (1:20) is prepared after previous extraction with cold water, to remove a bitter principle.

Chondrus, (Irish Moss, Carrageen).—The dried plant of the seaweeds *Chondrus crispus* and *Gigartina mamilliosa*. Yields a demulcent jelly with boiling water.

Cydonium.—Quince Seed.

Ispaghula, B.P.—Dried seeds of *Plantago ovata*. *Dose*, 3 to 10 Gm., 45 to 150 gr., B.P.

Dec. Ispagh., B.P.—1.5 per cent. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 2 ounces, B.P.

Salep.—The tubers of an orchid.

Sassafras Medulla.—Sassafras Pith.

Ulmus, U.S.P.; Elm (Slippery Elm).—The inner bark of *Ulmus fulva*.

GELATIN

Uses.—This is employed in pharmacy as a coating for pills, for making gelatin capsules, etc., and in the form of glycerinated gelatin as a base for suppositories. In the form of soups and jellies it is used as a nutrient, being easily digested and capable of replacing from one-fourth to two-thirds of the protein of an ordinary diet, especially if the carbohydrates are ample (Murlin, 1907). Subcutaneous injections of gelatin have been given to increase the coagulability of the blood, especially in aneurism. They are probably ineffective and have the serious objections of severe pain and danger of infection, since ordinary gelatin solutions are often not sterile, and may even carry tetanus.

Gelatin as Styptic.—The efficiency of gelatin is affirmed by some and denied by others. Burton-Opitz, 1906, found that it increased the viscosity of the blood on intravenous injection. Cmunt, 1912, claims the same effect hypodermically. Dastre and Floresco, 1897, and Grau, 1910, describe increased coagulability of the blood, lasting for several days. Zibell, 1901, and others are inclined to attribute the action to Ca, of which gelatin contains about 0.6 per cent. The contradictory data have not been explained. The gelatin was originally used subcutaneously (100 to 200 c.c. of sterile 1 to 5 per cent. solution, injected slowly into the thigh, *not* near the aneurism, every ten to fifteen days, until 10 to 20 injections have been given). The treatment is quite painful, and may raise the temperature to 103°F. Wood (1902) claims that the gelatin is just as effective, only somewhat slower, when given by mouth, and recommends eating 3 or 4 ounces of flavored 10 per cent. jelly, three times a day.

PREPARATIONS

Gelatinum (Gelat.), U.S.P., B.P.; Gelatin.—The purified, air-dried product obtained by the hydrolysis of animal tissues, as skin, ligaments, and bones, by treatment with boiling water. Insol. in cold water, but swells and softens when immersed in it, gradually absorbing from five to ten times its own weight of water; sol. in hot water, acetic acid or glycerin; insol. in alc. Watery solutions of 2 per cent. or over solidify on cooling. Precipitated by phenol or tannin; not by dilute solutions of metallic salts.

Gelatinum Glycerinatum (Gelat. Glycerin.), U.S.P.—Equal parts of gelatin and of glycerin. Used for making bougies, etc.

STARCH

Uses.—Dry starch is used as a dusting powder. By boiling with water, starch is converted to a colloid condition, starch-paste. This is used as an emollient, in the form of the glycerite; in poultices; and to secure the retention of enemas (teaspoonful, rubbed smooth with a little cold water and poured into a cup of boiling water). It is a chemical antidote to iodine. It is also employed as a nutrient, especially as "*arrow-root*," the starch of *Maranta*, which has a somewhat finer flavor than the official corn starch.

Barley-water is used as a demulcent decoction; and as a protective colloid in diluting cow's milk for infants, to prevent the precipitation of solid masses of casein in the stomach. It is prepared by boiling for twenty minutes 10 parts of washed pearl barley with 150 parts of water and straining. (B.P.C.)

PREPARATIONS

* *Amylum*, U.S.P., B.P.; Starch.—Prepared from maize, U.S.P.; from wheat, rice or maize, B.P.

Glycer. Amyl., U.S.P.—10 per cent. of starch.

Glycerin. Amyli, B.P.—20 per cent. of starch.

INDIFFERENT DUSTING POWDERS—ABSORBENTS

Very fine ("impalpable"), insoluble, non-irritant powders, such as talcum, chalk, starch, lycopodium, etc., are used as dusting powders to protect the skin, wounds and mucosæ. They form a protective covering, prevent friction, absorb secretions by capillary action, and are therefore drying. The insoluble bismuth salts also act largely in this manner.

The bismuth salts, chalk, kaolin (clay, bole), fullers' earth and charcoal are used internally for similar protective effects, against gastrointestinal irritation.

The efficiency of the dusting powders is partly mechanical, as has been explained, and partly through adsorption. By condensing dissolved or suspended substances on their large surface, they diminish their concentration in the solution and their absorption. This weakens the action of chemical agents, including bacterial products. At the same time, the drying renders the medium unsuitable for bacterial growth and so diminishes infection.

Face Powders.—The application of indifferent powders protects the skin against the irritation of sun and wind. The usual ingredients of the light powders are starch; of the heavy powders, barium sulphate and talcum. They are generally indifferent, but they tend to obstruct the ducts of the skin-glands, and so may themselves become irritants. Some powders contain zinc oxide, bismuth subcarbonate and even lead carbonate. The latter especially is directly harmful. *Rouge* consists mainly of zinc oxide and chalk, with more or less starch. The presence of aniline dyes and perfumes in powders and other cosmetic preparations are sometimes responsible for severe dermatitis (Cole, 1924; H. E. Miller and Taussig, 1925).

Charcoal against Indigestion and Flatulence.—Freshly heated charcoal adsorbs gases. This presumably led to its use against flatulence and heartburn. It is unsuccessful, for charcoal can not adsorb free gases when it is moistened.

Wood charcoal, which is generally used, is slightly alkaline, and this may account for what little efficiency it may possess. However, it would

be a wasteful and inadequate means of introducing alkali, since 1 Gm. neutralizes only about 5.5 c.c. of N/10 acid, and is therefore equivalent to about 42 mg. ($\frac{2}{3}$ grain) of sodium bicarbonate.

Absorbents in Diarrhea.—Bolus alba (Kaolin), fullers' earth, bone-black (carbo animalis), and tripoli (silica) check watery diarrheas and dysentery. In acute bacterial dysentery, large doses are given, 30 to 45 Gm. three times daily, stirred into hot tea (after a preliminary cleansing by calomel). Smaller doses suffice in chronic dysentery (Stumpf, 1914; Stoerk, 1915). However large or continued doses are apt to lead to dangerous accumulation of the absorbent in the intestines. Bone-black appears to be less subject to this than the heavier kaolin.

The anti-diarrheal effects are explained by the more solid consistence of the stools; by the checking of bacterial growth; and by the adsorption of the irritant putrefactive products (Kraus and Barbara, 1915). It has been reported that adsorbents restrain somewhat the activity of digestive ferments (Strauss, 1916; Petersen, 1917); but this is probably unimportant.

Water Absorbing Power.—This is important when dusting powders are used for drying. Sollmann, 1919, found it to range from 70 to 80 per cent. for fullers' earth, kaolin and starch; and from 53 to 65 per cent. for chalk and talcum.

Adsorption of Toxins and Antitoxins.—Diphtheria toxin and antitoxin are both adsorbed by animal charcoal; not by kaolin, talcum, kieselguhr or wood charcoal. This does not apply to other toxins and antitoxins. Tetanus toxin, for instance, is adsorbed by all the above agents (Jacque and Zunz, 1909; Zunz, 1913). In general, Gram-positive bacteria are adsorbed much more effectively than the Gram-negative (Eisenberg, quoted from Clark).

Diphtheria Carriers.—The application of dry kaolin to the nose and throat is being tried, with apparent success, to remove the bacteria of diphtheria carriers (Rappaport, 1916).

Charcoal as Antidote.—Many alkaloidal salts are quite effectively adsorbed by charcoal. This may slow their adsorption sufficiently to prevent toxic effects (Wicshowiki). However, only active charcoal (bone black or mineral charcoal) can be successful, and this is not always available (Joachimglu, 1922).

The protective adsorption of alkaloids and organic bases has been studied by Löffler and Spiro, 1920.

Colloidal carbon (caramel) is harmless, even on intravenous injection. It antagonizes alkaloids (strychnine) when mixed *in vitro*, and even somewhat when the strychnine is given by mouth, and the carbon by vein; but this antagonism is too uncertain for practical application (Sabbatani, 1913 and 1914).

Decolorization by Charcoal.—This is used to decolorize solutions. Different specimens vary greatly in activity. Tested by methylene blue, blood charcoal is generally the most active, but mineral charcoal may be more active than blood charcoal. Graphite and lampblack are almost inactive (Koltoff, 1919). Wood charcoal prepared from nut-shells is highly active; ordinary wood charcoal is poor.

Clarification.—Talcum and kieselguhr are used to clarify turbid mixtures.

Selective Adsorption.—The affinity of adsorbents varies for different substances. In general, it is most effective for colloids of the opposite electric charge. The following give an idea of the selective phenomena (Koltoff, 1919).

Adsorbent	Charcoal (blood)	Kaolin, talc	Silica	Alumina
Alkaloids.....		+	o	+
Basic Dyes (Congo).....		+	o	+
Acid Dyes (Methylene Blue).....	+	+	+	o
Iodine.....	+	o	o	o
Bacteria.....				+

Adsorption of Gases by Charcoal.—This increases with the pressure and decreases with the temperature. Gases of high temperature of liquefaction are generally better adsorbed. At 20°, active blood charcoal adsorbs about 7 volumes of hydrogen, 25 volumes of nitrogen, oxygen or carbon monoxide; 40 volumes of methane; 85 volumes of carbon dioxide; 200 volumes of ammonia or hydrogen sulphide (quoted from Bancroft).

Protection against Chemical Irritants.—The adsorbent powders protect the respiratory passages against irritant "gases;" also the skin (Sollmann, 1919).

Intravenous Injection of Colloidal Powders.—These tend to produce allergic shock. Kaolin is hemolytic when added directly to the blood (Friedberger and Tsumeoka, 1913). Colloidal silicic acid is discussed in the next section.

PREPARATIONS

Carbo Animalis.—Bone Black.—Used against dysentery, in dosage of 30 grams. Animal charcoal is preferred for this large dose, because the sharp particles of the vegetable charcoal might be irritant (Lichtwitz, 1914).

Carbo Ligni (Carb. Lig.), U.S.P., B.P.; Wood Charcoal.—Black, tasteless and odorless, very fine powder. *Dose*, 1 Gm., 15 gr., U.S.P., to 4 Gm., 60 gr.

Kaolinum, B.P.; Kaolin.—Native aluminum silicate (china clay; bolus alba), powdered and freed from gritty particles by elutriation.

Cataplasma Kaolini, N.F.—Essentially a thick mass formed of about 2 parts of kaolin and 1 part of glycerin, together with a little boric acid (4.5 per cent.) and flavoring oils. It is spread hot in a thick layer and left in place for twelve to forty-eight hours.

Lycopodium (Lycopod.), U.S.P.; Lycopodium.—The spores of *Lycopodium clavatum*. A light yellow, very mobile powder, nearly inodorous and tasteless. Insoluble in water.

* **Talcum Purificatum** (Talc. Purif.), U.S.P.; Purified Talcum.—A purified, native, hydrous magnesium silicate. A fine, white or grayish-white powder; odorless and tasteless. Insol. in water and dilute acids or alkalies.

Terra Silicea Purificata (Ter. Sil. Purif.), U.S.P. (Purified Kieselguhr, Purified Infusorial Earth).—A form of silica (SiO_2) consisting of the frustules and fragments of diatoms, purified by boiling with diluted hydrochloric acid, washing and calcining.

POULTICE MASSES

Poultices or cataplasms are used to convey heat, and to macerate the skin. A variety of pasty materials may be employed. The most common are linseed, starch, bread and clay. *Linseed poultice* is prepared by stirring 1 part of ground linseed into 3 parts of boiling water, to which a little baking soda may be added, to render it fluffy and less irritant. Clay or kaolin poultice is much heavier, but can be sterilized if desired. The rate of cooling of different poultice masses has been investigated by Pilcher, 1908. They do not differ materially. Whole linseed may be made into a demulcent decoction against bronchitis.

PREPARATIONS

* **Linum**, U.S.P.; **Lini Sem.**, B.P.; **Lini Sem. Contus.** (crushed or ground, "meal"), B.P.; Linseed, Flaxseed.—The ripe seeds of *Linum usitatissimum*.

PLASTERS

These serve for protection against irritation, for mechanical support; and for the slow conveyance of drugs to or through the skin. They are somewhat irritant, partly by preventing evaporation from the skin, and partly by the small quantities of volatile oils contained in the resins from which they are often prepared. The official plaster-masses are unimportant, since the commercial plasters are usually made by private formulas from some rubber mixture. "Court plaster" is made of isinglass (*Ichthyocola*), a variety of gelatin prepared from the swimming bladder of the sturgeon.

PREPARATIONS

Emplastrum Adhæsivum (Emp. Adhæs.), U.S.P.; Adhesive Plaster.—A mixture of rubber, resins, waxes and an absorbent powder (starch, zinc oxide, etc.), spread on cloth.

Emplastrum Resinae, B.P.; Rosin Adhesive Plaster.—Lead plaster with rosin and yellow wax, U.S.P.; hard soap instead of wax, B.P.

Emplastrum Plumbi Oleatis (Emp. Plumb. Oleat.), U.S.P.; *Emplastrum Plumbi*, B.P.; Lead Oleate Plaster, Lead Plaster (Diachylon Plaster).—A soap made by boiling lead oxide with olive oil and lard, U.S.P.; with olive oil, B.P.

Emp. Saponis (Emp. Sap.), B.P.; Soap Plaster.—Similar to preceding, with greater proportion of soap.

MECHANICAL PROTECTIVES

Certain substances which are used for this purpose may be mentioned in this place.

PREPARATIONS

**Collodium* (Collod.), U.S.P.; Collodion.—A 4 per cent. solution, U.S.P., 2.1 per cent. B.P., of Pyroxylin (gun-cotton) in a mixture of 3 vol. of ether and 1 vol. of alc. Should be kept in a cool place remote from fire. Clear or slightly opalescent, syrupy liquid; colorless, or slightly yellowish and having the odor of ether. Highly inflammable. Collodion dries rapidly into a firm film, which is used to protect small wounds. The film cracks easily and contracts considerably, exerting pressure on the tissues. Similar solutions may be prepared with acetone or other solvents.

**Collodium Flexile* (Collod. Flex.), U.S.P., B.P.; Flexible Collodion.—Collodion rendered flexible by the addition of a little Castor Oil and Camphor, U.S.P.; Castor Oil and Canada Turpentine, B.P. It does not contract or crack, but does not adhere quite so well.

Pyroxylinum (Pyroxylin), U.S.P., B.P.; Pyroxylin (Soluble Gun-cotton).—Obtained by acting on cotton with a mixture of nitric and sulphuric acids. Consists chiefly of cellulose tetranitrate, $C_{12}H_{10}O_8(NO_2)_4$. Slowly sol. in 25 parts of a mixture of 3 vol. of ether and 1 vol. of alc. (equal vol. of 90 per cent. alc. and eth., B.P.); sol. in acetone. *Celloidin*, N.N.R., is a purified form. Ordinary gun-cotton is a hexanitrate.

Gossypium Purificatum (Gossyp. Purif.), U.S.P.; (Gossyp.), B.P.; Purified (Absorbent) Cotton.—The hairs of the seed of *Gossypium herbaceum* freed from adhering impurities and deprived of fatty matter (so as to make it absorbent) and often sterilized. Consists of almost pure cellulose ($C_6H_{10}O_5$). Used in bandaging, etc., either as such, or as gauze (Tela, Carbasus), lint (Lintum), etc., or impregnated with antiseptics, astringents, etc.

Calcii Sulphas Exsiccatus (Plaster of Paris, Burnt Gypsum), $CaSO_4 + \frac{1}{2}H_2O$.—A fine white powder, which sets into a stone-like mass when mixed with half its weight of water. Used in bandaging. The "setting" takes place in fifteen to twenty minutes. It may be delayed to an hour by the addition of 5 per cent. of glycerin, or hastened by the addition of sodium silicate. Plaster of Paris must be kept dry.

Liquor Sodii Silicatis (Waterglass).—A colorless syrupy liquid, of alkaline properties, but not corrosive. Contains about 20 per cent. of sodium silicate. Forms a solid glassy mass on exposure. Used in bandaging.

Actions of Sodium Silicate.—When given by the mouth or skin, this acts like a typical mild alkali without showing any specific features. It is readily absorbed from the alimentary canal, and excreted by the urine. Injected intravenously it causes agglutination of blood corpuscles, and consequently intravascular clotting.

Silicates are normally present in all tissues, but in very small amount (Siegfried, 1901). There is no evidence that they play any physiologic rôle. Silica is also constantly present in hairs and feathers (H. Schulz, 1901). It constitutes up to 77 per cent. of the total ash of the feathers of the dove (Gonnermann, 1918).

Colloidal Silicic Acid.—Intravenous injection of large doses (150 mg. of SiO_2 per rabbit) produces death within 3 to 5 minutes, by intravascular coagulation. With sublethal doses, the coagulation of shed blood is accelerated; but the addition of silicic acid, *in vitro*, does not alter the coagulation time of normal blood.

With injections of 40 to 60 mg. death occurs after 3 to 5 days. The tissues show marked degeneration of the vascular endothelium and focal necrosis of the parenchymal cells, especially in the liver and kidneys. The daily injection of 5 mg. is well tolerated, but in the course of several months it leads to extensive fibrosis, especially in the liver and kidneys (Gye and Purdy, 1922, 1924).

Colloidal silicic acid has been tried in tuberculosis including experimental tuberculosis in guinea pigs, with alleged beneficial effects (Messner, 1922, Kahle, 1921). However, it failed to establish itself clinically.

PHENOMENA COMMON TO LOCAL IRRITANTS, CORROSIVES AND ASTRINGENTS

Uniformity of Irritant Phenomena.—The local actions of drugs are, as a rule, simple and uniform, since they occur ordinarily in only a few situations, especially the skin and mucous membranes. These agree closely in structure and functions. There are therefore many phenomena which hold true of all local irritant poisons. These may be studied once for all, and present only minor modifications in individual cases.

Chemical Basis of Irritation.—The majority of local poisons produce the typical phenomena of inflammation ("irritation"), by causing necrosis of protoplasm through coagulation, liquefaction, etc. Many of these reactions are purely chemic or physical, and can be reproduced in the test-tube with proteins. Remembering the extreme sensitiveness of protoplasm to reagents, it will be readily understood that almost all substances—even water—may be irritant under suitable conditions.

Degrees of Cutaneous Irritation.—The general phenomena of irritation can be studied very typically on the skin. They are identical with the familiar changes produced by scalds or burns of increasing severity.

Rubefaction.—The first degree of irritant action is shown in an arterial and capillary hyperemia, at first active, later passive. This constitutes the "dermatitis erythematosa" of the dermatologists. Speaking pharmacologically, it constitutes rubefaction, and the agents which produce it are therefore called *rubefacients*. The dilation involves at first the most superficial vessels, but progressively also those of the deeper subcutaneous tissue, partly directly and partly by reflexes.

The congestion is accompanied by sensory stimulation—by itching, burning or pain. This is often succeeded by more or less anesthesia.

If the irritant action does not go any further, resolution takes place without leaving any lesions, simply by a return of the vessels to normal. The pain may outlast the congestion. The upper layers of the skin are usually desquamated.

If the action is stronger than rubefaction, it may pass into vesication or pustulation.

Inflammatory Edema.—Increased permeability of the vessels is one of the early phenomena of acute inflammation. It may result in edema.

The *permeability to dissolved substances* is also increased. For instance, when trypan is injected by vein, it appears much more abundantly in the aqueous humour of an inflamed, than of a normal eye (P. A. Lewis, 1916).

Urticaria.—Localized edema of the corium is a rather special mild inflammatory reaction to many drugs, particularly in susceptible individuals. It may occur on systemic administration, or more readily by application to the scarified skin. It is not utilized therapeutically. The more important drugs producing this effect are: morphine and its esters; histamine and peptone. Milder grades occur with atropine, cocaine, formaldehyde, urea and many amines (Sollmann and Pilcher, 1917; Sollmann, 1917).

Vesication.—This occurs if the inflammatory action results in the formation of an exudate greater in amount than can be carried off by the lymphatics. Every hyperemia is accompanied by an increase of exudation, but up to a certain amount, as in rubefaction, this is readily

reabsorbed. When this limit is exceeded, an actual, visible effusion results. The liquid accumulates in the parts of the tissues offering the least resistance to distention. In the case of the skin, it penetrates readily through the lower layers of the rete Malpighii, but is arrested by the impermeable stratum corneum. It is therefore confined between the upper and lower layers of the rete Malpighii, and separates them, in this way causing blisters or vesicles. The agents which produce these are called *vesicants* or *epispastics*.

The vesicles appear as small points which gradually coalesce into a large blister. The fluid is at first clear, but later becomes turbid by leucocytes. The sensory stimulation is stronger than in rubefaction.

Resolution takes place in these cases without loss of tissue by the formation of a new stratum corneum from the remaining rete Malpighii. The area may remain pigmented for years.

If the overlying and separated layers of epidermis are removed, infection may easily occur, the lower layers of the rete Malpighii offering but little resistance. In this way there may be a loss of substance from secondary infection.

If the vesicant is allowed to act after the blister has been formed, the infiltration becomes purulent, with deeper destruction of the skin, and healing with scar formation. This degree of action should be avoided.

Pustulation.—This occurs if the irritant does not penetrate the epidermis, but only the cutaneous glands, especially if the acid secretion of these glands dissolves or liberates the irritant agent. Discrete and later confluent pustules are formed, which heal with more or less "pitting." They produce severe sensory irritation, but are now rarely used. The principal pustulants are croton oil and tartar emetic.

Aseptic Pus Formation.—A few drugs possess a specific chemotactic power on leucocytes; so that their injection (hypodermic or into serous cavities) leads to the collection of pus, even when sepsis is perfect. Turpentine, croton oil, petroleum, mercury, silver nitrate, digitoxin, cadaverine, aleuron suspensions, etc., are the principal examples. Turpentine also stimulates the chemotactic action of *B. coli* extracts (Hamburger, 1913).

Influence of Systemic Conditions on Cutaneous Irritation.—Luitlén, 1911, found that the local reaction to croton oil is increased by feeding with acids or oxalates and diminished by calcium. Different diets also modify the susceptibility. These systemic influences may be connected with the great variations in the susceptibility of different individuals to cutaneous irritants; and with such skin diseases as eczema, which do not seem to be explainable by local irritation. There are also, however, local differences in susceptibility, and if an irritative reaction has once been induced, the skin remains hypersensitive for some time.

Dermatitis from Systemic Drugs.—Many drugs cause a *dermatitis* when they are given by mouth (belladonna, arsenic, iodoform, quinine, salicin, antipyretics, iodides and bromides, digitalis, chloral, chloroform, etc.). This is sometimes due to changes in the cutaneous circulation, sometimes to the excretion of the drug by the skin, and often to allergic hypersusceptibility. It may take the form of scarlatinal, desquamating urticarial or papular rashes or acne.

The most common sources of drug eruption may be grouped, according to M. MacComar, as follows:

Erythematous or Polymorphic Eruption.—Antipyrine, arsenic (including arsphenamine), benzoic acid, boric acid, bromides, copaiba, chloral, iodide, morphine, quinine, salicylates.

Scarlatiniform Rashes.—Antipyrine, atropine, benzoate, belladonna, chloral, iodoform, ipecac, mercury, salicylates, sulfonal.

Urticaria.—Benzoate, copaiba, cubebs, iodide, quinine, salicylates, valerian.

Purpura.—Antitoxin, arsenic, chloral, copaiba, cubebs, iodide, mercury, quinine, sulfonal.

Morbilliform Eruptions.—Antipyrine, antitoxin, belladonna, copaiba, cubebs, mercury, opium.

Chronic eczema does not result from the internal administration of drugs.

Corrosion, cauterization, or direct destruction of tissue occurs if the agent (cauterizant or escharotic) acts chemically on the protoplasm, as do strong acids or alkalies, iodine, or bromine, some metallic salts, etc. This leads to the production of a scab or "eschar," and resolution by scar formation.

Areas of Corrosion.—The chemic destruction of tissue is generally preceded by inflammatory necrosis. Chemic cauterization therefore shows three areas: The first, situated at the depth and periphery of the ulcer, is an area of simple inflammation and hyperemia. Then follows a layer of necrotic tissue, the result of the inflammatory action; and last, a layer in which the chemic cauterization results in solution of the cells which have already been killed by the inflammatory process. These three—hyperemia, inflammatory necrosis, and chemic solution—are to be considered as successive stages in the same action; and by proper dilution, the second or first degree of action may be obtained without the succeeding stages.

The Eschar.—This (scab) is formed after corrosion by the coagulation of the inflammatory exudate and by the chemical products (albuminates, etc.) of the interaction of the corrosive agent with this exudate and with the killed cells. According to whether the proteins are dissolved (as by alkalies) or precipitated (as by most metals), the scab may be soft or hard. This has an important bearing on the penetration of the corrosive agent: if the scab is soft, the chemical will penetrate it, and spread and extend deeply. On this account the alkalies are not manageable for the purpose of cauterization. If, on the other hand, the scab is solid, it prevents deeper penetration, so that the action can be easily confined to the desired areas.

Astringent Action.—Agents which have a strong precipitant action produce a relatively mild irritation; and if their concentration is not too high, their primary inflammatory effect does not proceed to necrosis; on the contrary, it leads to diminution of any existing inflammatory process. This "astringent" (drawing together) action is characterized by visible contraction of the tissue; blanching and wrinkling of mucous membranes; and diminished exudation, or secretion of mucus, according to the place of application. These agents also possess a peculiar "astringent" taste. The effects are probably due to precipitation and hardening of the cell-surface and cement substance of the capillary endothelium, producing contraction and decreasing the permeability of the capillaries; and thus counteracting the essential phenomena of inflammation (congestion and exudation).

The blanching and puckering (produced only by the more concentrated solutions) is due to the coagulation analogous to cooking.

Astringents are used therapeutically to check diarrhea, reduce inflammation of mucous membranes, promote healing, and to arrest hemorrhage (by coagulating the blood).

The principal astringents are: metallic salts, tannins, dilute acids, and strongly hypertonic solutions.

Quantitative Estimation of Astringent Action.—This has been measured by Motolese, 1910, by noting the degree in which the extensibility of frogs' lungs is reduced after immersion in the astringent solution (Dreser's method). With 1 per cent. solutions, the order was: silver nitrate > tannin > lead subacetate > picric acid > lead acetate > alum > zinc sulphate.

Astringency may also be studied by the suppression of mucus secretion from the frog's skin (Schuetz); and more simply by the tanning of blood corpuscles or even by quantitative precipitation of proteins (Sollmann, 1920).

Astringent Effects are Strictly Local.—Since astringents are precipitated by proteins, they can not be absorbed nor exist in the blood or tissues, in effective form. It is therefore *irrational to expect a remote action from astringents*. The very facts of their action exclude such a possibility. Before this was well understood it was attempted to obtain astringent action throughout the body by external application or by giving astringents by the mouth. The want of success confirmed what has just been said.

Astringents on Peristalsis.—In the *intestinal canal* the astringents form a deposit along the lumen of the intestine, and diminish absorption, and the penetration of other irritant substances, and lessen peristalsis.

Irritation of Mucous Membrane.—Differences in detail are seen when irritants are applied to other surfaces than the skin; for instance, to the mucous membranes. These are explained by the anatomic peculiarities. There will, for instance, be less tendency to vesication, since the epithelium is not impermeable, as it is in the skin. The oral mucous membrane presents a transition; it blisters, but less readily than the skin. Pustulation can not occur since this depends upon the cutaneous glands. On the other hand, the mucous glands will be stimulated to an increased activity, producing "*catarrhal*" conditions.

Gastroenteritis.—The actions of irritants on the alimentary tract present some special features; the effects being stomachic, carminative, nauseant or emetic; diarrhea, dysentery; abortion; corrosion and perforation; according to the nature and degree of their action.

Respiratory Passages.—If an irritant poison is *volatile*, its main effects may fall upon the *respiratory passages*. The general phenomena are those of acute laryngitis, bronchitis, or pneumonitis. Similar effects follow the aspiration of non-volatile irritants.

Local Irritation of Wounds and Ulcers.—The effects are usually more marked than on the intact skin. Even the milder irritants destroy the superficial cells, especially if diseased; but the deeper cells multiply more rapidly, partly through direct stimulation and partly through the hyperemia. Mild irritants therefore *promote healing*. Astringents, balsams, quinine, salts and even water have this therapeutic action.

Hypodermic Injection of Irritants.—These produce more or less pain, and often aseptic abscesses or fibrosis. The danger of infection is also considerable if the tissues are killed by the irritant. With intramuscular injection, the pain is less severe.

Antiseptic Action.—All irritants are somewhat antiseptic for they destroy the protoplasm of the bacteria just as they do that of the tissue cells.

Concentration.—The degree of the local action depends usually upon the concentration, rather than on the absolute quantity of the irritant.

A small quantity of concentrated acid will do much more damage than much larger quantities diluted; just as a gram of MgSO_4 in solid form introduced into a solution may precipitate all its globulin, while an unlimited quantity may be added in 5 per cent. solution, without any such effect.

Specific Differences between the Different Irritants.—These concern the strength of their action in different situations. Some, for instance, act especially on the alimentary canal, and to a very small extent on the skin. This is probably connected with differences of absorbability. A drug which can not penetrate the skin, can not, of course, act upon it. It will be remembered that the epidermis is impermeable to many substances. In order to penetrate, the irritants must be either fat soluble like

croton oil or turpentine; or they must actually destroy the epidermis, like caustics.

Irritant Effects after Absorption.—None of the irritants acts indiscriminately on the body at large. Many are not absorbed; and even when absorption occurs they are too greatly diluted to have much effect, except at the place of their absorption and excretion; *i.e.*, the liver and kidneys. Other tissues are involved only if the administration is long-continued, as in alcohol or lead poisoning. Such chronic intoxications lead to increase of connective tissue, arteriosclerosis, cirrhosis, etc.

Drug Nephritis.—These are produced by all absorbable irritants and often occur acutely. The inflammation may involve all the renal tissues; or it may be predominantly glomerular or parenchymatous, according to the poison. Continued administration leads to interstitial nephritis.

Phenomena.—The inflammation is characterized by albuminuria, casts, and the histologic lesions. The urine flow is increased in the early stages, and decreased later (Schlayer and Hedinger, 1907). The excretory efficiency is diminished (Eisenbrey, 1911, 1913), as estimated by the phenolsulphonephthalein test of Geraghty and Rowntree, 1911. The changes in nitrogen and chloride excretions are complex (Austin and Eisenbrey, 1911). The nitrogen excretion is decreased in tubular nephritis (uranium), not in glomerular (arsenic). Retention of nitrogen in the blood occurs, especially in tubular nephritis (Foster, 1915). Renal glycosuria may occur (E. Franck, 1913; Pollak, 1911); also hepatic edema (Opie, 1912), and sometimes slight myocardial changes (Walker, 1911). Hemorrhagic nephritis is seen with cantharides, turpentine, formaldehyde, etc. Edema occurs only with uranium, at least in animals. The restoration of the blood-volume after saline injections is delayed in uranium, chromate and tartrate nephritis (Bogart, Underhill & Mendel, 1916; Boycott, 1913 and 1914; Chisholm, 1914).

Experimental Nephritis.—These have been extensively investigated (bibliography in R. M. Pearce, 1910).

Tubular nephritis with little or no primary glomerular injury is produced by uranium, chromate, mercuric chloride and aloin. The anatomic changes in the early stages of uranium and chromate nephritis are confined essentially to the tubules, especially the convoluted; they consist of granular and fatty degeneration and necrosis. Mercury acts similarly but mainly on the ascending loops of Henle, with deposition of lime salts. The glomeruli are at first unaffected but later show thickening of the capillary walls, and vascular disturbances can be shown by physiologic methods.

Glomerular Nephritis.—This, generally with some secondary involvement of the tubules, is produced by arsenic, cantharides and snake venom. Diphtheria toxin acts on all the structures; and many other irritants act diffusely. The anatomic changes vary according to the poisons. Arsenic produces little or no anatomic change, except dilatation of the capillary tufts, filling Bowman's capsules. Physiologic methods, however, show serious vascular injury. The cantharides changes involve both the glomerular tufts and space. The capsules are filled with desquamated cells, whose origin is disputed. There is also functional vascular injury. The functional changes are not proportional to the anatomic.

Chronic Nephritis.—This is difficult to produce experimentally, the acute experimental lesions usually ending in rapid and complete recovery. Positive results have been obtained by Ophüls with lead, by Dickson with uranium, and by Klotz, 1914, with infections.

Reflex Effects of Irritants.—Stimulation of sensory areas acts reflexly on the vasomotor, cardiac, respiratory and other centers, producing changes in the circulation, respiration and other functions. These vary according to the place, extent, speed, intensity and kind of the stimulation. As "counterirritation" they are used extensively in therapeutics.

The Respiratory Reflexes.—These are of special therapeutic importance. They differ according to the state of the center: if the respiratory center is depressed, as in collapse, morphine poisoning, anesthesia, asphyxia, etc., moderate counterirritation produces marked stimulation; and if the collapse is not too deep, natural respiration may be restored (Meissner, 1923; Hanzlik, 1923).

If the respiration is normal, mild cutaneous irritation may either slow or quicken the rate. If the irritation is strong, the respiration is always slowed. Sudden and extensive stimulation, as by cold douches, produces momentary standstill, followed by deep inspirations.

Hanzlik, 1923, has utilized the respiratory response as an index of local irritation.

Consciousness.—This is also often revived by counterirritation, *f.i.*, in fainting or light coma. The usual measures for this purpose are dashing with cold water, slapping with wet towels, or inhalation of dilute ammonia vapor (smelling salts or aromatic ammonia).

Circulation.—Local irritation gives rise to augmentory and inhibitory vasomotor and cardiac reflexes, which vary with the degree, the kind, and the site of the irritation, and with the state of the centers. The application of heat to the skin causes general vasodilatation of the skin, whilst cold results in constriction. *Mild tactile stimulation* (for instance blowing on the skin) also tends to produce widespread vasoconstriction and therefore some rise of blood pressure (Gruetzner and Heidenhain, 1877). The vasoconstriction involves mainly the cutaneous vessels, except those which are dilated by direct contact with the irritant. The renal vessels are also constricted, while those of the brain are dilated (Wertheimer; Roy and Sherrington). The cutaneous vasoconstriction tends to raise the internal temperature. The heart rate is quickened (Naumann). The tactile and auditory constrictor reflex occurs only if the brain is intact, *i.e.* it requires psychic stimulation, the heat and cold reflexes persist after decerebration.

Stimulation of sensory nerves, if weak or slow, i.e. of the kind to evoke reflexes of the voluntary muscles, tends to produce vasodilatation and fall of blood pressure. This is seen most typically in the depressor nerve. It involves inhibition of the vasoconstrictor tone, stimulation of the vasodilator innervation, and stimulation of the cardiac inhibitory center (Bayliss, 1908).

Strong stimulation of sensory nerves produces vasoconstriction and rise of blood-pressure, increasing with the intensity of the stimulation, which must be 20 to 200 times that which suffices for the depressor response (Stiles and Martin, 1915). This is also the primary response of *pain*.

Reflex Shock.—If the strong stimulation is prolonged and especially if the subject is conscious, the rise of pressure is followed by fall of blood pressure and of internal temperature. This occurs especially if there is violent pain, and in connection with extensive corrosion. Different mechanisms may be concerned. The heart may go into fibrillation by disturbance of conduction, the response of the vasomotor centers may be inverted by the psychic impulses or by exhaustion; and in corrosion, toxic shock may develop by the absorption of the proteolytic products.

The literature of vasometer reflexes is discussed by Ransom, 1921.

Hypodermic Injection of Mild Irritants.—The injection of ether, camphor, whiskey or oil of turpentine generally produces a slight and transient rise of blood pressure; the effect differing quantitatively according to the site of the injection, being, for instance, greatest from the nasal septum. The effect fails when the vasomotor center is depressed, as in deep anesthesia, shock or hemorrhage (Lieb and Herrick, 1917).

Gastro-intestinal Irritation.—Sollmann, Brown and Willams (1907) have shown that irritation of the stomach or peritoneum has practically no effect on the blood pressure in anesthetized animals, even when the anesthesia is light. There is generally a marked increase of respiration, and sometimes a slight and momentary rise of blood pressure, but no fall is noticed for several hours. This holds true both for mild irritants,

such as peppermint, mustard or moderate heat; and for strong corrosion by formaldehyde, concentrated acids, or actual cautery, even when these measures produce perforation.

Irritation of the Mouth and Larynx.—This produces very much more marked effects (Sollmann); even contact with 5 per cent. acetic acid causes struggling, convulsive rise of blood pressure and dyspneic respiration.

Volatile Irritants on Blood Pressure.—The vapors of strong smelling substances, when applied to the nose of rabbits, raise the blood pressure; but lower it when applied to the trachea. Both effects are reflex (Yamada, 1920).

Metabolism.—Mild stimulation of extensive skin areas (salt-water baths) increase metabolism. Paalzow found increased oxygen consumption and carbon dioxide excretion on applying sinapism to animals; Zuntz and others have demonstrated increased nitrogen excretion.

Counterirritation.—Irritation of the skin may relieve inflammation in deeper seated structures, diminishing the pain and probably the congestion, and perhaps leading to an earlier and more conservative termination. This treatment by "counterirritation" was employed more extensively by the older physicians, who imagined that the dilation of the skin-vessels would draw the blood out of the neighboring vessels, and so "deplete" the congested area, by a direct "derivative action." This crude mechanical conception had to be abandoned as the anatomy and physiology of the circulation became better known.

The fact of such "action at a distance," however, may be definitely shown. For instance cold applied to one hand constricts the vessels of both hands, and heat dilates them (G. N. Stewart, 1913; Hewlett, 1913). Whilst irritation of the hand by mustard does not increase the local blood flow, as might be expected from the rubefaction (Wood and Weisman, 1912; Hewlett, 1913), nor is the skin-temperature increased by mustard or turpentine rubefaction (N. B. Taylor, 1923). The effects of counterirritation are due mainly to nervous reflexes, partly sensory and partly vascular. The sensory vasomotor reflexes which have been described, like reflexes in general, exhibit the predilection for the homologous nerve paths, *i.e.* a quantitative localization of the response to definite areas. In a sense these are the reversal of the "referred pain" which occurs in definite skin areas when the corresponding viscera are irritated (Head). This explains the empirical observation that counterirritation is most effective, when applied at a definite place for each internal inflammation (Figs. 3a and 3b).

Relief of Pain by Counterirritation.—This is partly explained by homologous reflexes; but largely also by the diversion of the attention of the patient from the disease-pain, to the usually more bearable sensations of the counterirritant.

Influence of Pain on Inflammation.—According to some observers, the response to chemical inflammation may be diminished or abolished by local anesthesia or central analgesia. Others, however, have failed to find anything more than the normal individual variation.

Bruce, 1913, reported that mustard oil failed to produce conjunctival congestion and edema (chemosis), if the sensory fibers were degenerated, or paralyzed by local anesthetics. The inflammation would therefore be conditioned on a sensory reflex, which he assumed to be reflected on the vasodilator collaterals of Bayliss, 1901, 1902, without passing to the spinal cord. The observations were confirmed by Januschke and Bardy, 1914. The latter also claimed that the inflammation was prevented by nicotine, and that therefore the phenomena involved the sympathetic synapse. Others, however, believed that spinal reflexes were involved, especially as central analgesics, such as ether and morphine, were also said to be effective. Similar results were claimed for calcium chloride, antipyrine, quinine, salicylates, cinchophen, bromides, etc., and substances yielding available oxygen. (Amberg, Lævenhart and McClure, 1917.)

On the other hand, H. H. Stevenson and Reid, 1915, report that neither nerve degeneration nor local anesthesia influenced the ordinary course of mustard oil chemosis. Morphine and chloral tended to prevent the edema, but only in toxic doses, and presumably as a result of the circulatory collapse. They also call attention to the fact that patients with degenerated nerves, with hysteria and with central anesthesia all react to cantharidin-vesication. Hanzlik et al. also showed that paraphenylenediamine edema is not influenced by the analgesics and anesthetics, but only by agents that markedly restrict the local circulations.

Changes in the Blood.—Irritation of the skin produces changes in the blood which may influence inflammation: Winternitz, 1896, found at first leucopenia, then *leucocytosis*. Van den Velden, 1912, claims that the coagulability of the systemic blood is increased by a number of local irritant and especially vasoconstrictor processes (ice to the skin; astringents or epinephrine to the mouth; cocaine to the nose; turpentine inhalation, etc.).

FIG. 3a.—Diagram of the body showing some of the points where blisters or sinapisms are usually applied. Front view (Brunton).

Therapeutic Indications of Cutaneous Irritation.—This is employed mainly in the following conditions:

1. *In certain skin diseases*, for the local effects—alkalies, sulphur, chrysarobin, etc.
2. *To promote diaphoresis*—alcohol, frictions, heat, etc.
3. *For reflex stimulation of the central nervous system*, in fainting, collapse, narcotic poisoning, accidents of anesthesia, etc.—ammonia inhalation, heat or cold.
4. *To alter the distribution of blood*, to prevent colds—mustard; to relieve congestion of viscera—poultices, vesication; or to promote the absorption of exudates—iodine, vesication.

Counterirritation is, as a rule, useful only in chronic inflammation. In acute inflammation there is danger of increasing the process or of causing it to extend to neighboring organs.

5. *To diminish pain*, especially in neuralgic and rheumatic affections—turpentine and other volatile oils, capsicum, chloroform.

6. *As a general tonic*, in the form of salt-water baths or alcohol frictions.

Therapeutics of Cauterization.—Cauterization—the destruction of tissue—is sometimes employed for severe *counterirritation*, but particularly to *remove tissue*: (1) In cases of poisoning, snake-bite, etc.; (2) for the removal of pathologic tissue, tumors, warts, etc.; (3) indolent granulations, etc.; (4) to cause cicatricial contraction of hypertrophied mucous

FIG. 35.—Diagram of the body showing some of the points where blisters or sinapisms are usually applied. Back view (Brunton).

membranes (nose, etc.); (5) for removing the nerves of teeth; and (6) to remove superfluous hair.

In many cases the chemic cautery has been replaced by galvano- and thermocautery, which are more prompt and permit a more exact limitation of the cauterized area. On the other hand, the slower effect of chemic caustics is of advantage in permitting a graduation in the strength of the action, or in confining it to certain tissue elements. Pathologic formations, with poor blood-supply, are in this way more profoundly altered than normal tissue.

The caustics may be applied in solid form (sticks, or fused at the end of a probe), in paste, or in solution—the first being the most strictly local-

izable, the last the most diffuse. In the latter case, or when the chaser liquefies, the surrounding tissue should be protected by court-plaster.

GENERAL TOXICOLOGY OF IRRITANTS

The phenomena produced by irritant poisons depend in the first place upon the part of the body with which they are brought into immediate contact. The most prominent symptoms therefore arise from the skin, alimentary canal, or respiratory organs; the last only in the case of volatile poisons. Later symptoms may appear in the urinary organs.

The extent of the action depends upon the concentration of the poisons, the time during which they act, and the extent of surface with which they come into contact—less upon their absolute amount. If taken by the alimentary canal, their action is also modified by the presence of food.

Cauterization of the Skin.—This may be accidental or criminal. In the latter case it is often by sulphuric acid ("Vitriol"). The *results* are the same as in the case of extensive burns. The *diagnosis* usually offers little difficulty. The character of the stains is that described in the next section. Sufficient of the corrosive can generally be collected from the clothing, etc., to establish its identity by chemic means. The *treatment* is like that for burns, after previous neutralization and removal of the corrosive agent. Salves and oils are useful.

Caustics in the Eye.—These are best washed away by liberal application of water.

Caustic Poisoning by the Alimentary Canal.—The phenomena vary according to whether the irritant produces actual cauterization—a destruction or solution of the tissues; or whether it causes only inflammation.

Irritants Which Do Not Destroy the Tissue.—To this class belong elaterium, croton oil, and most of the other organic irritants, such as volatile oils, formaldehyde, etc.

The symptoms are those of a violent *gastroenteritis*: nausea, vomiting, and diarrhea. If the poison acts only when dissolved, and is insoluble in the stomach, as is croton oil, the nausea and vomiting may not be present, but only the diarrhea. The symptoms appear correspondingly late. The abdomen is usually distended and painful, especially on pressure. As a result of the gastroenteritis, there is extensive dilatation of the splanchnic area, and consequently withdrawal of blood from other parts of the body. This produces marked changes in the circulation. The pulse is soft, small, and quick. The *lowered circulation* reacts upon other organs, and most conspicuously upon the *central nervous system*. There is great anxiety, vertigo, delirium, convulsions, then *collapse*, and finally coma and death. This picture is common to the entire series of irritant poisons.

Abortion.—The hyperemia is not confined to the intestine, but all the abdominal organs partake in the inflammation, although they do not come into direct contact with the irritant. The organic irritants, especially oil of savin, of tansy, and of pennyroyal, have been used to procure criminal abortion. The ecboic effect is only secondary to the gastroenteritis, and the latter is very often fatal without accomplishing the object for which it was produced.

The *postmortem appearances* consist in intense congestion of the entire alimentary canal, often with inflammatory exudate into the lumen of the intestine. The congestion may be so violent as to produce ecchymoses.

If these are present, the vomit and stools are tinged with blood during life. Destruction of tissue is rare. It may, however, occur from gangrene due to the interference with the circulation.

The Fixed Caustics.—The most important are the mineral acids; oxalic acid, which, however, stands apart on account of its specific toxic action; other organic acids, the alkalies and their carbonates; the haloid substances, bromine, chlorine, and iodine. Phenol and the metallic salts are also to some extent corrosive, but not usually sufficiently so to produce perforation. The alkalies and bromine produce the most extensive destruction of tissue, because of their deep penetration. With them, the scar formation is also the most extensive.

Corrosive effects occur especially in those situations which are in prolonged contact with the caustic: the lips; mouth and pharynx; esophagus at its beginning and end, and where it crosses the left bronchus; and the stomach, especially the pyloric end (because the caustic follows the lesser curvature and accumulates at the pylorus). The firm closure of the pylorus furnishes more or less protection to the intestines.

Characteristic Appearance of the Corrosions and Stains.—These are of diagnostic importance, since they may be recognized about the mouth during life:

Alkalies cause transparent swelling of the epithelium, which may detach as a gelatinous mass, exposing the scarlet-colored inflamed area beneath. The other corrosives, which precipitate proteins, produce at first a grayish-white opaque stain. This persists in the case of the metallic poisons. The acids, however, change the hemoglobin in the neighboring area into the dark acid-hematin, and the color of the stain consequently becomes dark or black. Nitric acid is an exception: its stain takes on a yellow color. This differs from that of picric acid by being changed to orange by alkalies, while the picric acid stain remains unaltered. Bromine produces a characteristic light brown or orange stain; iodine stains a mahogany color. The silver stain turns black after a time.

Removal of Stains.—The stains of iodine and silver are frequently a source of annoyance. They can be readily removed: The iodine by ammonia water or by thiosulphate; the silver by potassium cyanide or by painting first with iodine and then with ammonia.

Symptoms of Corrosive Poisoning.—These begin in the mouth, with burning pain, dysphagia, and loss of tissue. *The taste* of many of the substances is often characteristic—acid, alkaline, metallic, astringent, etc.

The further symptoms are those of gastroenteritis, similar to those described under non-corrosive irritants, but generally more severe. The vomiting and diarrhea are more frequently bloody. In the case of acids the vomited blood is frequently very dark in color on account of the formation of acid hematin. This is the so-called “coffee-grounds” vomit. The pain is very much more marked with corrosive poisons. The destruction of the tissue gives rise to reflexes which may take the form of “shock.” The absorption of the chemic products of corrosion may produce fever; or the temperature may be lowered by collapse. If perforation occurs, the clinical picture turns into that of peritonitis.

Death.—This may occur from shock before the local symptoms have time to develop; or it may follow after one or two days of more gradual collapse; or it may result later from peritonitis; or finally, after recovery from the acute effects, the formation of *scar-tissue* in the corroded areas may lead to stenosis and thus to gradual starvation.

Portmortem Examination.—This shows the characteristic stains and corrosions in the mouth, esophagus, stomach and duodenum; with the metallic corrosives, the cecum and large intestines may exhibit the principal changes since many metals are excreted in these situations.

When the action has not progressed to actual corrosion, there is often very marked hyperemia and ecchymosis. The color is frequently much darker than corresponds to the amount of congestion, especially in the case of acids (due to acid-hematin).

Treatment of Poisoning by Corrosives.—The first measure is *dilution*, since the action is proportional to the concentration. The drinking of water in abundance and the washing out of the stomach are therefore important. If corrosion is already advanced, it is not advisable to pass the stomach-tube. The further treatment consists in the administration of *demulcent* substances, such as mucilage or boiled starch; or white of egg; or milk. The proteins are especially useful against the metallic poisons, since they form rather insoluble albuminates.

The pain may require the exhibition of *narcotics* in free doses. Most of the irritant poisons can be treated by *chemic antidotes*; in the case of alkalis, by acids (vinegar, lemon juice, or any acid diluted to 1 to 5 per cent.); in the case of acids, by means of non-corrosive alkalis; preferably magnesium oxide; or in emergencies by soap.

The free alkalis are usually too caustic, and the carbonates involve danger of rupturing the corroded stomach by the evolution of carbon dioxide gas. Potassium compounds are objectionable because of the danger of toxic absorption from the corroded mucosæ. In case of necessity any alkali may be used, such as whitewash or chalk.

Iodine, chlorine or bromine may be neutralized by sodium bicarbonate.

VOLATILE IRRITANTS

These comprise ammonia, chlorine, bromine, the fuming mineral acids, the gaseous acids, such as sulphurous, nitrous, etc.; the volatile organic acids—acetic, formic, etc., formaldehyde; the volatile oils, especially the oil of mustard; and the various “war gases.” Some of these, (for instance, phosgene, palite and mustard gas) irritate little directly, but develop hydrochloric acid in contact with the tissues. Others, such as “chloropicrin,” were inhaled as dust, rather than as gas.

When swallowed, the volatile irritants produce the ordinary phenomena of gastro-intestinal irritation. When inhaled, they irritate mainly the respiratory passages and other exposed mucous membranes, causing conjunctivitis, rhinitis, bronchitis, pulmonary edema and pneumonia. The phenomena differ in detail according to the degree of irritation, *i.e.* according to the concentration and the duration of action of the gas. They are essentially uniform for man and other mammals, and for all volatile irritants, and they may therefor be discussed together. They may be grouped as the acutely lethal concentrations, the subacutely toxic concentrations, and the chronic intoxications. The direct irritants, and those which become irritants only through chemical changes, also differ in the relative intensity of the effects on the upper and deeper respiratory passages, and in the sensory irritation and reflexes, which arise only above the bronchioles. Chlorine, bromine, nitrous vapors, sulphur trioxide and dioxide, and chloropicrin are examples of the direct irritants; phosgene, superpalite and palite, of the indirect irritants. Chlorine may be taken as a type of the direct, and phosgene of the indirect irritants.

Poisoning by gases occurs mainly through accidents in industry and chemical laboratories, and through their use in chemical warfare. The latter greatly stimulated the study of the toxicology of gases.

Volatile Irritants in Warfare.—The use of "gas-shells" has extended the significance of "volatile" beyond those substances that are gaseous at ordinary temperature, so that it includes liquids and even solids that can be vaporized or simply atomized by the heat or force of the explosion of the shell.

Available Substances.—Practically every substance of sufficient heat stability and toxicity may thus become an implement of "gas-poisoning."

The choice of the substances is limited by the fact that they must be capable of producing their effects even when highly diluted. In practice, this requirement is best met by irritants. Curiously, it has largely excluded such substances as hydrocyanic acid, arsine, phosphine and hydrogen sulphide—substances that owe their sinister reputation mainly to rapidity of action, but which apparently can not be used with sufficient concentration in ordinary military operations.

The substances actually used are numerous, but they can be reduced to a few types, from the standpoint of their actions, or more precisely, according to the usual location of the irritation; *viz.*, Pulmonary Irritants, Lachrymators and Blistering "Gases." These last will be discussed in another section.

The actions are not sharply localized, but differ according to circumstances, especially according to the concentration and duration of exposure. However, the effects adhere pretty closely to the type-classification under ordinary conditions.

Acutely Lethal Concentrations.—Prompt death occurs especially with high concentrations of the direct irritants, (for example, 1 to 5 per cent. of chlorine) through reflex spasm or acute edema of the glottis, or by obstruction of the pulmonary irritation. The symptoms are those of violent respiratory irritation and rapid asphyxial syncope.

The experiments of Schaefer, 1915, showed that 1 per cent. of chlorine in the air may be ineffective for several minutes; then, often suddenly, the respiration becomes deep, convulsive, and arrested. The blood pressure falls. Rapid recovery occurs in fresh air.

With 5 per cent., death is rapid and inevitable. The respiration becomes slowed and is arrested in one to three minutes. The blood pressure falls to zero in three to four minutes, the heart still beating well. Artificial respiration does not cause recovery.

The bronchioles are not constricted, air passing at least as well as normally. Secretion of mucus is also unimportant, for the course is not modified by atropine. The systemic circulation is also unaffected directly, the changes being secondary to the asphyxia. Even the right heart is not especially congested.

The essential changes are seen in the pulmonary circulation. The lungs are intensely hyperemic, microscopic examination showing engorgement of the capillaries and edema of the interstitial tissue and alveoli. The epithelium proper is normal. Perfusion of the pulmonary vessels with Ringer's solution shows marked obstruction of the flow when chlorine is injected into the trachea or perfusion fluid. Schaefer assumed that this phenomenon occurs during life and that this obstruction is the cause of all the symptoms. (It is probable that chlorine coagulates the endothelium, as do other astringents.) Bromine vapor is more irritant, but less fatal.

Respiration.—Inhalation of high concentration of chlorine (admitted directly into the trachea) arrests the respiration completely, for 20 seconds or longer. This is followed by peculiar, abortive abdominal movements; and this by restoration of practically normal respiration. Further chlorine does not again arrest the respiration (Schultz, 1918).

Inhalation of air containing chlorine 1:5,000 to 1:1,000 produces quickening of the respiration and transient broncho-constriction; due partly to edema of the bronchial mucosa (Azzi, 1918). There may also be a direct action on the bronchial musculature; for excised rings are strongly contracted when placed in Ringer's solution containing fairly high concentrations of chlorine. Low concentrations relax. Rings of *pulmonary artery and vein* behave similarly; but it is doubtful whether they are exposed sufficiently in life.

Heart.—In mammals, inhalation of concentrated chlorine often produces prompt temporary arrest of the heart. If the heart resumes, the pulse and respiration remain greatly slowed. These effects are absent if the vagi have been divided.

The exposed frog or terrapin's heart and especially the mammalian heart are immediately depressed by chlorine in Ringer's fluid, or in the air (Schultz, 1918).

Subacutely Toxic Concentrations of Volatile Irritants.—The greater number of accidental intoxications and practically all war gas casualties belong to this group. The distinguishing feature is the occurrence of profuse pulmonary edema. In the case of the direct irritants, this may be preceded and accompanied by sensory phenomena, reflexes and inflammation of the respiratory passages.

Absence of Direct Systemic Toxicity.—Most of the irritant gases are not absorbed as such from the lungs. They therefore do not have direct systemic actions. All their effects are explainable as direct or indirect results of the local irritation. The indirect effects are produced by asphyxia or by reflexes.

The fatigue and exhaustion of the mild cases, and the loss of consciousness in severe cases are asphyxial. Retching and vomiting result from pharyngeal irritation and from the cough. Diarrhea is emotional.

The kidneys are practically unaffected.

Stages of Poisoning.—The phenomena of gas poisoning may be advantageously grouped into several stages:

(a) *The immediate sensory reflexes*, coughing, choking and vomiting. These are conspicuous in the case of direct irritants, such as chlorine; and delayed or absent with the slower acting poisons (phosgene).

(b) *The pre-edemic phenomena*, constituting the *first stage* in phosgene gassing.

(c) *The stage of pulmonary edema*, the *second stage* of phosgene poisoning, progressing to acute death or toward recovery.

(d) *The phenomena of restoration*, the *third stage* of phosgene.

(e) *Secondary infections of the respiratory tract*, generally responsible for the delayed deaths.

(f) *Persistent lesions*, induced either by the chemical irritation or by the secondary infections.

The rapidity of the development, and the severity of the earlier symptoms, and the acute and subacute mortality, vary directly with the concentration of the gas, and the duration of the exposure, as well as with the nature of the irritant.

The details of these phenomena and of their treatment have been studied on animals, gassed under standard conditions, with greatest detail perhaps on dogs exposed to phosgene, about 1:13,000, for half an hour.

The results of the German experiments with war-gases are described in the thirteenth volume of the *Zeitschrift für die gesammte experimentale Medizin*.

Sensory Phenomena and Reflexes.—These start with the first two or three inspirations of the directly irritant gases, for instance, chlorine 1:1,000 to 1:10,000, or with ammonia vapor, etc. There is a sensation of pain and choking, which causes a reflex temporary arrest of the respiration, in expiration, spasmodic closure of the glottis, and bronchial constriction and reflex inhibition of the heart. These are conservative reactions, which temporarily exclude the poisonous gas and prompt the subject to seek pure air. They explain why fatal effects are relatively rare; but excessive spasm or edema of the glottis may be directly fatal. The protection can only be temporary if exposure to the gas continues. The air-hunger leads to dyspneic, spasmodic and painful respiration, resembling asthma, although the bronchi may not be constricted. Asthmatic individuals are indeed especially sensitive to direct respiratory irritants. There may be violent coughing, with frothy expectoration. Acute asphyxia develops, with cyanosis and great anxiety, then mental confusion and lethargy, and finally unconsciousness. Eventually the condition passes into pulmonary edema and circulatory collapse. These, rather than the immediate phenomena of irritation, are the fatal features of the intoxication. (L. Lewin, 1908.)

The irritation also affects the conjunctiva, resulting in lachrymation and congestion. Swallowing of the irritant with the saliva may inflame the esophagus and stomach, with protracted hemorrhagic gastritis (Loeper et al., 1915).

Acute Epithelial Injury by Gases.—This increases progressively in inverse ratio to the robustness of the cells, from the trachea to the alveolar endothelium. The functional injury may be much greater than the histologic changes. In acute gas cases, particularly, severe edema may occur before the cells present any morphologic abnormalities.

Lesions of Upper Respiratory Tract.—Chlorine and other direct irritants including "mustard gas" produce more or less violent inflammation of the larynx, trachea and bronchi. In case of survival these are likely to lead to secondary infections; to laryngitis, tracheitis, bronchitis and lobular pneumonia.

Those gases which liberate chlorine only on contact with water (phosgene, palite, superpalite, etc.) cause little or no inflammation of the upper respiratory tract. They are also somewhat less liable to secondary pneumonia.

Peculiarities of Irritative Pulmonary Edema.—This edema is the essential danger-factor with all the volatile pulmonary irritants; its mechanism, phenomena and treatment being essentially the same for all.

The pulmonary edema as produced by gas differs from the pulmonary edema of ordinary civilian practice in several important respects; in the manner of its production, as well as in its phenomena:

Ordinary pulmonary edemas are either early stages of pneumonia, in which case they are more circumscribed; or they are due to disturbance of the pulmonary circulation, in which the alveolar endothelium is involved secondarily.

In gas poisoning, the order is reversed; the endothelial injury is primary, and the circulatory disturbance is secondary.

However, the study of the mechanism and treatment of all kinds of pulmonary edema is greatly assisted by that of the irritant gases.

Other Forms of Experimental Pulmonary Edema.—The methods that have been employed are reviewed by Schlomovitz, 1920. They may be arranged into the following groups:

1. Embolism of artery by fat, lycopodium, etc.; intravenous collargol.
2. Injury to pulmonary capillaries by excessive hydremia; excessive blood concentration and anoxemia.

3. Injury to pulmonary capillaries by intravenous acetic ether, or ammonia.
4. Injury to respiratory epithelium; irritant gases.
5. Clinical inflammatory type; mainly by vascular injury.
6. Disproportion in the work of the right and left ventricle; compression of the left ventricle (Welch); epinephrine-injection; muscarine asphyxia.
7. Combinations.

Pre-edemic Stage. (*First Stage of Phosgene Poisoning*).—This is characterized by congestion and stasis in the pulmonary circulation; dilation of the right heart, dilution and increased volume of the blood.

Thrombosis of the Pulmonary Vessels.—This is especially prominent in chlorine poisoning. Many of the pulmonary capillaries are occluded by agglutinated red cells. This process reaches its maximum rapidly, in one or two hours at the latest, and then gradually diminishes.

The thrombosis may be partly the result of the usual inflammatory stasis; but probably is largely due to the direct action of the acid gases on the blood corpuscles; for agglutination may be produced *in vitro* by dilute chlorine, phosgene or hydrochloric acid.

Hemoglobin and Blood Volume in the Pre-edemic Stage.—The hemoglobin and corpuscle content of the blood is materially diminished during the first stage, thus producing a hydremia. This may be partly attributed to the withdrawal of corpuscles from the systemic circulation, by their stagnation in the pulmonary vessels (Meek and Eyster, 1920). However, direct estimations show an actual increase in the total blood-volume in most cases (although it is not strictly parallel to the hemoglobin dilution), so that there must be a flow of fluid from the tissues into the blood. The cause of this has not been established.

During this stage, the *chloride content* of the blood drops sharply, this being accompanied by a marked increase in the chlorine and water content of the lungs.

Oxygenation of the Blood and Tissues; Respiration.—The oxygen content of the blood decreases considerably, nearly parallel to the deficiency of the hemoglobin. This, together with the obstruction in the pulmonary circulation and the venous stasis, produces some asphyxia and dyspnea; but the respiratory symptoms in this stage of phosgene poisoning are not severe. There are no physical signs, but X-ray examination of the lungs in the pre-edemic stage shows diffuse cloudiness.

Dilation of the Right Heart.—Prior to the edema, the right heart dilates considerably as shown, *f.i.*, by X-ray measurements. The left heart is never dilated.

The changes are doubtless due to the increased resistance in the pulmonary circuit, and to the increased volume of the blood. The dilation persists for two to four hours, then gradually disappears as the edema sets in.

The pulse in this stage is practically normal.

Acidosis.—*Chlorine poisoning* is always accompanied by temporary acidosis. This is indicated by the urinary constituents, and by diminished alkali reserve (diminishing CO₂ capacity) of the blood.

In case of survival, the acidosis is only temporary, the blood recovering its normal values rapidly, often in a few hours. The alkali reserve of the tissues was therefore not seriously depleted.

In fatal cases, however, the reserve alkali of the blood continues to fall progressively. This is of prognostic importance.

In *phosgene poisoning*, acidosis occurs only shortly before death; *i.e.*, there is only the terminal acidosis that is likely to precede death from any cause.

Changes in Urine.—In dogs, gassing by chlorine is followed by increased protein metabolism, shown by increased elimination of total nitrogen, ammonia, creatinine, uric acid, and phosphate.

Acidosis is indicated by increased output of ammonia, and by increased H-ion concentration of the urine. These changes are generally absent in phosgene poisoning.

The kidney-function tests give normal values. Other signs of renal disturbance are also absent (negative albumen, glucose, blood, etc.).

Stage of Pulmonary Edema. (*Second Stage of Phosgene Poisoning*).—The pulmonary capillaries, which were irritated and obstructed in the first stage, become gradually permeable, leading to pulmonary edema. Heubner, 1919, believes that the pulmonary stasis plays a greater part than the direct irritation of the endothelium.

The edema results in diminished blood-volume, concentration of the hemoglobin, and decreased size of the heart. This is apt to develop quite rapidly, especially in chlorine poisoning, and may reach extreme degrees; affecting the circulation as well as the respiration. Most of the fatalities occur in this stage, from anoxemia and decreased blood-volume (Meek and Eyster, 1920).

Blood Concentration.—The dilution of the blood, which was characteristic for the pre-edemic stage, rapidly returns to normal as edema develops, and is then replaced by progressive concentration, so that the blood-count and hemoglobin content and viscosity rise. In chlorine, the concentration occurs rapidly; in phosgene very slowly, reaching its maximum about the 5th to 8th hour. It may then remain stationary for some time.

The rapidity and degree of the concentration is proportional to the severity of the intoxication, and is therefore of prognostic importance. In dogs poisoned by phosgene, *f.i.*, a hemoglobin content above 130 forecasts death during the edemic stage (about the 9th hour); while hemoglobin figures below 110 occur only in cases that are not fatal (unless by infectious complications).

The increased blood concentration is partly responsible for the circulatory phenomena.

Blood Volume.—This decreases with the loss of fluid and the concentration of the blood. It doubtless contributes to the circulatory and respiratory disturbances.

Size of the Heart.—The dilution of the pre-edemic stage gradually disappears as the edema comes on. This is seen first in the left heart, perhaps because of the impeded access of the blood to the left auricle; after 2 to 4 hours, however, all chambers become distinctly smaller. Establishment of compensatory capillary channels in the lungs and the diminished volume of blood, explain the change in the heart.

In fatal cases, the heart continues to diminish in size until the approach of the terminal asphyxia, when the heart again dilates somewhat.

Circulatory Collapse.—Severely gassed patients suffer more or less from circulatory collapse, as shown by a gray pallor; by rapid and feeble pulse, and by venous congestion and dilatation of the right heart (never of the left). The collapse is often the immediate cause of death.

The circulatory collapse is due mainly to the asphyxia; but is aided by the local conditions in the lungs; by the increased viscosity and thrombosis; and by the compression of the capillaries and veins through the edema.

Temperature and Pulse-rate.—The effects of chlorine have been investigated by Barbour, 1919. Low (irritant) concentrations (24 to 36 per million) produces considerable rise in temperature.

Medium (irritant to depressant) concentrations (180 to 200 per million) causes considerable fall in temperature, with slowing of the pulse rate, during the inhalation. Both disappear soon after removal from the chlorine.

Lethal concentrations (800-900 per million) produce more persistent effects. The pulse becomes slow, later weak and rapid. The temperature falls, and with the collapse the animals become practically poikilothermal. Excessively warm environment may then be as detrimental as cold.

Development of the Pulmonary Edema.—The fluid exudes first into the air sacs and from there overflows into the bronchioles and bronchi. Here it is churned into foam by the tidal air. As this foam mounts toward the larger air tubes, it provokes the cough-reflex, and is more or less effectively expelled, until, if the condition progresses, the exudate and foam become so excessive that they produce fatal asphyxia.

The edema compresses the pulmonary capillaries, this being another factor in the impeded pulmonary circulation. Some of the exudate may also form in the pleural cavity; but usually in scanty amount.

During this stage, the chloride content of the blood returns toward normal, while the water and chloride content of the lungs reach a maximum later, falling gradually.

The edema fluid comes largely from the blood. This becomes more concentrated, as already explained; whereas there is no change in the water-content of the muscles.

Respiration.—The minute volume of respiration is always increased after the symptoms of gassing develop. With chlorine, the sensory phenomena dominate the respiration. With phosgene, the increase of respiration is asphyxial, and therefore increases with the edematous stage.

Disruptive Emphysema.—This is especially serious in chlorine gassing, because of the violent coughing and inspiratory efforts provoked by the irritation of the gas. These efforts tend to tear the partitions between the alveoli. The pulmonary tissue may be ruptured so extensively that air escapes even into the subcutaneous tissue of the neck.

The much milder sensory irritation of phosgene poisoning leads to less violent muscular efforts, and emphysema is therefore less prominent. However, the air hunger leads to super-ventilation; and this may cause some emphysema, especially when the air-tubes are narrowed by bronchiolitis or bronchiolar spasm.

In any case, disruptive emphysema diminishes permanently the breathing area; so that survived patients are apt to suffer indefinitely from shortness of breath.

Gas-exchange in Irritative Pulmonary Edema.—This is best studied in phosgene poisoning, in which the phenomena are not so complicated by sensory irritation.

In chlorine poisoning, air hunger sets in very rapidly. On the other hand, soldiers gassed with phosgene do not complain of air hunger for some time, although they may show an intense grayish cyanosis, and may even die. This is a condition of anoxemia analogous to mountain-sickness.

If the patient survives, the cyanosis gradually changes to the ordinary blue tint, and he develops air-hunger and intense hyperpnea. These are the phenomena of carbon dioxide poisoning. In other words, the patient passes first through a condition of pure anoxemia; this is then complicated by the accumulation of CO_2 , which develops much more slowly.

Haldane explained the early dissociation of the oxygen and carbon dioxide factors of asphyxia by the relative solubility of the two gases. CO_2 is twenty-five times more soluble in water than is oxygen. Consequently, when the exudate begins to form and interposes an extra film, as it were, between the alveolar air and the alveolar blood, this film will interpose a much greater obstacle to the passage of oxygen, than to the passage of CO_2 , to which it is quite freely permeable. This would result in the anoxemia without carbon-dioxide accumulation, as noted clinically.

However, these conditions change when the edema becomes more abundant; when it fills the alveoli, and its foam mounts more and more into the bronchioles and bronchi. When this happens, the air is totally prevented from reaching the alveoli. The respiratory exchange stops in that part of the lung, and CO_2 accumulates.

The edema develops with unequal rapidity and severity in different parts of the lungs. At first, therefore, some parts of the lungs will still be in communication with the air. The tendency to the accumulation of CO_2 produces more or less hyperpnea; and this produces an over-ventilation of those functioning portions of the lung. Their CO_2 will therefore fall below the normal level.

The blood returning to the left heart will be a mixture derived from the over-ventilated and from the unventilated parts of the lung—the first with a deficiency of CO_2 , the second with an excess of CO_2 . These two factors will tend to balance each other, so that the CO_2 excess of the mixed blood is not at first very great. It increases, naturally, in proportion as more and more of the lung is thrown out of function.

On the other hand, over-ventilation does not increase the oxygen of the blood anywhere, since the hemoglobin in the functional part of the lung is practically saturated with oxygen by ordinary ventilation. This oxygen saturation cannot be increased by over-ventilation. Therefore, the over-ventilated portions of the lung do not compensate for the asphyxiated portions. The uncompensated oxygen deficit therefore continues greater than the more or less compensated CO_2 excess.

The administration of oxygen reverses these conditions: oxygen diffuses gradually through the foam, and thus the foam near the alveoli becomes so much enriched in oxygen, that a sufficient quantity of the oxygen can diffuse into the alveolar exudate.

The CO_2 excess is of course not aided in any way by this. So that oxygen inhalation abolishes the cyanosis and diminishes the danger of asphyxial death; but it does not diminish the hyperpnea. The air-hunger, the amplitude and rate of respiration, are not changed by the oxygen.

Since the oxygen must diffuse through the foam before it can be effective, the relief is rather slow, coming on only after about five minutes. This contrasts with the instantaneous response to oxygen in ordinary obstructions.

Blood-gases.—In untreated gas poisoning, the oxygen of the blood falls, often to very low values. This is especially conspicuous in the venous blood. The carbon dioxide content increases more slowly, as has been explained.

Post-mortem Findings.—These differ somewhat for chlorine and phosgene (Winternitz, 1919).

Chlorine Followed by Acute Death (Inside of Twenty-four Hours).—The trachea and bronchi are red and congested, edematous, and may be more or less filled with serous exudate. The lumens of the bronchioles may be filled with debris. The lungs are heavy and edematous with overdistended, emphysematous areas scattered through the purplish collapsed and depressed structures. On section, serous fluid flows abundantly.

Post-mortem Findings for Phosgene.—When death has occurred within two hours after exposure, the lungs are found uniformly edematous, airless, and purple. There is little or no emphysema. The lungs exude abundant fluid on section. There is also considerable fluid in the pleural cavities.

When death occurs later (second or third day) the pulmonary edema is lighter, the lung containing some aerated areas. This may be because all the cases of severe edema die early. However, it is conceivable that in non-fatal cases a reabsorption of the edema occurs from the second day; since even deeply cyanosed patients may ultimately recover.

The degree of the pulmonary edema may be determined accurately post mortem by the water-content of the lungs; or by the ratio of the weight of the lungs to that of the heart.

Prognosis in the Edema Stage.—Experience with animals indicates that the severity of the intoxication and the direct fatality in phosgene poisoning may be judged with fair certainty by the course of the blood concentration and by the temperature. The more rapidly the blood concentration sets in, and the higher its degree, the more grave is the danger. The temperature does not change in light cases. In severe cases, there is a preliminary rise, followed by a later fall. This fall is rapid in fatal cases, gradual in those that survive.

Phenomena of Restoration (Third Stage of Phosgene Poisoning).—If the patient does not succumb to the pulmonary edema, the excessive concentration of the blood gradually disappears, so that it finally becomes slightly more dilute than normal. The edema is slowly reabsorbed; and there is a fairly rapid re-adjustment and eventual return to a practically normal condition.

However, the stage of restoration is often complicated by secondary respiratory infectional pneumonia or bronchitis, which may run a fatal course.

Late Effects of Irritant Gases.—Inhalation of phosgene dichlorethyl sulphide, and especially of chlorine may be followed by chronic respiratory lesions. However, even heavily gassed dogs are essentially normal after 2 to 12 months; only a small minority show unimportant focal fibrosis (Koontz, 1925). Similarly favorable results are reported for soldiers. Four months after miscellaneous "gassing," the physical findings were normal in about 50 per cent. of the patients, chronic bronchitis was present in 30 per cent.; emphysema in 2 per cent. (Berghoff, 1920).

Exceptional cases develop persistent gastro-intestinal or nervous changes, due to hemorrhages into these situations.

Treatment of Poisoning by Pulmonary Irritants.—This is directed against the immediate local irritation and bronchial spasm: the anoxemia and acidosis; the abnormal blood-volume; the circulatory collapse; and the later bronchitis and secondary infections.

Since these factors vary in importance and urgency at different stages of the intoxication, and in different patients, the treatment should also

vary. However, the pulmonary edema, and the consequent asphyxia and circulatory collapse dominate all other indications.

In this discussion the individual measures are arranged generally in the order of their application.

Rest.—Rest is the simplest and perhaps most important single factor in the treatment of gas casualties because of the difficulty of combating the edema and emphysematous asphyxia directly. More or less asphyxia is always present. In this state, every exertion, even standing, means a more rapid exhaustion of the difficultly obtainable oxygen; a more rapid accumulation of the difficultly excretable CO_2 ; and an added mechanical and chemical strain on the overloaded heart, which may easily bring on acute discompensation.

The rest must be as absolute as circumstances permit. Sleep should be encouraged, as it generally brings improvement. Restless and excited cases must have morphine. The indication of rest must be observed absolutely or relatively as long as the patient reacts to exertion by cyanosis or dyspnea, or extra rapid pulse. Usually, if the rest is thorough in the start, the patient can return to light duties in a few weeks.

Warmth.—This is a useful precaution against collapse. Severe cases should therefore be heated. Ordinary cases should at least be protected against chill, but they should at the same time receive the benefit of fresh air.

Morphine.—This is used as a sedative, to secure rest, and to check spasmodic cough and mechanical trauma. It should be used only when these indications exist and should be avoided when there is deep cyanosis. However, if the patient is very restless, he may receive morphine even though he be deeply cyanosed.

The objection to morphine lies in the fear that it would depress the respiration at a time when the maximum respiratory ventilation is needed to offset the diminished lung-area. This is largely obviated by employing rather small doses, not to exceed 0.015 to 0.02 Gm. of the morphine.

From pharmacologic and physiologic considerations, small doses of morphine would be expected to improve the respiratory conditions. The characteristic effect on therapeutic doses consists in a slowing but deepening of the respiration. This would counteract the rapid and shallow respiration that follows as a vicious circle on oxygen deficiency (Haldane and Meaking, 1918).

Barbour *et al.*, 1919, found in animals gassed with chlorine (0.08 per cent.) that large doses of morphine (10 mg. per Kg, twice daily) were rather unfavorable. Smaller doses (3 to 5 mg. per Kg) did not materially effect the fatality.

Ammonia-inhalation.—Ammonia was carried in ampules, and a few whiffs inhaled at intervals, during the first day. It acts as a respiratory stimulant, usually making breathing easier and less exhausting. Its benefits were so universally admitted, that its use had been established as a routine. A few patients are made more uncomfortable by it, and in such cases it is not continued.

Ammonia as Antidote.—Some early attempts were made to neutralize the inhaled chlorine, by the continuous inhalation of ammonia. They were entirely unsuccessful, since the ammonia could only reach the chlorine excess in the upper air-passages. These would not require the neutralizant, since they would be quickly flushed by fresh air. On the other hand, the irritant action of the ammonia if unskillfully used, may add itself to that of the chlorine so as to increase the local injury.

Analeptics.—*Brandy* (small sips) is rather useful, until collapse becomes established.

Camphor and ether have been used hypodermically, against the later collapse, with the usual discordant opinions as to their efficiency. *Pituitary solution*, 0.5 c.c. every three hours, intramuscularly, and *strychnine* are useless.

Atropine.—This was proposed originally with the object of diminishing "pulmonary secretion." Naturally, it proved entirely useless, since the exudate of pulmonary edema is of inflammatory origin, and therefore is not affected by atropine.

Atropine might be of advantage against *bronchial spasm* (Symes, 1915; Cow, 1915). However, this is not a serious feature of gassing; and besides, the ordinary doses of atropine are apparently not sufficient to relieve it. On the other hand, the tendency of atropine to accelerate the heart would be detrimental in asphyxia.

For these reasons, it is not advisable to use atropine in the early stages. It may find employment later on against bronchitis.

In animals gassed with chlorine, Barbour, 1919, found the fatality unchanged by atropine.

Epinephrine.—This was tried especially to relax bronchial spasm. It is efficient, although the relief is only temporary (1 c.c. of 1:1,000, hypodermically). However, it is not employed extensively, probably because the bronchial spasm is not an important factor in gassing. Barbour, 1919, found it inefficient in animals.

Oxygen Inhalation.—The dominant indications, with the onset of edema, would be to facilitate the access of oxygen, and later the elimination of carbon dioxide. The control of the carbon dioxide is difficult; but the anoxemia can be relieved considerably by oxygen inhalation. The mechanism of this relief has been discussed.

Clinically, the efficient administration of oxygen generally diminishes the cyanosis, and is believed to increase the chances of survival. By its persistent use, patients may recover after being cyanosed and unconscious for two days. It may be recalled that it does not diminish the air-hunger; nor would it be desirable to have this diminished, since it is needed for the elimination of carbon dioxide.

The reported clinical benefits of oxygen inhalation have not thus far been reproduced in animal experiments. In these, oxygen had practically no influence on the fatality from chlorine, and not very much on that from phosgene. However, there is a distinct increase in the oxygen of the arterial blood at the time when it is most needed; and whilst this may not be enough to do much good in a restless animal, it may be of greater benefit in a resting patient.

Administration of Oxygen.—Since the oxygen exchange must be effected through a more or less thick layer of foam, it must be given in concentrated form, through a valved mask. Inhalation through a funnel over the mouth, or even through a tube in the mouth, is said to be useless.

On the other hand, the oxygen need not be supplied more rapidly than it is absorbed; that is, the important point is the concentration, not the absolute quantity of the oxygen. Therefore the administration need not be continuous. It suffices to breathe the gas for three or four minutes every quarter hour, but this must be done night as well as day, as long as the cyanosis tends to recur.

The intermittent administration was of military importance, for the difficulties of transportation to the front make the utmost economy imperative. For this reason, the oxygen was not given to all patients, but was restricted more or less to selected cases. It is not necessary in mild cases and it is superfluous in hopeless cases. It is most useful in borderline cases that verge on the desperate; especially those who are still deeply cyanotic on the second day.

Hypodermic or intravenous injections of oxygen would be more economical, but less convenient. They are at present considered "useless" under field conditions.

Venesection.—This was introduced early in the gas-war, and has maintained itself for all forms of irritant gases. Neither the clinical nor the experimental data are quite conclusive as to its efficiency for saving life; but the balance of the evidence is in its favor. The clinical relief is often striking, especially in the early severe cases, with deep-blue cyanosis and full pulse (corresponding to acute asphyxial dilation of the heart). Under such conditions, the abstraction of 15 to 20 ounces of blood is said to relieve the headache, ease the breathing, and often lead to strengthening sleep. The relief, however, may be only temporary.

Bleeding must *not* be used when collapse has started, as indicated by a poor pulse; or when the condition of the patient is in any way immediately dangerous.

This confines the usefulness of bleeding to the pre-edemic stage. It is advised to apply it as soon as possible after gassing, generally in half an hour or an hour; after phosgene, it may be useful up to 4 hours.

The benefits of venesection would naturally be attributed to relief of the distending right heart. This diminishes not only the immediate results of the venous engorgement, but also conserves the heart so that it can meet more successfully the conditions of the subsequent edema. If the distention and asphyxia have already weakened the heart too extensively, the abstraction of blood would tend to be harmful.

It might also be assumed that the relief of the pulmonary circulation, and the diminished blood-volume, would tend to lessen the liability to edema. Practically, however, this tendency does not appear to be important; for venesection has not been found to modify the subsequent edema in gassed animals.

The best conditions for venesection and transfusion have been worked out experimentally on animals; but these details have not yet been tried sufficiently under field conditions. Even in animal experiments, the results of different workers have not been uniform.

Venesection Treatment of Chlorine Gassing.—Since this runs a rapid course, the measures must be applied in prompt succession; as soon as possible after the gassing, the patient is to be bled about 1 per cent. of the body weight. This is followed at once by the intravenous injection of an equal volume of normal saline. After this, sodium bicarbonate may be given freely by stomach. The reasons for these measures will be discussed presently.

Venesection Treatment of Gassing by Phosgene, Superpalite, Etc.—The relatively slow course necessitates modifications of the treatment, so that the successive measures may be applied at the proper time. This is controlled mainly by the hemoglobin content of the blood, as the most convenient index of the concentration and volume of the blood.

Bleeding is practiced as soon as practical after gassing, if possible within an hour; but it may be beneficial even after four hours. At first $\frac{1}{2}$ per cent. of the body weight is withdrawn. The hemoglobin and temperature are then observed at half-hour intervals.

If the temperature remains normal, and the hemoglobin concentration does not diminish, no further treatment is necessary. If the temperature rises rapidly, with a simultaneous fall of hemoglobin concentration, a second venesection of $\frac{1}{2}$ per cent. of the body weight is made. This may be repeated once more if necessary.

This treatment prevents the development of pulmonary edema in most of the animals gassed with standard doses of phosgene. If, however, in spite of this treatment, the blood becomes markedly concentrated and the temperature falls materially, the condition is critical. In this case, fluid should be administered freely; either by mouth, or by rather slow infusion of normal saline. This is only necessary in serious cases. The injudicious use of infusion is dangerous. Alkali is not needed in phosgene poisoning.

Saline Infusion.—During the stage of pulmonary edema, the blood becomes markedly concentrated, more viscid, and diminished in volume. Injection of normal saline (1 per cent. of the body weight, *i.e.*, equal to the quantity of blood withdrawn at the venesection) has been tried to relieve this condition, but with doubtful benefit. Simple saline remains in the circulation at most half an hour and generally less, so that the benefit would at best be temporary; and the use of hypertonic salt or glucose solutions was found rather to increase the fatality.

Saline infusion therefore is not very promising, although it has some experimental support. If used at all, it must be confined to cases showing actual concentration of the blood; otherwise, it is more likely to do harm.

Underhill believes on the basis of animal experiments that it distinctly improves the chances of recovery, when used after bleeding at the time of the greatest concentration.

Alkaline Treatment.—The most hopeless element in the treatment of the severe cases is the acidosis, due to the inability of the edematous lung to eliminate carbon dioxide. A moderate restriction of lung area may be compensated automatically by hyperpnea. This, however, soon reaches its effective limit. Beyond this, the carbon dioxide must continue to accumulate and use up the reserve alkali of the blood, and thus lead gradually to a fatal acidosis. There is no method of increasing the elimination of carbon dioxide when the lungs become inadequate. Some good may be accomplished by introducing alkali into the blood; but the efficiency of this is also limited when carbonic acid is not being excreted. This is an essential difference from other forms of acidosis.

Consequently, the success of the alkali treatment has not been brilliant. Intravenous injection of sodium bicarbonate would be useless, since this is already saturated with carbon dioxide. Oral administration of bicarbonate is more promising. Sodium lactate has been used for the same purpose, 8 Gm. as 50 per cent. solution, by stomach, every four hours; but the official comment is: "The main features of gas poisoning are not influenced by this method of treatment."

Digitalis and Ouabain.—These would conceivably be effective against the cardiac dilatation. Digitalis has been tried by mouth, without much benefit, nor could much be expected from the slow absorption of the small doses that were generally used.

Ouabain (crystalline strophanthin) has been used intravenously with better effect. The usual dosage is 0.25 mg., then 0.5 mg. per day, till a total of 1.5 to 1.75 mg. is reached. Barbour, 1919, however found it useless with chlorine gassing.

Acetphenetidin and Acetyl-salicylic Acid.—These were tried against the headache; but are not advised, for fear of aiding the tendency to collapse.

Quinine, Calcium Lactate.—These did not affect the fatality in chlorine inhalation (Barbour, 1919).

Discharge of the Exudate from the Lungs.—Attempts have been made to remove at least some of the exudate from the air-passages mechanically, especially during the first day; but they are not promising.

The coughing is a natural device for this purpose. However, it tends to become so violent as to threaten mechanical injury to the lung, and therefore generally rather needs to be allayed.

Something can be accomplished by *position*. The head is turned to the side, and the foot of the stretcher or bed raised two or three feet or higher, for a few minutes at a time.

Schaefer's method of artificial respiration has been applied. It is not likely to do good, and may do harm.

Emetics.—These were tried rather extensively with the hope that the movements of vomiting would also expel more or less of the contents of the lungs. They appear to be ineffective for this purpose; and in the later stages the depression is certainly detrimental. This is true especially of the emetic drugs, such as apomorphine, or large doses of ammonium carbonate.

In the first few hours after gassing, emesis is often beneficial, not by emptying the lungs, but by relieving nausea. If, therefore, the patient feels inclined to vomit, soon after being gassed, he may provoke vomiting with the finger in the throat, or by drinking a pint of water containing a tablespoonful of salt.

Expectorants.—On the first day ordinary expectorants are useless, and may indeed be harmful by exaggerating the tendency to nausea. An exception may be made for demulcents.

On the second day, if the general condition is good, treatment of the bronchitis may be begun, with ammonium carbonate, 0.3 Gm., or Tr. Ipecac, 0.5 c.c. every 6 hours.

Later, the treatment of the bronchitis should be continued by the ordinary methods. Steam inhalation charged with Eucalyptus oil or Comp. Tr. Benzoin is used extensively.

Protection against Poison-Gases.—Perfect protection against all gases so far employed in warfare is provided by simple respirators and filters. These are masks, covering the eyes, nose and mouth, and communicating with the air through layers of absorbent and neutralizing chemicals. These chemicals now used (charcoal, permanganate and soda-lime) protect at once against all the gases so far used, in their ordinary concentrations. This is obviously a great advantage under field conditions, although special chemicals for each "gas" might have advantages for experimental conditions.

British Type.—This contained essentially active charcoal and alkaline permanganate.

German Type.—This contained three layers: The inside layer pumice with methenamine; this protects against phosgene. The middle layer active charcoal; the outer layer a mixture of baked earth, potassium carbonate, and fine charcoal.

Special Absorbents for Chlorine.—Chlorine is so highly reactive that it can be easily neutralized. Even water is fairly effective. Thiosulphate and alkalies are the special absorbents.

The Effects of Small Quantities of Volatile Irritants in the Air.—This has an economic importance, in view of their escape from chemical factories, etc. There can be little doubt that even a small proportion tends to produce bronchitis, and to diminish the resistance to infections (Ronzani, 1908: low concentrations of Cl, SO₂, NO₂). They may possibly cause cachectic conditions; but it is difficult to assign the limits between which these poisons are harmless, objectionable, and dangerous.

On the other hand, the inhalation of diluted chlorine and of acid vapor (von Kapf, 1920) has been tried therapeutically against colds and other infections of the air passages; but their usefulness and their harmlessness appear doubtful (see Chlorine and Iodine).

Individual Irritant Gases.—Some special data as to concentrations, etc. may be added; but the reader is referred to the preceding section for the description of the general phenomena.

CHLORINE

Minor Toxic Effects of Chlorine.—These have arisen mainly from its use in the arts. Air contaminated with chlorine produces irritation of the conjunctiva and respiratory mucous membranes, etc.; 0.001 to 0.002 per thousand of air is said to be harmless;

0.003 is disagreeable, and 0.004 irrespirable (Matt, 1889). Continuous exposure produces cachexia. The foliage of plants is destroyed by concentrations which are not noticeable for man.

Use in "Gas Clouds."—Chlorine was the first gas used in the war, being the sole constituent of the original "gas-cloud" attacks of Ypres in April of 1915. It was efficient, but because of the ease of protecting against it, it has been replaced almost entirely by phosgene mixtures, which were used almost exclusively in the gas-clouds of 1916.

Effective Concentrations.—The concentration of the toxic gas in cloud-attacks probably never rises above 1:1,000, and more commonly is nearer 1:10,000. These are effective concentrations. With concentrations below 1:100,000, chlorine gas is practically ineffective under military conditions, although long exposure is followed by bronchitis.

Fate of the Inhaled Chlorine.—Chlorine is not absorbed as such. However, the chloride content of the plasma is said to be increased for a few hours after gassing, and the chloride excretion by the urine is raised on the second day following severe gassing. Presumably, chlorine-protein compounds are formed in the lungs and are absorbed, especially by the corroded tissue. These would break down in the tissues, liberating chloride ions, which would then appear in the urine.

Therapeutic Use of Chlorine.—The inhalation of diluted chlorine has been suggested as a treatment of acute respiratory affections. However, this cannot exert any antiseptic actions; and whilst it is conceivable that the irritation may sometimes produce a beneficial degree of hyperemia, it is more probable that it would lower the resistance of the tissues. The clinical results do not appear convincing.

CHLORINE ANTISEPTICS

Strong and prompt germicidal effects are produced by chlorine as gas or in solution, and by substances capable of yielding "active" chlorine, such as the hypochlorites and chloramines (*i.e.*, compounds containing NCl groups). However, they attack all organic matter, and are thus likely to be corrosive and to become inactive. These objections can be overcome by proper technic and selection of the preparations.

Mechanism of Action.—Chlorine itself acts partly by oxidation, partly by the chlorination of the organic matter. With the hypochlorites the chlorination appears to be the chief element. It is supposed to occur in the amino-acid groups of the proteins, yielding chloramines.

In chloramine-sulphonetoluene derivatives, the chlorine of the chloramine is still "active," *i.e.* for instance, it liberates iodine from iodides. It is readily transferred to proteins, so that it acts essentially like the hypochlorite, and is at least equally germicidal (Dakin, 1916).

Toxins are also destroyed.

Historical.—A review of the use of hypochlorites is given by Dakin, 1915; and Carrel and Dehelly, 1918.

Hypobromites and Hypoiodites.—Free chlorine, bromine and iodine are practically equally germicidal; but whilst the activity of sodium hypochlorite is about equal to that of free chlorine, the hypobromite has only about a hundredth of the activity of bromine, and hypoiodites react very feebly with proteins and amino acids (Dakin).

Chlorinated Lime.—(Bleaching Powder.)—This is quite irritant, and therefore not well adapted to application to the tissues: but is used largely as a disinfectant for excreta. High dilutions are employed to sterilize water, especially for temporary emergencies.

Toxicology.—When swallowed, bleaching powder produces gastro-intestinal irritation. The treatment would be by evacuation and demulcents.

Disinfection of Excreta.—Six ounces of chlorinated lime are mixed with a gallon of water; a quart of this is added to each discharge and allowed to stand an hour.

Sterilization of Water.—Five to 15 pounds of chlorinated lime are used per million gallons according to the impurities and other conditions. This imparts a slight taste, but no other bad effects have been demonstrated. On a small scale a level teaspoonful is rubbed with 4 cups of water and a teaspoon of this solution is added to 2 gallons of the drinking water, and left for at least ten minutes.

For snake bites, 10 c.c. of a 1 per cent. solution is injected hypodermically about the wound (Calmette, 1907).

For the disinfection of the hands, these are moistened and rubbed with a little dry chlorinated lime and washing-soda.

Labarraque's solution is used as a deodorant on fetid ulcers, being diluted 10 or 20 times. Chlorinated lime itself has been used on wounds; 2 tablespoons of the compound being dissolved in a basin of warm water and used as a lotion, twice daily (Muench, 1915). Internally, it has been tried as a gastro-intestinal antiseptic, but would be useless in the presence of organic matter. Liq. Chlori Co. is employed as a gargle in infections of the throat, being diluted with 6 or 8 parts of water.

Surgical Solutions of Hypochlorites.—(Dakin-Carrel Solution.)—The experience of the war shows that the continuous saturation of wounds with dilute hypochlorite solutions practically abolishes sepsis, dissolves dead tissue, and promotes healing. The skin must be protected by petrolatum gauze, since it is often irritated even by the correct solution.

It must be remembered that the solution is merely a tool to a specially developed surgical technic (Carrel and Dehelly, 1918) and its success depends on the care with which the principles of the technic are followed. To be effective, the solutions must contain between 0.43 and 0.48 per cent. of available chlorine corresponding to 0.45 to 0.5 per cent. of NaOCl. Higher percentages are too irritant. The alkalinity must be adjusted to pH 9–10, for the tissues are more irritated on either side of this range (Cullen and Austin, 1918; Cullen and Taylor, 1918).

Since the hypochlorite tends to become alkaline by hydrolysis, it is necessary to add a buffer. The U.S.P. utilizes sodium phosphate for this purpose; the Daufresne formula, widely-used abroad, employs a mixture of sodium carbonate and bicarbonate; the original buffer was sodium borate. The preparation and titration of the U.S.P. solution is fairly simple. It must be protected from light and not be kept longer than a week. More permanent solutions can be prepared by electrolysis and the addition of a trace of permanganate or sodium silicate.

Solvent Action.—Hypochlorite solution is markedly solvent for necrotic tissues, even when the reaction is strictly neutral (Taylor and Austin, 1917). This helps to give better access to the bacteria. At best, however, the action is superficial and damaged tissue must be promptly excised.

Chloramine and Dichloramine T are without solvent action (Taylor and Austin, 1917).

Living Tissues.—There is also a fibrinsolvent action on living tissue cultures (Lambert, 1916). However, the injury to the phagocytes and other living cells is distinctly less serious than with most antiseptics.

Ligatures.—Silk ligatures are soluble in hypochlorite, and can therefore not be used with it. Catgut ligatures tend to slip, and thus incline to secondary hemorrhage (K. Taylor, 1917).

Toxic Effects from Serous Cavities.—Intraperitoneal injection produces experimentally marked irritation, corrosion, collapse and death.

Intravenous injection is relatively less toxic; but larger doses cause laking and delay the coagulation time (Mann and Crumley, 1918). The hypochlorite is rapidly destroyed by the blood serum, which partly accounts for the low toxicity (Dakin, 1916).

Blood-coagulation.—The addition of Dakin's solution to blood (1:10) prevents clotting by interfering with the thrombin. Clotting occurs if tissue extract is added, so that the interference would not be important in wounds (Githens and Meltzer, 1918).

Chloramine T; *Sodium Para-toluene Sulphonchloramide* (also called *Chlorazene*).—This may be used in place of Dakin's solution and has the advantage that its watery solutions are practically stable. In equimolecular solution it is about four times as germicidal as NaClO . This may perhaps be explained by less side-reactions with non-bacterial proteins. Weight for weight, the germicidal power is about the same. It is less irritating and has but little solvent action on necrosed tissue. It is decomposed by oils.

Application.—It is employed in wounds as 1 to 2 per cent. solution by the saturation technic. A "paste" of 1 per cent. of the drug in 5 per cent. sodium stearate is mildly antiseptic and is used to prevent re-infection of wounds.

Strengths of solutions for eye, 0.1 per cent.; nose and throat, 0.2 per cent.; bladder and urethra, 0.25 per cent. (Dakin, 1916; Eicher, 1917).

Dichloramine T; *Toluene Parasulphondichloramide*.—This is much more germicidal than chloramine T. Only traces dissolve in water, but it is readily soluble in most organic solvents and oils, sparingly in paraffin and petrolatum. When such solutions are applied to the tissues, they give up the drug very slowly and thus exert a continuous antiseptic action, until all of the SO_2NCl_2 dichloramine T has been used up. A single application therefore lasts for hours, or even a day, according to the strength of the solution (Dakin, Estell, etc., 1917).

The results are about as good as with Dakin's solution; whilst the application is more convenient. There is but little irritation of the skin. Catgut is not affected, so that the danger of secondary hemorrhage is avoided (F. Rosengarten, 1917; Lee and Furness, 1918).

On the other hand, the solution causes rather painful though short smarting of sensitive wounds; is more or less irritant to granulations; and is said to retard epithelization; the dressings adhere to the wound, causing mechanical injury (Morrison et al., 1918).

The solvent action on dead tissue is less marked than with Dakin's solution (Taylor and Austin, 1917). However, Dakin's solution and Chloramine T tend somewhat to prolong capillary hemorrhage (Hanzlik, 1918).

Application to the peritoneum produces inflammation (Reismann and Magoun, 1918). Injection into the gall-bladder is followed by induration. Introduction into the pleura is followed by rapid death (reflex?) (Grey, 1918).

Application.—The dichloramine T is generally applied as solution in "chlorcosane" (N.N.R.), a paraffin liquefied by chlorination. These solutions deteriorate rather rapidly, but retain considerable activity for a week or longer.

The usual concentrations are: for *open wounds* 2 to 10 per cent.; sterilization of the *nasopharynx*, 2 per cent. spray for fifteen minutes, several times daily (Dakin and Dunham, 1917); for *eye-infections*, 0.5 to 1 per cent. every four hours (Green and Green, 1918).

Contact with yellow petrolatum destroys dichloramine T very rapidly. A paraffin ointment (Surgical paraffin, 3; liquid petrolatum, 7) is very much less destructive, and may be used as a covering, especially in burns, to prevent adhesion of dressings to the wound (Sollmann, 1910).

Solvents for Dichloramine T.—These are discussed by Hessler, 1918.

Halozone.—*Para-sulphon-dichloramino-benzoic Acid*, N.N.R.—This was introduced by Dakin and Dunham, 1917, for the extemporaneous purification of drinking water (4 mg. per liter). It sterilizes in about 30 minutes, and has very little taste.

PREPARATIONS

* *Calx chlorinata* (Calx Chlorin.), U.S.P., B.P.; Chlorinated Lime (Chloride of Lime, Bleaching Powder).—A product resulting from the action of chlorine upon calcium hydroxide and containing 30 per cent. of available chlorine. Consists mainly of a mixture or weak compound of calcium hypochlorite and calcium chloride. It occurs as a grayish-white granular powder of chlorine odor and repulsive salty taste. It is only partially sol. in water or alc.

Liq. Calcis Chlorin., B.P.—10 per cent. of Calx Chlorin., representing 3 per cent. of available chlorine.

* *Chloramina* (Chloram.); U.S.P.; Chloramine Sodium Paratoluenesulphonchloramide, Chloramine T [$C_6H_4(CH_3)(SO_2NNaCl) \cdot 3H_2O$].—Contains not less than 11.5 per cent. and not more than 13 per cent. active chlorine. U.S.P. White or faintly yellow crystals or crystalline powder having a slight chlorine odor; slowly decomposes on exposure to air, losing chlorine. Sol. in water, (1:7), boiling water, (1:2). Insol. in benzene, chloroform and ether. Decomposed by alcohol.

Dichloramina (Dichloram.), U.S.P.; Dichloramine, Dichloramine T, Paratoluenesulphondichloramide [$C_6H_4(CH_3)(SO_2NCl_2)$].—Contains not less than 28 per cent. and not more than 30 per cent. of active chlorine. Pale yellow crystals or yellowish crystalline powder, having odor of chlorine. Decomposes on exposure to air, losing chlorine. Almost insol. in water. Sol. in eucalyptol and in chlorinated paraffin hydrocarbons. Decomposed by alc.

Paraffinum Chlorinatum (Paraff. Chlorinat.), U.S.P.; Chlorinated Paraffin (Chlorcosane).—A chlorinated paraffin, used as a solvent for Dichloramine. A light yellow, clear, thick oily liquid; odorless; stable in air. Its chlorine is not "active" nor antiseptic, but serves merely to protect the dichloramine.

Liquor Sodæ Chlorinata (Liq. Sod. Chlorin.), U.S.P.; B.P.; (Labarraque's Solution). Not less than 2.5 per cent. of available chlorine. Made by decomposing Calx Chlorin. with Sod. Carb.

Javelle Water is a similar preparation of chlorinated potash.

* *Liquor Sodæ Chlorinata Chirurgica* (Liq. Sod. Chlorinat. Chir.), U.S.P.; Surgical Solution of Chlorinated Soda (Modified Dakin's Solution).—Prepared by the interaction of sodium phosphate and assayed chlorinated lime. Yields from 0.43 to 0.48 per cent. of available chlorine, and tested for the proper alkalinity.

Iodine and Bromine.—These are also local irritants, corrosives and antiseptics; but it seems more convenient to consider them in connection with the Iodides and Bromides; see Index.

PHOSGENE; CARBONYL CHLORIDE; $COCl_2$

Mechanism of Action.—Phosgene is fairly indifferent in itself; but in the presence of moisture, it decomposes with the production of hydrochloric acid:

Its effects are therefore relatively slight in the upper air-passages, where the moisture is relatively small, and reach their maximum in the alveoli, where the air is saturated with water. With prolonged inhalation, however, sufficient is decomposed in the bronchi and trachea to produce corrosion.

The site of action, as determined by the decomposition, probably also explains the greater toxicity of phosgene, as compared with chlorine. The slight degree of the irritation of the sensory nerves in the upper air passages does not suffice to deter from the inhalation of the gas, so that the patient is likely to inhale it more deeply than he would equivalent concentrations of chlorine or other directly irritant vapors. Moreover, the reactive chlorine would be partly neutralized and bound in the upper air passages, whilst the indifferent phosgene would escape this destruction.

History and Use.—Previous to the war, this substance was known in toxicology mainly as the irritant product of the combustion of chloroform. Its use in gas warfare followed soon after that of chlorine. It incapacitates the men more slowly than chlorine, but is

more dangerous in the end. For physical reasons, it was generally mixed with some chlorine when used as clouds. It was also employed extensively in shells.

Properties.—Phosgene is a gas at ordinary temperatures, but liquefies at 8.2°C . It may be prepared by passing a mixture of carbon monoxide and chlorine over heated charcoal.

Limits of Tolerantion.—The highest concentrations that can be breathed without prompt distress are 1:50,000 to 1:500,000; generally about 1:125,000. Even this, however, produces definite eye irritation. Gas clouds generally contain about 1:10,000.

The high mortality may be judged by the result of animal experiments: Of dogs exposed for half an hour to concentrations of 1:17,000 to 13,000 about 42 per cent. died within two days; with concentrations 1:13,000 to 1:10,000 the deaths were 62 to 69 per cent.

Differences in Symptoms from Chlorine.—The eye-irritation is stronger than with chlorine.

The sensory irritation of the respiratory passages is much less than with chlorine; for the irritation begins in the finer bronchial division, beyond the sensory nerves. Consequently there are generally no acute symptoms or cough. If cough occurs, it is less violent than with chlorine, so that there is much less emphysema.

Although cyanosis and asphyxia may develop promptly, the ordinary onset is slow and insidious. The soldiers usually felt little inconvenience for an hour or two except some weakness; and then developed progressive pulmonary edema, with "grayish-white" collapse, that may soon terminate in death.

Phosgene gas is much more likely to be followed by circulatory collapse; *i.e.*, it is much more likely than chlorine to develop irrecoverable pulmonary edema.

Protection.—Phosgene is not nearly as reactive as chlorine, and caused considerable difficulty in the early days. The first special masks contained alkaline sodium phenate. Later patterns were saturated with methenamine. However, the ordinary respirators confer complete protection.

Superpalite, Diphosgene Trichloromethyl-chloroformate (Cl COOC Cl_3).—This was the chief constituent of the "Green cross" shells, where it was usually mixed with some chloropicrin ("vomiting gas") or diphenyl chlorarsine ("sneezing gas"). It was perhaps the principal "killing" gas for shells, and is highly effective, acting essentially like phosgene, *i.e.*, by the liberation of hydrochloric acid on contact with water. The pathology and treatment are identical with those of phosgene.

It is an oily liquid, of disagreeable, suffocating odor.

Palite, Chloromethyl-chloroformate ($\text{Cl COOCH}_2\text{Cl}$).—This is a liquid which was also used extensively in shells. It belongs to the same class as superpalite and phosgene.

Chloropicrin, "Vomiting Gas," Nitrochloroform, Nitro-trichloro-methane ($\text{C Cl}_3\text{NO}_2$).

All irritants, even the asphyxiants, are likely at times to provoke vomiting; but chloropicrin was used in the war particularly for this purpose.

It is a neutral, colorless fluid, boiling at 113°C . It was therefore used in shells, but may be used in gas clouds if mixed with more volatile substances. It was intended partly for the purpose of inducing the men to remove their masks, and thus inhale the more toxic substances (diphosgene, diphenyl-chlorarsine), with which it was generally mixed. However, it is itself a potent pulmonary irritant, intermediate between chlorine and phosgene.

Effects.—Chloropicrin irritates all surfaces. It therefore produces lachrymation, bronchitis, and pulmonary edema, as well as vomiting. It also irritates the skin.

Lachrymation.—Dilutions of 1:1,000,000 are detected by the eyes of most subjects. Concentrations of 1:200,000 would incapacitate victims within ten minutes. The eyes smart and pain, as with all lachrymators.

Respiratory Effect.—There is considerable irritation of the throat, cough, etc. Exposure is generally followed by bronchitis and asthmatic attacks. Death may follow from the pulmonary complications.

Blood Concentration.—In experimental exposures of dogs to moderate concentrations the blood picture is that of phosgene poisoning, *i.e.*, a pre-edemic fall in hemoglobin, followed by a rise as edema develops. With high concentrations, the edema may set in so rapidly that the hemoglobin appears increased almost from the start.

Emetic Effect.—This is presumably due to direct gastric irritation from swallowing saliva impregnated with the poison.

Skin.—Contact with the liquid causes severe burns, usually with blistering, and may lead to ulceration. Abrasions, if exposed to the vapors, tend to become septic.

Kidneys.—These appear to be injured more frequently than with any of the other "gases." For this reason prolonged exposure is dangerous even in very low concentrations.

After-effects.—Chloropicrin poisoning is likely to be followed by serious sequels: Severe anemia, with general asthenia; weak and irregular heart, sometimes cardiac dilation; the patient ages rapidly.

There is a liability to recurrent asthmatic attacks, leading to emphysema. (These are treated like ordinary asthma, by epinephrine, morphine, and atropine.)

Those who have been poisoned appear to be hypersensitive to the poison. This is also observed in animals.

NITRIC VAPORS, CHIEFLY NITRIC PEROXIDE (NITROUS ACID)

Occurrence.—These constitute the brown vapors arising from the action of nitric acid on metals. They may be formed in various chemical industries, by all kinds of nitration processes, especially in the manufacture of nitrocellulose and picric acid, and thus give rise to "fume-sickness." They are also produced in large amount in the combustion (not in the explosion) of nitroglycerin and gun-cotton. When they develop in confined space, they may be very dangerous.

Effects.—These are peculiar by the long delay in the onset of the pulmonary edema. The cause of this has not been explained.

Immediate Effects.—During exposure, there is some irritation of the eyes, and of the respiratory mucosæ; but this subsides promptly when exposure ceases. The patient may then feel perfectly normal for four to eight hours.

Delayed Effects.—If the primary exposure has been sufficient, this latent period is followed by the rapid development of pulmonary edema, entirely similar to that of phosgene, and often ending fatally within 48 hours (F. C. Wood, 1916; A. Hamilton, 1917).

The treatment and the post-mortem findings correspond to those of chlorine and phosgene.

Protection.—The fumes are freely soluble in water, and a damp cloth furnishes considerable protection. A sponge wetted with sodium carbonate solution, or the army gas-masks, are more effective.

Sulphur Trioxide, SO_3 .—This belongs to the simple respiratory irritants, and resembles chlorine. It is a solid, forming strongly acid fumes on contact with moist air. It was used somewhat in grenades and shells.

Dimethyl Sulphate $(\text{CH}_3)_2\text{SO}_4$.—This is a liquid of high boiling point ($188^\circ\text{C}.$), said to have the odor of onions. It was used in hand-grenades.

It is a strong corrosive of all surfaces, producing lachrymation, skin-corrosion, and pulmonary edema.

The edema may be localized in a single part of the lung, probably as a consequence of obstruction of a bronchus by inflammatory pseudomembrane. This would produce the effect of a cupping-glass on the corresponding portion of the lung (Auer, 1918).

A peculiar analgesia of the skin has been described, which in animals is said to last for six months after exposure. It does not include the nerve-trunks. (Auer, 1919.)

The treatment is as for chlorine. The local effects are treated with alkalis.

LACHRYMATORS

Benzyl and Xylol Bromide.—These were used in "tear-shells." The original lachrymators were *benzyl bromide* ($\text{C}_6\text{H}_5\cdot\text{CH}_2\text{Br}$) and *xylol bromide* ($\text{CH}_3\text{C}_6\text{H}_4\cdot\text{CH}_2\text{Br}$). These are liquids of rather high boiling point (175 and $215^\circ\text{C}.$), made by bromating the higher fractions of coal-tar distillates. Their odor is reminiscent of mustard; most of the lachrymators have a similar odor.

Effects.—Dilutions of 1:1,000,000 make the eyes water severely. Somewhat stronger concentrations also make the eyes smart; and as the concentration increases the tears and the burning pain in the eyes blind the man and thus put him out of action.

Ordinarily, the symptoms go no further, and recede rapidly after exposure ceases. Within an hour or two the man is practically normal, except for slight hyperemia of the eyes, which may last twelve hours.

There are no toxic after-effects, and the men are fit for duty as soon as the eye irritation lets up. No special treatment is needed. Lavage with 1 per cent. bicarbonate sol. is advisable.

The lachrymators also produce pulmonary irritation; but the benzyl and xylol bromides do not reach a sufficient concentration to produce respiratory symptoms.

Other Lachrymators.—*Benzyl Chloride*, $\text{C}_6\text{H}_5\cdot\text{CH}_2\text{Cl}$. This acts like the bromide, but is less effective. It has been used in shells.

The following lachrymators, also used in shells or hand grenades, produce more respiratory irritation, and thus approach the chlorine and phosgene types:

Bromo Ketone.— $\text{CH}_2\text{Br}\cdot\text{CO}\cdot\text{C}_2\text{H}_5$ or $\text{CH}_2\cdot\text{CO}\cdot\text{CH}\cdot\text{Br}\cdot\text{CH}_3$ (Shells).

Di-bromo-ketone.— $\text{CH}_3\cdot\text{CO}\cdot\text{CHBr}\cdot\text{CH}_2\text{Br}$ (Shells).

Bromo-acetone.— $\text{CH}_2\text{Br}\cdot\text{CO}\cdot\text{CH}_3$ (Grenades).

Chloro-acetone.— $\text{CH}_2\text{Cl}\cdot\text{COCH}_3$ (Grenades).

Dichloromethyl Ester.— $(\text{CH}_2\text{Cl})_2\text{O}$ (Shell).

Chlorosulphonic Acid.— $\text{SO}_3\cdot\text{HCl}$ (Grenades and Smoke-pots).

Methylchlorosulphonate.— $\text{CH}_3\cdot\text{Cl}\cdot\text{SO}_3$ (Grenades).

Phenyl-carbylamine Chloride.— $\text{C}_6\text{H}_5\text{NC}\cdot\text{Cl}_2$ (Shells); probably the principal lachrymator used by the Germans.

Acrolein.— $\text{CH}_2\cdot\text{CH}\cdot\text{CHO}$.

Stannic Chlorid.— $\text{Sn}\cdot\text{Cl}_4$.

Bromacetic Ether.— $\text{CH}_3\text{BrCOOC}_2\text{H}_5$.

Iodacetic Ether.— $\text{CH}_2\text{I}\cdot\text{COOC}_2\text{H}_5$.

“SNEEZING GAS”: DIPHENYL CHLORARSINE, “BLUE CROSS SHELLS” (C_6H_5)₂AsCl

Uses.—This was used in shells, mixed with high-explosive shells, shrapnel or other gas-shells. It is quite toxic, but apparently was used more with the idea of producing sneezing that would make it impossible to keep on the masks. It was not considered a military success.

Sternutatory Effect.—The substance is solid, and was used as a very fine powder. Diffused in the air in the proportion of 1:1,000,000 it produces intolerably violent sneezing for some 15 minutes. Even more dilute mixtures are effective sneezing agents.

Higher Concentrations.—These act as respiratory irritants. With animals, fatal concentrations produce inflammation of the whole respiratory tract; fibrinous bronchitis, pulmonary edema, or pneumonia. The toxicity is as great as that of phosgene (Underhill, 1918).

Intraperitoneal injections also produce pulmonary congestion. There is a conspicuous absence of the intestinal and renal changes produced by ordinary arsenicals.

FIXED IRRITANTS AND ASTRINGENTS

CAUSTIC ACIDS

Dilute acids alter the surface charges and the solubility of colloids, and produce stimulation and irritation. Concentrated acids destroy the tissues by direct chemical action and are therefor corrosive. They convert the proteins into acid-proteinates, which are soluble in concentrated and in very weak acids, but insoluble in moderately strong acids. Concentrated acids are therefor penetrating caustics, and moderately strong acids are astringents. The *connective tissue* undergoes a rather peculiar change. It is not dissolved, but is softened and rendered more soluble in boiling water. (This explains why meat becomes more tender on keeping.) The concentrated acids have a similar effect upon *epithelium*. Without actually dissolving it, they soften it in such a manner that it is readily detached. Dilute acids, on the other hand, harden it.

The concentrated acids have an affinity for water, and withdraw this from the cells. This affinity is so strong in the case of concentrated H_2SO_4 that not only the formed water is withdrawn from the tissues, but the elements H and O are split off from their chemic combinations with carbon, leading to carbonization. All soluble acids and acid salts dissolve calcareous material, for instance, the enamel of the teeth.

Members.—The most typical acids in regard to the local action are *sulphuric* and *hydrochloric acid*. *Nitric acid* produces the same effects, but differs from these in its chemic action, forming xanthoproteic acid from the proteins. *Sulphurous acid* also has a marked corrosive power. *Hydrofluoric acid* has a specific toxic action, penetrates very deeply, and is especially strongly corrosive, producing obstinate ulcers. Its inhalation from air containing 0.02 per cent. produces acute catarrhal irritation. Of the *organic acids*, those of the fatty series act similarly, but are weaker. *Trichlor*

acetic acid is the most corrosive of these. *Oxalic acid* occupies a place by itself on account of its specific action, produced probably by the precipitation of the calcium.

The *compound acids*—such as ethyl-sulphuric, etc.—act like organic acids. The *aromatic acids* act partly as acids, but this is greatly obscured by their collapse action.

The irritant action of the acids is also shared to some extent by the *acid salts*, acid tartrates, acid sulphates, etc.

Uses.—Because of the intense pain, deep penetration and extensive scar formation, acids are not desirable cauterizants. *Nitric* and *trichlor-acetic acid* form relatively firm eschars, so that their action is more circumscribed and less painful. *Sulphuric acid* has been made into a paste with various inert powders (charcoal, sawdust, lead sulphate, etc.) to localize its action, but is still painful and difficult to control (Pusey, 1913). *Lactic acid* has a relatively mild action on normal tissues. *Chromic acid* may cause poisoning when used as a caustic.

Antiseptic Action.—The destruction of proteins makes acids efficient antiseptics. Even quite dilute solutions, such as the gastric juice, suffice to limit the growth of bacteria. The concentrated acids destroy them outright.

Local Effects of Dilute Acids.—These produce a mild irritation, and at the same time harden the epithelium, without destroying it. They differ from the volatile organic irritants in that they do not penetrate so deeply, and do not cause nephritis.

They may be used in the form of baths, in the strength of about 30 c.c. (1 ounce) of concentrated acid to the bath (30 gallons). Or they may be applied as lotions. Formic acid especially is applied in the strength of about 4 per cent. or 5 per cent. in alcohol.

Acids are used to harden the epidermis against excessive secretion of sweat (sweating feet). For this purpose 5 or 10 c.c. of concentrated hydrochloric acid are put in a basin of water and the feet placed in this until they become painful. This is done about twice a week.

The irritant action of the volatile acids is sometimes employed to produce reflex stimulation of the central nervous system by inhaling vinegar, etc.

Poisoning by Concentrated Acids.—This presents the usual phenomena of caustic poisoning. It is extremely painful. The “coffee-grounds” vomit is characteristic. Scar formation and stenosis are frequent. The prognosis and toxic dose depend upon the concentration, and the parts affected. Sulphuric acid poisoning is the most common.

The *treatment* consists in liberal dilution with water, and the administration of mild alkalies, preferably magnesia, but in its absence, of chalk or even sodium bicarbonate or soap. This should be followed by a demulcent, a tumbler of oil, or better of thin flour paste.

Continued exposure to the vapors of acids, such as occurs in certain trades, give rise to chronic bronchitis. They also attack the teeth and from these the necrosis may spread to the jaw, as with phosphorus.

PREPARATIONS

Acidum Hydrochloricum (Acid. Hydrochl.), U.S.P., B.P.; Hydrochloric Acid (Muriatic Acid).—About 32 per cent. of HCl. Colorless, fuming liquid. Pungent odor. The *commercial acid* (strength = 31 to 33 per cent.) has a golden yellow color due to Fe and free Cl. Since it often contains As, it should not be used in internal medicine.

Acidum Lacticum (Acid. Lact.), U.S.P., B.P.; Lactic Acid.—A liquid containing Lactic Acid (optically inactive α -hydroxypropionic acid, $\text{CH}_3\text{CHOH-COOH}$) and lactic anhydrides. A colorless, or slightly yellow, syrupy liquid, nearly odorless, acid taste, absorbing moisture on exposure to air. Miscible with water, alc. or ether. *Dose*,

1 to 2 c.c., 30 to 60 minims, B.P. Used as caustic, especially for dissolving diphtheritic membranes.

Acidum Nitricum (Acid. Nitric), U.S.P., B.P.; Nitric Acid.—About 70 per cent. of HNO_3 . Fuming liquid, very caustic and corrosive. Peculiar, somewhat suffocating odor. Used as a caustic for warts (glass rod); against hyperhydrosis of feet (1 to 2 ounces to pail of water); as disinfectant (corrodes metal vessels or pipes).

Commercial nitric acid contains about 60 to 64 per cent.; the "fuming" acid is almost absolute HNO_3 , saturated with NO_2 .

Acidum Nitro-hydrochloricum Dilutum, B.P.—Nitric acid, 24 c.c.; Hydrochloric acid, 32 c.c.; Water, 200 c.c.; kept fourteen days before use. *Dose*, 0.31 to 1.2 c.c., 5 to 20 minims. B.P., diluted. On account of the free chlorine, it may be supposed to have a stronger local irritant action than HCl. It is popularly supposed to "stimulate the liver," but its action does not differ in kind from that of other acids.

Acidum Osmicum, Osmic Acid, OsO_4 .—Intraneural injections are used to produce degeneration of nerves for the relief of persistent neuralgias (Billroth and Neuber, 1885). The treatment is best applied by injecting $\frac{1}{2}$ to 1 c.c. of a fresh 1 to 2 per cent. solution directly into the, preferably exposed, nerve. The result is sometimes immediate, but more commonly it is not complete until after one or two weeks, or it may even fail entirely. If successful, the effects persist at least for several months, when it may become necessary to repeat the injection. They are rarely if ever permanent. The local reaction is always painful but not serious. It is probably not advisable to use osmic acid in the presence of renal disease (Eastman, 1906).

Acidum Sulphuricum (Acid. Sulphuric.), U.S.P., B.P.; Sulphuric Acid.—About 95 per cent. of H_2SO_4 . An oily, colorless liquid, acquiring a brown color if exposed to dust. Very intensely corrosive, charring organic substances. Miscible in all proportions with water or alc. with the evolution of much heat. (Such mixing must be done very cautiously by slowly pouring the acid into the water, under constant stirring.) The *Commercial Sulphuric Acid* (Oil or Vitriol) is very apt to contain arsenic, and should not be employed in medicine.

Acidum Trichloroaceticum (Acid. Trichloracet.), U.S.P.; Trichloroacetic Acid.—A monobasic organic acid, CCl_3COOH . Colorless, deliquescent crystals, having a slight, characteristic odor. Very sol. in water or alc. Used in substance or strong solution, especially against warts, being less painful than nitric acid.

THE LOCAL ACTIONS OF METALLIC SALTS

Mechanism of Action.—Metallic salts combine with proteins to form more or less difficultly soluble compounds containing varying amounts of the metal and proteins. The acid of the metallic salt is thus set free. If, for instance, a solution of ferric chloride is added to egg-albumen, the result is an albuminate of iron, and free hydrochloric acid.

The local effects of metallic salts, therefore, rest on two factors: the precipitant action of the metal, and the irritant action of the liberated acid. Both influence the total effect.

Corrosive and Astringent Metallic Salts.—Some of the metal albuminates are almost insoluble in water; some are soluble in excess of protein, especially when neutral salts are present; others are not. If the precipitate is soluble, there is no obstacle to the penetration of the metal, and its action, irritant or caustic, is deep. If, on the other hand, the precipitate is insoluble, as in the case of lead salts, penetration cannot take place; the irritation is confined to the surface, and an astringent action results. In regard to this, the metals stand in about the following order: The most astringent is lead; then comes aluminum; then iron; then zinc, copper, silver, and tin, which are about on a level; the most caustic is mercury. As to the liberated acids, the strongest caustic action appears in hydrochloric acid; then comes nitric acid; then sulphuric; then phosphoric; the weakest of all are the organic acids—acetic, citric, and tartaric.

By proper combination between the metals and the acids, one may obtain any grade of action from pure caustic to pure astringent.

The most typical caustic would be mercuric chloride, the most typical astringent, lead acetate.

The strength of action depends also upon the concentration in which the salt is used, and this is often limited by its solubility. The chloride of silver would, theoretically, be a stronger caustic than the nitrate, but since it is not soluble, it can not be used in the same concentration.

It must not be forgotten that the irritant, the astringent, and the caustic action, are merely degrees of the same process. The astringent action always precedes the caustic action; and, consequently, by proper dilution, one may obtain astringent effects from salts which are ordinarily purely caustic. For instance, silver nitrate can be so graduated in strength as to have a purely astringent action, without any caustic effect whatever.

It is, therefore, impossible to establish a perfectly definite classification between the metallic salts. An approximation to it is given in the following table:

Mainly Caustic: All Hg salts; ZnCl_2 ; SnCl_4 ; SbCl_3 ; tartar emetic; CuSO_4 .

Both Caustic and Astringent: Fe salts; ZnSO_4 ; ZnAc_2^* ; CuAc_2 ; AgNO_3 ; $\text{Pb(NO}_3)_2$; PbI_2 .

Mainly Astringent: Alum; PbAc_2 ; Pb_2OAc_2 ; ZnO ; Bi subnitrate; white precipitate.

The Caustic Action of Metallic Salts.—This was formerly used quite extensively, but it has now been largely abandoned. Most are not sufficiently powerful for this purpose; others are too toxic, being absorbed in sufficient amount to produce poisoning. To the latter class belong arsenic, antimony, and mercury. Zinc chloride and antimony chloride (Butter of Antimony) are very active caustics, but rather too diffident. Their scab is so soft that their action can not be kept within bounds. In fact, of all the metallic caustics, silver nitrate in the form of sticks (Lunar Caustic), and to a less extent copper sulphate, are alone used to produce a purely caustic action. *Arsenic*, were it not for its toxicity, would be a useful corrosive. Its action is so slow that it can be very readily limited. It was believed to destroy only pathologic formations, leaving healthy tissue intact. This would be easily understood, from the fact that the former are much less stable. *Silver nitrate* is also quite easily controlled, since its action may be stopped at once by washing with NaCl , which converts it into AgCl .

Metallic Salts Used for Astringent Action.—The soluble zinc salts are most commonly used on mucous membranes and ulcers; the aluminum salts are employed especially on the skin. Iron salts are used in gargles. Silver nitrate is applied in dilute solutions. Lead salts are effective astringents, but should not be used internally, nor for any length of time externally, because of the danger of chronic poisoning.

Mixtures of astringents are sometimes employed; but they have no serious advantage, and their penetration can not be controlled as exactly.

Insoluble Metallic Compounds.—These are also somewhat astringent; partly because of their mechanical action, partly because small quantities of the metal are dissolved by the protein of the tissues. To this class belong zinc oxide and carbonate, and bismuth subnitrate and subcarbonate.

Therapeutic Applications.—For use on open wounds, ulcers, abscesses, etc., for the astringency and a mild stimulation leading to repair, silver nitrate is used extensively, also the soluble zinc salts and alum. They are applied in strengths of from 12 per cent. to 5 per cent. The insoluble astringents may be used as dusting-powders, or in the form of ointments—5 per cent. to 20 per cent. It must not be forgotten that absorption is fairly free from open surfaces, and calomel, bismuth, lead, etc., must be used with caution. Zinc oxide is quite safe, and is one of the most useful.

The *mucous membranes* which are easily accessible to the local action of astringents are those of the mouth conjunctiva, nose, genito-urinary tract, and rectum. The same salts as in the case of open wounds can be

*Ac = Acetate.

used, as also tannin. They are employed in somewhat weaker solution, as gargles, washes or injections. The usual strength is from $\frac{1}{2}$ to 1 per cent. For vagina or rectum, double this; in the conjunctiva and nose, perhaps one-fourth of this. In the case of the genito-urinary tract, irritation is particularly undesirable. For this reason non-irritant protein compounds of silver have become popular.

Astringents cause actual constriction of the mucous membranes, and may in this way bring about the complete disappearance of small *polypi*.

In the *alimentary canal* the astringents are useful mainly by diminishing results of inflammation; *i.e.*, the vomiting and diarrhea.

Against *vomiting*, especially when caused by ulceration, bismuth subnitrate or subcarbonate seem to be the most useful. These act not only in virtue of their astringency, but also somewhat after the manner of inert dusting-powders, affording an artificial protective covering to the walls of the viscus by adhering to them. Silver nitrate is also sometimes used in doses of about 0.01 Gm. ($\frac{1}{16}$ grain), dissolved in water and given three times a day.

Their action on *diarrhea* is entirely similar. Bismuth is again preferred; silver nitrate is often very useful in the summer diarrhea of infants.

Further details will be found under the respective metals.

TANNINS AND VEGETABLE ASTRINGENTS

Actions and Uses.—The tannins are a group of widely distributed vegetable principles, which precipitate proteins and are therefore astringent; and which give blue or green compounds with iron salts. They are less destructive than the metals; and being practically non-toxic they are especially suited for use in the alimentary canal. They do not decrease peristalsis directly, but do so indirectly, by allaying the underlying inflammation. Their employment in diarrhea dates back at least beyond the fourth century B.C.

Methods of Testing Astringent Action.—Ordinarily astringent action depends on the precipitation of the proteins (Mitscherlich, 1842; Lewin, 1881; Harnack, 1889). This may be tested directly; or by measuring the diminished extensibility of tissues, for instance the lungs (Dreser); or by the shortening of tissues which ensues when their proteins are precipitated (Crawford, 1818); or by the property of rendering red corpuscles resistant to hemolysis (Sollmann, 1920); or by the suppression of secretion on the frog's skin (Schuetz); or by observation of blood-vessels in the exposed mesentery (Heinz); or by the clinical response in catarrhs or diarrheas; or very simply and with rather surprising accuracy, by the taste.

Influence of Reaction (H-ion Concentration).—The tannin-protein precipitates are soluble both in acids and alkalies beyond a certain concentration; *i.e.*, precipitation and astringency occur only within a limited range of H-ion concentration. The exact range varies somewhat with conditions; but under ordinary conditions, this lies between $\text{PH} = 1$ and 8.3, *i.e.*, between the acidity of 0.35 per cent. hydrochloric acid or the maximum acidity of the gastric juice; and the alkalinity of a sodium bicarbonate solution, or of the extreme alkalinity of the intestinal juice. The optimum reaction is somewhat toward the acid side, *i.e.*, $\text{PH} = 3$ to 5, or about the turning point of methyl orange which is at $\text{PH} 3.1$ to 4.4 (Sollmann, 1920).

These differences are important for the therapeutic action of tannin. The reaction of most mucous membranes and tissues evidently falls

within the precipitation range; but in the intestinal tract the conditions are rather complicated.

Behavior of Tannin in the Intestinal Tract.—The reaction of the stomach varies. The empty stomach, when resting, has reactions within the precipitation range; and tannin would thus be astringent. With the secretion of acid juice, the reaction would at first become more favorable to precipitation, and astringency would increase.

When taken with food, the food proteins would combine with much or most of the tannin, and the astringent action on the gastric mucosa would be slight. The degree of precipitation would again vary with the reaction: It would at first increase with the acidity; but as this approached a maximum, part of the protein-tannate would be redissolved. The gastric digestion of protein would not modify the conditions materially, since albumoses and probably peptones are also precipitated by tannin.

In the duodenum, the tannin would arrive mainly as tannin-proteinate; partly precipitated and partly in solution, depending on the reaction. Some tannin may have been adsorbed by the precipitate, and thus be present in free form.

On arriving in the duodenum, the unfavorably high acidity of the chyle would be partly neutralized, and the reaction would thus be most favorable to protein-tannin precipitation and therefore to astringency.

In the ileum, the reaction becomes gradually more alkaline and correspondingly less favorable to precipitation. The tannin can therefore precipitate less protein than in the duodenum; and therefore there can be no astringency by the tannin proteinates that arrive from the duodenum; although, if free tannins were added directly to the ileum some precipitation and astringency would occur.

The level of the ileum where astringency ceases varies with the difference in reaction, and perhaps still more with the length of the sojourn in the duodenum. The shorter this sojourn, the less marked will be the difference in the reaction of the chyle at the several levels, and the greater will be the chances of prolonging the astringency. This may be one reason why the constipative effects of tannin are much more pronounced in diarrhea than in normal individuals. In no case, however, does the astringency extend into the large intestines.

Some free tannin is actually added by the complete cleavage and absorption of the proteins; but this also does not extend very far, since the alkaline intestine gradually decomposes tannin into non-astringent compounds.

Masked Tannin Compounds.—The astringent and irritant action of free tannin on the gastric mucosa is undesirable. This has prompted the introduction of various preparations that hold their tannin in such form that its solution or action is delayed; ideally, until it would reach the intestines; or better still, so that the liberation of the tannin would extend through the whole course of the intestine.

Astringent Plant-extracts.—Preparations of krameria, gambir (catechu), kino, etc. have been supposed to act more slowly than tannic acid, because of the protective influence of their colloids. In vitro, they precipitate proteins just as readily; but the colloids probably protect the gastric mucosa somewhat by hindering its contact with the tannin. In practice, however, they have been generally displaced by the synthetic compounds.

Synthetic Tannin Compounds.—The general aim in devising the synthetic compounds has been to make them insoluble in water and acid fluids, and soluble in alkaline solutions. This ideal was based on mistaken views as to the true reaction of the intestinal contents; but these properties are still commonly claimed, although they have not been realized in any instance (Leech, 1920). All the commercial preparations are somewhat soluble in water; and most are about as soluble in dilute acid as in dilute alkali. This is rather fortunate; for the reaction of the small intestines is more often acid than alkaline. The real advantage of the compounds lies in the fact that their tannin is dissolved or becomes active quite slowly, whatever the reaction. The slower this process, the smaller will be the effect on the stomach, and the farther will the astringency extend into the intestines.

The two compounds that have established themselves in practice, are excised tannin albuminate and acetyl-tannic acid.

They are about equally effective astringents in the small intestine. The albuminate has a stronger action on the stomach, while the acetyl would usually extend its astringent action further into the lower intestines. Clinically, however there seems to be little difference between them.

Excised Tannin Albuminates (Albutannin; Tannalbin).—Contrary to the prevailing opinions, these dissolve rather better in artificial acid-gastric juice than in bicarbonate-trypsin solutions. However, their solubility is so slow that they can only be slightly astringent in the stomach. Considerable astringency would develop in the duodenum, when the acidity is reduced; and the effects would continue somewhat into the large intestine, following the cleavage of the undissolved proteinate (Sollmann, 1920).

Tannyl-acetyl Esters (Acetannal; Tannigen).—Commercial brands are mixtures of varying quality; some specimens containing considerable free tannin. The best specimens, however, appear fairly uniform, and but slightly soluble and astringent in acid solution. Bicarbonate dissolves them and hydrolyzes them slowly. The astringency goes parallel to the hydrolysis, so that the action would continue for several hours, and could thus extend into the lower intestines. However, they do not deserve full confidence until the commercial products are more uniform (Sollmann, 1920).

The official "tannic acid" is derived from nut-galls.

In the course of its absorption, tannin is decomposed into the non-astringent gallic acid, pyrogallol, etc.

Varieties of Tannin.—Ordinary "tannin" or gallo-tannic acid is derived chemically by the elimination of a molecule of H_2O from 2 molecules of gallic acid (Tri-hydroxybenzoic acid, $C_6H_2(OH)_3COOH$). The numerous other varieties are of different composition, in many cases unknown. Some are compounds of gallic acid with sugar or with phlorhizin.

Constipative Action.—This has been studied on cats with the X-ray method by Hesse, 1913. In the absence of diarrhea, tannalbin has no effect on the intestinal movements beyond a slight delay in the emptying of the stomach; nor had it any influence on the diarrheas produced by milk-feeding or senna; and but little on the catharsis of castor oil. However, it arrested certain dietetic diarrheas (bread), and that produced by the colon-action of colocynth. Its action is therefore not on peristalsis, but on the inflamed mucosa.

Pharmacologic Peculiarities.—Tannins form more or less insoluble compounds with many metals, alkaloids, glucosides, etc., and are therefore useful as antidotes. They also precipitate proteins, gelatin and connective tissue (leather), and thus act as astringents, styptics, and antiseptics (mainly by depriving the bacteria of food). The different tannins are not equivalent in these respects. Some (which are perhaps misnamed), such as those of coffee and ipecac, are practically non-precipitant. Others present differences in the firmness and solubility of the precipitate, which, when better known, may prove of therapeutic importance.

Fate.—This is imperfectly known; but all of the tannin, even if injected intravenously, undergoes decomposition into gallic and pyrogallic acid and other decomposition products, before being excreted. These appear both in the urine and feces (E. Rost, 1897; the older contradictory statements were based on faulty tests for tannin). Only the insoluble tannates (Tannigen, Tannalbin, etc.) pass in part undecomposed into the feces. The decomposition must, therefore, take place to a large extent in the intestines. With oral administration, the urine contains at most 1 per cent. of the gallate of the tannin.

The use of tannin as antidote has been discussed under "General Toxicology."

The insolubility of tannin compounds has been utilized in securing a more *prolonged local action of the kations*. It will be remembered that this is one reason for the more lasting local effects of galenics as compared with alkaloids. It has been suggested to prepare such combinations artificially, but these have not come into general use.

The effect of the continued administration of small amounts of tannins has considerable importance, because they are contained in a number of beverages; as tea and certain wines. A mild astringent action may be locally tonic and beneficial; but large quantities prove actually irritant, and may lead to gastroenteritis.

Even small amounts of tannin interfere somewhat with *absorption*. This is largely due to their precipitating proteins. But these combinations are again decomposed in the alkaline intestine, so that the interference is not large.

In the actual experiments of Biberfeld (1903) on the absorption of normal saline solution from a Vella fistula, this was accelerated by 0.01 per cent. of tannin; 0.04 per cent. had no effect; 0.1 to 1 per cent. delayed absorption.

On the whole, one may say that the small quantities of tannin ordinarily taken with the food and drink are not injurious; but that large quantities (excessive tea drinking) are probably deleterious. The tannin of coffee is scarcely astringent, and therefore lacks this action.

Effects of Larger Doses.—These produce irritation and corrosion, especially if the stomach is empty; pain, vomiting, diarrhea or obstipation.

PREPARATIONS

**Acidum Acetyltannicum* (Acid. Acetyltan.) U.S.P.; Acetyltannic Acid (Acetannin, Diacetyltannic Acid, Diacetyltannin (H. Meyer, 1894), Tanningen, Tannyl Acetate).—A product obtained by the acetylation of tannic acid. Yellowish-white or grayish-white, slight acetous or odorless powder; darkens on exposure to light. Slightly sol. in water and alc. Practically insoluble in stomach, slowly sol. in intestines. Incompatible with alkalies and with hot water. *Dose*, 0.6 Gm., 10 grains, U.S.P., as capsules.

Acidum Gallicum (Acid. Gall.), $C_2H_2(OH)_3CO_2H + H_2O$.—Occurs in many plants, usually with tannic acid. It does not precipitate alkaloids, albumin, or glue. The reputed astringent effect is perhaps due to a small quantity of tannin which is usually present (Sollmann, 1920). Sol. in water (1:87); freely sol. in alc. (1:4.6) or glyc. (1:10). *Dose*, 1 Gm., 15 gr. Externally, 1 per cent., as weak astringent.

**Acidum Tannicum* (Acid. Tan.), U.S.P., B.P.; Tannic Acid (Tannin, Gallotannic Acid, Digallic Acid); $HC_{14}H_9O_9$.—A tannin obtained from nut-gall. Very sol. (1:1), in water, glyc. and alc. Almost insol. in eth. or chlorof. Watery solutions gradually spoil on keeping, although they still color iron. Incompatible with alkalies, alkaloids, salts of iron and most other metals, proteins and gelatin. *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 0.6 Gm., 5 to 10 gr., B.P. Locally, for urethra, 1 to 2 per cent.; vagina, 5 per cent.; enema, 1 to 2 per cent.; rectal irrigation (cholera) $\frac{1}{4}$ to $\frac{1}{2}$ per cent.; skin and ulcers, 5 to 20 per cent., or the Glycerite.

**Glycer. Acid. Tan.*, U.S.P., B.P.—20 per cent. *Dose*, 2.5 c.c., 40 min., U.S.P.

Ung. Acid. Tan., U.S.P.—20 per cent.

Supp. Acid. Tan., B.P.—0.2 Gm., 3 gr. (against hemorrhoids).

Troch. Acid. Tan., U.S.P.—0.06 Gm., 1 gr.

Troch. Acid. Tan., B.P.—0.03 Gm., $\frac{1}{2}$ gr.

Albumini Tannas, (Album. Tan.), U.S.P., Albumin Tannate (Albutannin, Tannalbin; Exsiccated Albumin Tannate).—Yellowish white, odorless and almost tasteless powder; almost insoluble in water; decomposed by aqueous solutions of alkali hydroxides and carbonates; (slowly and incompletely sol. in intestinal and pancreatic juice). Used in diarrhea, especially of children. *Dose*, 2 Gm., 2 $\frac{1}{2}$ drachms, U.S.P.; in powder or tablets, followed by water; infants, 0.3 to 0.5 Gm. in gruel. Albumin Tannate contains about 50 per cent. of tannic acid (Gottlieb, 1896).

TANNIN-DRUGS

These are very numerous, and many might well be dispensed with. Gambir (Catechu) or Krameria would fulfill all indications.

Acaciæ Cortex, B.P., Acacia Bark.—The dried bark of *Acacia arabica* and *decurrens*. Astringent and demulcent.

Dec. Acac. Cort., B.P.—6 per cent. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 2 ounces, B.P.

Belæ Fruct., B.P.—The fresh fruit of *Aegle Marmelos*.

Ext. Belæ Liq., B.P.—*Dose*, 4 to 8 c.c., 1 to 2 drachms, B.P.

Buteæ Sem., B.P.—The seeds of *Butea frondosa*.

Buteæ Gum., B.P. (Bengal Kino).—The inspissated juice of *Butea frondosa*.

Galla, U.S.P., B.P.; Nut-gall.—An excrescence on the young twigs of *Quercus infectoria* and other allied species of *Quercus* (Oak), induced by the punctures on the leaf-buds and by the deposited ova of a wasp, *Cynips tinctoria*. Contains 50 to 60 per cent. of tannin, 2 to 5 per cent. of gallic acid. *Dose*, 0.5 Gm., 8 gr., U.S.P.

Ung. Gall., U.S.P., B.P.—20 per cent. It is used especially against external hemorrhoids.

Ung. Gall. C. Opio, B.P.—The preceding, with 7.5 per cent. of powdered Opium.

Catechu, B.P.; Catechu (Pale); Identical with Gambir, U.S.P.—A dried extract of the leaves of young shoots of *Uncaria Gambir*.

Tr. Catechu, B.P.—20 per cent., with Cinnamon. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Pulv. Catech. Co., B.P.—Catechu, 40 per cent.; Kino and Krameria, each 20 per cent.; Cinnamon and Nutmeg. *Dose*, 0.6 to 4 Gm., 10 to 60 gr., B.P.

Troch. Catech., B.P.—0.06 Gm., 1 gr.

Catechu Nigrum (Catech. Nigr.), B.P.; Black Catechu.—An extract from the wood of *Acacia Catechu*.

Embelia (Embel.), B.P.—The dried fruit of *Embelia Ribes* and *robusta*. *Dose*, 4 to 16 Gm., 60 to 240 gr., B.P.

Gambir, U.S.P.; Gambir (Pale Catechu); identical with Catechu, B.P.—A dried extract prepared from decoctions of the leaves and twigs of *Ourouparia Gambir*. Contains 33 to 47 per cent. of catechu-tannic acid. *Dose*, 1 Gm., 15 gr., U.S.P.

Tr. Gambir Co., U.S.P. (Compound Tincture of Catechu).—5 per cent. in 50 per cent. alcohol; flavored with cinnamon. *Dose*, 4 c.c., 1 drachm, U.S.P.

Hamamelidis Cortex, B.P.; Hamamelis Bark (Witch Hazel Bark).—The dried bark of *Hamamelis virginiana*.

Tr. Hamam., B.P.—10 per cent. of bark. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Hamam. Fol., B.P.; Hamamelis Leaves.—Fresh or dried. 8 per cent. of tannin (Straub, 1899).

Ext. Hamam. Liq., B.P.—50 per cent. of dried leaves. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

Ung. Hamam., B.P.—10 per cent. of the preceding.

Hæmatoxyli Lignum, B.P.; Logwood.—The heart-wood of *Hæmatoxylon campechianum*. 12 per cent. of Hæmatoxylin.

Dec. Hæmattox., B.P.—5 per cent. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Kino, U.S.P., B.P.; Kino.—The dried juice from the trunk of *Pterocarpus Marsupium*. 75 per cent. of Kino-tannic acid. *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P. It is used especially in gargles, but its popularity is waning.

Tr. Kino, U.S.P., B.P.—10 per cent. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Pulv. Kino Co., B.P.—5 per cent. of opium. *Dose*, 0.3 to 1.2 Gm., 5 to 20 gr., B.P. *Kino Eucalypti* (Kino Eucalyp.), B.P. (*Eucalyptus Gum*, Red Gum).—An exudation from the stem of *Eucalyptus* species. *Dose*, 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Troch. Kino Eucalypti, B.P.—0.06 Gm., 1 gr.

Krameria, U.S.P., *Kramer. Rad.*, B.P.; *Krameria* (*Rhatany*).—The dried root of *Krameria* species. *Dose*, 1 Gm., 15 gr., U.S.P.

Ext. Kramer., B.P.—A dry extract. *Dose*, 0.3 to 1 Gm., 5 to 15 gr., B.P.

* *Tr. Kramer.*, U.S.P., B.P.—20 per cent. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Inf. Kramer., B.P.—5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Troch. Kramer., B.P.—0.06 Gm., 1 gr.

Myrobalanum, B.P., *Myrobalans*.—The dried immature fruit of *Terminalia Chebula*. *Dose*, 2 to 4 Gm., 30 to 60 gr., B.P.

Ung. Myrobal., B.P.—20 per cent.

Ung. Myrobal C. Opio., B.P.—The preceding with 7.5 per cent. of Opium.

Rhus Glabca, (*Rhus Glab.*), U.S.P.; Sumac Berries.—The dried ripe fruit of *Rhus glabra*. An acidulous astringent, used mainly in pharyngitis. *Dose*, 1 Gm., 15 grains, U.S.P.

Fldext. Rhois Glab., U.S.P.—*Dose*, 1 c.c., 15 minims, U.S.P.

Sappan, B.P.—The heart-wood of *Caesalpinia Sappan*; similar to Logwood.

Dec. Sappan., B.P.—5 per cent. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 2 ounces, B.P.

Diarrhæa Mixtures.—These are generally "shot-gun" prescriptions of which the following are types:

Mistura Contra Diarrhæam, N.F. (*Sun Cholera Mixture*).—Equal parts of Tincture of Opium, Capsicum, Rhubarb, Camphor, Peppermint. *Dose*, to one teaspoonful. Or, *Tr. Opium*, *Tr. Catechu*, *Tr. Rhubarb*, *Sp. Peppermint*, *Bismuth subnitrate*. (History, Raubenheimer, 1916.)

ASTRINGENT STYPTICS

All the metallic salts, the irritant as well as the astringent, and also the vegetable astringents, act as local styptics; *i.e.*, arrest capillary hemorrhage. They do so mainly by the formation of precipitates which occlude the lumen of the small vessels, just as it is occluded ordinarily by fibrin. They also injure the vessel walls and thus tend to produce thrombosis. This is claimed especially for zinc chloride.

Astringents can act only when they come into actual contact with the bleeding vessels. They can not act through a large clot of blood, and if such exists, it must first be removed. At one time they were used internally with the idea of producing astringent action in remote places; iron was given by the mouth to check bleeding in the uterus. This was entirely irrational. Their action can not even extend beyond the stomach, since they are precipitated or decomposed in the intestine.

The indications for the use of styptics are to lessen bleeding, especially capillary oozing. They have no effect on spurting arteries or large veins. They are sometimes injected into hemorrhoids, and have even been injected into aneurisms. Their injection into larger vessels is dangerous, as it may produce embolism.

The most useful of the metallic styptics are the iron salts, especially ferric chloride and ferric sulphate. The ferric chloride is used either as the solution, or tincture, quite largely diluted with water. Cotton may be steeped in this, forming "styptic cotton." Next comes alum, especially the burnt alum. Then the soluble tannins in any form.

Other Hemostatic Measures.—Any substance which gives a precipitate with proteins may act as astringent styptic; e.g., dilute acids in concentrations which need not be caustic (vinegar and lemon juice). A number of purely mechanical measures favor the formation of clot; for instance, ordinary cotton or Pengawhar Djembe (this also contains tannin). Cobwebs form a popular and effective means for producing the same result, but are usually septic. One may obtain the same effect by fine powders which have a strong attraction for water. In case of emergency, powdered or granulated sugar is a good styptic, and is at the same time antiseptic. Kephalin and tissue extracts hasten coagulation in vitro but are of little use on wounds. Other styptic measures are position, raising the limb and keeping it quiet so as to reduce the local congestion; local pressure; depression of the vasomotor center by narcotics; direct constriction of the vessels by the application of cold, or by drugs, such as epinephrine, cocaine, etc.

Efficiency of Local Styptics.—This has been tested experimentally by noting the quantity of blood lost when a skin-wound is irrigated with the styptic (Hanzlik, 1918). The efficiency was in the following order; epinephrine, the most active, being taken as the standard:

Epinephrine = 1; pituitary solution = $\frac{1}{4}$; tyramine = $\frac{1}{4}$; acetic acid = $\frac{1}{250}$; ferric chloride = $\frac{1}{600}$; tannin = $\frac{1}{5,000}$; cocaine = trace.

The following actually increase bleeding; antipyrine; apothesine, procaine, and other synthetic local anesthetics; chloramine, cotarine salts, Dakin's solutions, emetine, hydrastis, orthoform, peptone.

AMMONIA

This differs from other alkalies by its volatility.

Use as Counterirritant.—It passes through the stratum corneum of the epidermis, and, acting upon the lower layers of the skin, may produce blisters. It is sometimes used for this purpose instead of cantharides, especially in nephritis, where the latter can not be employed. It is, however, more painful.

It is frequently used in more dilute form as liniment for counterirritation.

The Inhalation of Ammonia.—Free, or in the form of aromatic spirit, or of carbonate, this is used for reflex stimulation in fainting, etc. Care must be used, since too high concentrations of the vapor may produce bronchitis or pneumonia. For man, it becomes insupportable in the concentration of 1:1,000.

Poisoning by Swallowing Ammonia.—This presents the same phenomena as other caustic alkalis except that the respiratory passages are more involved by the inhalation of the vapor. Five to 10 Gm. of the official solution would be toxic; 30 Gm. is generally fatal, although recovery has occurred from 60 Gm.

The *treatment* consists in dilution with large quantities of water, to which vinegar, lemon juice or other dilute acid should be added. This should be followed by a tumbler of olive oil or other salad oil.

For *Preparations*, see Index.

FIXED ALKALIES

These include sodium and potassium hydroxide, which corrode even the skin; quicklime, which because of its limited solubility is caustic only when used in substance; the carbonates of sodium and potassium which are not caustic, but which produce inflammation and necrosis; and the mildly alkaline salts, such as the bicarbonates, borates and basic phosphates which merely soften the epithelium.

The free alkalis combine with the tissue elements to form alkaline albuminates, or with the fats to form soaps, and in this way produce a destruction of substance. They are also very hygroscopic, and withdraw water from the cells, which contributes to the necrosis. The scab which they produce is very soft, and the compounds which they form are very soluble; consequently the alkalis penetrate deeply, are very painful, their action continues for several days, and leads to extensive scar formation. It is therefore difficult to circumscribe their effects. This is only partly remedied by mixing them with the non-diffusible quicklime as in the "*Vienna Paste*," a mixture of equal parts of KOH and CaO, stirred into a thick paste with alcohol.

Poisoning by Caustic Alkalies (Lyes).—This is quite common. Half an ounce of potassium carbonate or an ounce of the liquor would generally be fatal. Sodium carbonate is less toxic. On account of the deep action, *stricture of the esophagus* is a frequent sequel, and the fatality is fairly high.

The *treatment* is the same as for ammonia (see preceding section).

Dilute Alkalies on the Skin.—These soften the epidermis and hair, and emulsify and dissolve fats. They are employed in skin diseases (seborrhea, acne, ichthyosis, psoriasis, and epidermal proliferations); to facilitate the penetration of antiseptic remedies into the skin (in scabies, favus, ringworm); to emulsify cutaneous remedies (mercury, tar, sulphur); as lubricants for liniments (soap liniment); as cleansing agents (detergents), especially in the form of soaps and borax; and as depilatories (especially the sulphides).

Alkaline Baths.—In skin diseases, these are best administered at bedtime. Any of the alkaline salts can be used; such as sodium carbonate or bicarbonate, potassium carbonate, or borax, in the proportion of about 100 Gm. per bath; for lotions, 2 per cent.

The internal actions and uses are discussed in another section, see Index.

Actual and Potential Alkalinity.—The "actual" or immediately effective alkalinity of a solution depends on the dissociated OH ions; but as these combine with the tissues, further OH ions are split off ("potential" alkalinity), which continue the action. The total effect, therefore, depends upon the total quantity of OH ions which can be split off under the conditions of the body (Dreser, 1910). This can be estimated by appropriate indicators.

PREPARATIONS

* *Potassii Hydroxidum* (Pot. Hydrox.), U.S.P.; *Potassa Caustica* (Potass. Caust.), B.P.; Potassium Hydroxide (Caustic Potash, Potassium Hydrate); KOH.—White flakes or masses or pencils; odorless; caustic. Very sol. in water (1:0.9), freely sol. in alc. (1:3). Used as caustic, to remove warts, etc.; and to soften epidermis (2 per cent.).

* *Liq. Pot. Hydrox.*, U.S.P.; *Liq. Potass.*, B.P.—5 per cent. Sometimes used internally as alkali. *Dose*, 1 c.c., 15 minims, U.S.P.; 0.6 to 1.8 c.c., 10 to 30 minims, B.P.; freely diluted.

Potas. Carbonas (Pot. Carb.), U.S.P., B.P. (Salts of Tartar); K_2CO_3 .—White granular powder; odorless; strongly alkaline taste. Very deliquescent. Very sol. in water (1:0.9), practically insol. in alc. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Sod. Hydrox., U.S.P. (Caustic Soda); NaOH.—Dry, white flakes, or fused masses or pencils. Very sol. in water (1:0.9) and alc.

Liq. Sod. Hydrox., U.S.P. (Solution of Soda).—5 per cent. *Dose*, 1 c.c., 15 minims, U.S.P.

* *Sodii Carbonas Monohydratus* (Sod. Carb. Monohyd.), U.S.P.; $Na_2CO_3 + H_2O$.—A white, crystalline, granular powder; strongly alkaline taste. Freely sol. in water (1:3) and in glyc. (1:7); insol. in alc. Used as lotion (0.5 per cent.). Is nearly twice as strong as the ordinary crystallized carbonate. *Dose*, 0.25 Gm., 4 gr., U.S.P.

Sod. Carb., B.P.; Sodium Carbonate (Washing Soda); $Na_2CO_3 + 10 H_2O$ (equivalent to 37 per cent. of Na_2CO_3).—Freely sol. in water (1:2). *Dose*, 0.3 to 2.0 Gm., 5 to 30 gr., B.P.

Sod. Carb. Exsic., B.P.; Na_2CO_3 .—*Dose*, 0.2 to 0.6 Gm., 3 to 10 gr., B.P.

Calx, U.S.P., B.P.; Calcium Oxide (Lime, Quicklime); CaO.—Hard, white or grayish-white masses, or a white powder; odorless, caustic taste. Slightly sol. in water (1:840); sol. in glyc.; insol. in alc. When sprinkled with about half its weight of water, calcium oxide becomes heated, and is gradually converted into a white powder (calcium hydroxide or *slaked lime*). When this is mixed with about 3 or 4 parts of water, it forms a smooth magma (*milk of lime*).

Calc. Hydr., B.P. (Slaked Lime); $Ca(OH)_2$.—White powder.

* *Liquor Calcis* (Liq. Calc.), U.S.P., B.P.; Solution of Lime (Lime-water).—A saturated solution of $Ca(OH)_2$, containing about 0.14 per cent. Clear colorless liquid; odorless; alkaline taste. *Incompatible* with carbonates or "hard" water. Used as antacid, against diarrhea and externally against burns. It is often added to milk (1:4). *Dose*, 15 c.c., 4 drachms (about 0.02 Gm. of the hydroxide), U.S.P.; 30 to 120 c.c., 1 to 4 ounces, B.P.

Liq. Calcis Saccharatus (Liq. Calc. Sacch.), B.P. (Syrup of Lime).—Contains about 2 per cent. of CaO. Antacid, and antidote for phenol poisoning. *Dose*, 2 c.c., 3 minims.

* *Linimentum Calcis* (Lin. Calc.), U.S.P., B.P.; Lime Liniment (Carron Oil).—A mixture of equal volumes of lime-water and oil (olive, B.P.; linseed, U.S.P.). Applied to burns, on cloths, frequently renewed.

SOAPS

The alkaline salts of fatty acids act as mild alkalies, but are more effective than the mild alkaline salts, and not as irritant as the carbonates. Their action is due partly to their considerable store of potential alkali, which is made available by hydrolytic dissociation, and partly to their high surface-affinity, and the formation of tough surface films, by which they emulsify fats. They are therefore detergent and also quite effectively antiseptic; partly mechanically, and partly by altering the protective surface-membranes of the parasites. This quality is not much enhanced by the incorporation of other antiseptics. Red blood cells are hemolyzed. The lubricant properties of soap are utilized in liniments that are applied by friction (see below, Soap Liniment). Soap may be used in skin diseases, similarly to the alkaline salts.

On mucous membranes and exposed surfaces, soap is markedly irritant.

In the rectum, soap secures prompt evacuation. It is used for this purpose as warm soap-suds enemas; or solid, formed into a suppository.

Soap is soluble in alcohol, and forms colloidal salts with water. The sodium salts are solid, potassium soaps are pasty.

The Detergent Action of Soaps.—This is due to the mechanical effect of the foam, the emulsification of the grease, and the softening of the epidermis, so that the superficial layers are readily removed with the adherent dirt.

Antiseptic Action.—Strong soap solutions are fairly antiseptic. Even weak solutions are rapidly fatal to *treponema pallidum* (Reasoner, 1917). Dixon and Bates recommend 2.5 per cent. solution of common yellow soap as non-irritant wound antiseptic. J. F. Norton, 1920, found that ordinary soaps remove bacteria from the hands more effectively than the special antiseptic soaps, and pointed out that the addition of germicides would not be effective under practical conditions.

Hemolytic Action.—Alkalies, and especially soaps, are hemolytic. These also sensitize pneumococci to serum-lysis (Flexner, 1913).

Phagocytosis.—This is stimulated by soaps, even in fairly high concentrations; but excessively strong solutions are detrimental (Hamburger and de Haan, 1913).

PREPARATIONS—SOAP

* *Sapo*, U.S.P., *Sapo Durus* (Sap. Dur.), B.P.; Soap (White Castile Soap).—Prepared from sodium hydroxide and olive oil. A white solid; sol. in hot water and alc.

Sap. Animal., B.P.; Curd Soap.—Hard soap prepared from animal fat.

* *Sapo Mollis* (Sapo Moll.), U.S.P.; (Sap. Moll.), B.P.; Soft Soap (Green Soap, Sapo Viridis, Sapo Kalinus).—Made from potassium hydroxide and vegetable oil (cottonseed, U.S.P., olive, B.P.). A soft, unctuous, yellowish mass.

* *Linimentum Saponis* (Lin. Sapon.), U.S.P.; Soap Liniment (Opodeldoc).—An alcoholic solution of 6 per cent. of soap, 4.5 per cent. of camphor, and 1 per cent. of rosemary oil.

* *Lin. Sap.*, B.P.—Similar to the preceding.

* *Lin. Sapon. Moll.*, U.S.P. (Tincture of Green Soap).—2 parts of the soap, 1 part of alcohol, flavored with lavender oil.

ALKALINE SULPHIDES

When applied to the *skin*, the sulphides (K, Na, Ca) soften the stratum corneum, much like the alkalies, and they are used in the same conditions. Their action on hair is even greater, so that they are valuable as depilatories, especially calx sulphurata and barium sulphide. When taken by *mouth*, they act as irritants and corrosives, through the liberation of sulphuretted hydrogen and free alkali.

Toxic Doses.—These produce the systemic effects of hydrogen sulphide. Death has occurred from 12 to 15 Gm. Smaller doses have little systemic action, as they are rapidly oxidized. They are *excreted* in the urine mainly as sulphates; but there seem to be also some organic sulphur compounds.

A small amount of some volatile sulphur compound is also excreted by the *lungs*, giving the peculiar H₂S odor of the breath, and causing some *expectorant action*.

When injected *intravenously*, the sulphides produce violent convulsions, followed by depression of the medullary centers. This is due to a direct action.

Therapeutic Uses.—The sulphides are used externally, in skin diseases (psoriasis, acne, etc.); and as parasitocides in scabies (solution of the skin and eggs of the mite).

The sulphides have been proposed as an *antidote for hydrocyanic acid*, since they would form sulphocyanides, which do not have the hydrocyanic acid action. This has not been tested. It is possible that the reaction goes on too slowly to be of value. They have also been tried in mercury poisoning (see Mercury).

PREPARATIONS

Calx Sulphurata (Calx Sulphur.), B.P.; Crude Calcium Sulphide, Sulphurated Lime.—A mixture containing about 55 per cent. of CaS. A pale gray or yellowish powder; faint odor of hydrogen sulphide; nauseous alkaline taste. Very slightly sol. in cold water; more readily sol. in boiling water with partial decomposition; insol. in alc. Used as depilatory, mixed with an equal quantity of starch and made into a paste. Internally it is used against boils and other suppurations. Its efficiency is doubtful. *Dose*, 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P.

Vlemingke's solution is a solution of calcium polysulphides, used in scabies (1:1), and as a bath in skin diseases (2 drachms per gallon).

Pusey, 1920, recommends it against warts. These are just covered with a dressing soaked in the undiluted solution, applied every night until irritation is produced; then less frequently till the wart disappears or can be removed.

Potassa Sulphurata, U.S.P.; (Potass. Sulphur., B.P.); Sulphurated Potash (Liver of Sulphur).—A mixture composed chiefly of potassium polysulphides and potassium thiosulphate. Freely sol. in water (1:2). Used in baths (30 to 200 Gm., 1 to 6 ounces, per bath).

HYDROGEN SULPHIDE

This gas (H_2S) occurs in sewer gas, in chemical industries, and in laboratories. It acts as a local irritant, producing conjunctivitis even when the gas is very dilute. More concentrated gas, especially with prolonged exposure, also causes pulmonary irritation and pulmonary edema. In acute poisoning, however, the violent systemic effects predominate. They consist mainly in stimulation of the respiration and spinal convulsive centers; and with higher concentrations in direct paralysis of the respiratory center. Hydrogen sulphide is much more toxic than is commonly realized. It approaches hydrocyanic acid and cyanogen in toxicity and in rapidity of action.

Occurrence.—Hydrogen sulphide is formed in putrefaction, particularly of sewerage. "Sewer gas" consists essentially of CO_2 , NH_3 , CH_4 , and 2 to 8 per cent. of H_2S . Small quantities are also formed in intestinal putrefaction, giving rise to diarrhea and possibly to some of the symptoms of "intestinal autointoxication." It may be removed by the administration of bismuth salts, and its further formation checked by cathartics and intestinal antiseptics.

Operatives in artificial silk factories are subject to ophthalmic irritation, which is to be attributed to H_2S ; but it has also been suggested that the irritation may be due to other gaseous by products (Bakker, 1924).

Symptomatology in Relation to the Concentration.—With dogs, exposure for many hours to air containing 0.01–0.015 per cent. of H_2S may produce some irritation of the conjunctiva and bronchial mucosa. With 0.02 to 0.03 per cent. an hour's exposure is followed by these local irritations, and more prolonged exposure may cause slight systemic symptoms. With 0.05 per cent. these effects occur within an hour and are more pronounced. They resemble asphyxia, *i.e.*, they consist in hyperpnea, nausea, giddiness, headache, cerebral excitement, and finally narcosis; 0.07 per cent. produces death after an hour under coma, often with convulsions; with 0.1 per cent., these phenomena lead to death by apnea in less than 30 minutes; with 0.15 per cent. in 15 to 30 minutes. With 0.2 per cent. death, occurs almost immediately through paralysis of the respiration (Lehmann, 1892; Haggard, 1925).

Pulmonary Edema.—The relatively low solubility of H_2S causes it to penetrate deeply into the lungs, so that the alveoli participate in the irritation. Pneumonia is therefore apt to follow prolonged exposure to non-fatal concentrations.

Respiratory Phenomena.—These are insignificant with concentrations below 0.1 per cent. With 0.1 to 0.2 per cent., violent hyperpnea sets in. This does not occur if the vagi were cut, so that it is apparently due to irritation of the afferent endings of the pulmonary vagus. The hyperpnea leads to acapnia vera. With concentrations above 0.2 per cent., the respiratory center is paralyzed directly. The respiration may resume spontaneously after acapnia, but not after the paralysis. (Haggard and Henderson, 1922.)

Other Phenomena.—Jactitation, muscular rigidity and convulsions may be due to direct stimulation of the nervous centers, analogous to the hyperpnea; or they may be due to asphyxia. Marked slowing of the heart, profuse salivation, and cold perspiration may occur with concentrations too small to produce other acute systemic effects. Aside from the occasional slowing, the heart is little affected and may beat strongly for several minutes after the respiration has stopped (Haggard).

Fate.—Hydrogen sulphide is readily absorbed from the lungs and from the alimentary canal. It exists in the blood partly free, and partly as sulphides. It is excreted as H_2S by the lungs, and as sulphides by the urine. It is rapidly oxidized into non-toxic products (sulphate, etc.).

Action on Hemoglobin.—In vitro, H_2S reduces the hemoglobin, and converts the reduced hemoglobin into sulphhemoglobin, also called sulphmethemoglobin. This is a firm compound, appearing brown in thick layers and as a dirty green in thin strata. It is responsible for the discoloration of cadavers. It has been suggested that sulphide poisoning is due to asphyxia through the formation of this compound (Lewin). However, it is not formed during life by the administration of sulphides (E. Meyer, 1898; Haggard, 1921). Its spontaneous formation in disease (sulphhemoglobinemia) is attributed to the formation of a reducing agent in the intestinal tract (References in Haggard).

Chronic Poisoning.—Repeated prolonged exposure to dilute concentrations is said to produce local irritation of the eyes and respiratory tract, digestive disturbances, headache, lassitude, skin-eruptions.

Prophylaxis.—This is secured by adequate ventilation, and by the wearing of masks and goggles. The odor of the gas is characteristic, but is about as strong with concentrations that are nearly harmless as with those that would be immediately fatal. Hydrogen sulphide is also readily detected in air by blackening lead or silver-paper. In case of death, it may be recognized by the blackening of a silver coin laid on the skin.

Treatment of Acute Poisoning.—Artificial respiration (by Schaefer's prone-method) promises success if started while the heart is still beating. It may be aided by the inhalation of oxygen, containing 5 per cent. of carbon dioxide, during and for a short time after artificial respiration (Y. Henderson and Haggard, 1922).

Sulphur Springs.—Hydrogen sulphide is contained in small quantity in a number of mineral waters (sulphur springs). These are recommended for a variety of obscure disorders—rheumatism, gout, diabetes, etc. When these waters are administered for some time, they cause diuresis and diaphoresis, irritation of the urinary passages, intestinal irritation, and muscular pains. Their therapeutic effects are probably to be referred to their laxative, diuretic and diaphoretic actions, although the general hygienic conditions must contribute largely to the results, as with other mineral waters (Boecker, 1895).

SULPHUR

Sulphur is employed as a parasiticide in itch; as a mild cutaneous irritant in skin diseases (sulphur ointment); and internally as a laxative for softening the stools, especially in hemorrhoids (as Compound Licorice Powder, or mixed with an equal amount of Potassium bitartrate). Like other intestinal irritants, sulphur somewhat increases the elimination of uric acid (Abl, 1913).

Manner of Action.—Sulphur itself is inactive, but by contact with proteins and alkalies it is slowly converted into the active sulphides. This process is so gradual that the action is always mild and protracted, unless the finely divided "precipitated" sulphur is used. Ordinary or "washed" sulphur therefore deserves preference. Sulphur is somewhat soluble in ointment bases, and this facilitates its action (Sabbatani, 1913). Sulphur is also burned for fumigation, the disinfectant action being due to the sulphur dioxide (see next section).

Formation of Sulphides.—This is effected on the skin by the cutaneous secretions. No change occurs in the stomach; but a considerable amount (to 10 per cent.) is converted into H_2S in the intestine, as may be readily seen from the increased secretion of sulphate by the urine. This change was formerly referred to the alkalies of the intestine; but Heffter (1904) points out that the alkali exists as bicarbonate, which can not affect the conversion. He showed that it is produced by proteins of all kinds even after these are boiled. The hydrogen sulphide is formed most abundantly in the large intestines (Taegen, 1912). (Frankl, 1911, claims that the effects are due to the formation of sulphites.)

Colloid Sulphur.—A new modification of sulphur in "colloid solution" produces H_2S much more rapidly, also on intravenous injection; and thus causes typical H_2S

poisoning without other visible effects (Sabbatani, 1908, 1913, 1914). Its preparation is described by Luman, 1917.

Alopecia.—Sulphur (2 to 4 per cent.) is used in the seborrheic form, as are also other irritants (salicylic acid, 1 to 2 per cent.; mercuric chloride, 0.1 to 0.4 per cent.; betanaphthol, 1 to 2 per cent.; pilocarpine, 0.15 per cent.; cantharides; resorcin (1 to 2 per cent., discolors the hair). These agents may be dissolved in water, glycerin or oils, or applied as ointments (Dore, 1914).

PREPARATIONS

* *Sulphur Sublimatum* (Sulphur Sublim.), U.S.P., B.P.; Sublimed Sulphur (Flowers of Sulphur).—A fine, gritty, light yellow powder, of slight odor, and faintly acid taste. Insol. in water; nearly insol. in alc.; slightly sol. in fat solvents and oils; freely sol. in carbon disulphide. For fumigation, it is used in the ratio of 2 pounds per 1,000 cubic feet. It contains some free acid and other impurities, but is sufficiently pure for medicinal use, although the Washed should be preferred. It enters into all the B.P. preparations, whilst those of the U.S.P. are made from Washed Sulphur. *Dose*, 4 Gm., 1 drachm, U.S.P.; 1.2 to 4 Gm., 20 to 60 gr., B.P. Sulphur also enter into Pulvis Glycyrrhizæ Co. (see Index).

Sulphur Lotum (Sulphur Lot.), U.S.P.; Washed Sulphur.—This is prepared by washing the preceding with ammonia water to remove the acid. Its properties are similar to the preceding, but it is tasteless and odorless. *Dose*, 4 Gm., 1 drachm, U.S.P.

Sulphur Præcipitatum (Sulphur Præc.), U.S.P.; (Sulphur Præc.), B.P.; Precipitated Sulphur (Lac Sulphuris, Milk of Sulphur).—This is prepared by precipitating sulphurated lime with acid. An amorphous, pale yellow powder. It is a much finer powder than sublimed sulphur and is therefore rather more active; but its dose is the same.

* *Unguentum Sulphuris* (Ung. Sulphur.), U.S.P., B.P.; Sulphur Ointment.—15 per cent. of sulphur, U.S.P.; 10 per cent., B.P.; in benzoinated lard.

Conf. Sulphur., B.P.—45 per cent. of Sulphur, 11 per cent. of Potass. Bitart. *Dose*, 4 to 8 Gm., 60 to 120 gr., B.P.

Troch. Sulphur., B.P.—0.3 Gm. of Sulphur.

SULPHUR DIOXIDE (SULPHUROUS ACID)

This was formerly used extensively for the disinfection of rooms, but is not reliable against bacteria (Koch), and has the objection of bleaching colors. However, it is effective against most insects (McClintock, etc., 1911), especially against mosquitoes and bed bugs; and therefore against certain insect-borne diseases, malaria, yellow fever, etc. It is quite ineffective against lice (Barot, 1918).

Sulphur dioxide is generated by burning 3 pounds of sulphur for each 1,000 cubic feet of space. To avoid danger of fire, the sulphur is placed in tin pans raised from the floor by bricks. Its action is materially greater when the air is saturated with moisture.

Toxic Effects.—These arise from its use in disinfecting and bleaching. Large quantities occur also in coal smoke, and become particularly objectionable in foggy weather. It is eventually oxidized in the air to sulphuric acid (T. W. Schaefer, 1907). Its inhalation produces irritation of the respiratory passages, etc. and extreme discomfort in dilutions of 0.001 per cent. by volume; and 0.1 per cent. is promptly fatal by paralysis of the respiratory center (Ogata, 1884; K.B. Lehmann, 1893).

Acidum Sulphurosus (Acid. Sulphuros.), B.P.—An aqueous solution corresponding to 5 per cent. of SO₂. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

SODIUM SULPHITE

This is somewhat rarely used in medicine, as mouth wash in aphthæ, and as 10 per cent. lotion in ringworm and other parasitic skin diseases (pityriasis versicolor).

The principal importance of the sulphite arises from its use in preserving foods. The quantities ordinarily used do not seem to be directly harmful. Even much larger quantities do not act systemically, being

rapidly oxidized to sulphates; but they may produce local gastric irritation by the liberation of sulphurous acid. Their harm is mainly indirect in that they improve the odor and appearance of spoiled meat so that it is sold as fresh. They are therefore properly prohibited.

Toxic Effects.—The harmlessness of ordinary quantities even when continued for very long periods has been shown particularly by Rost and his co-workers (1904, 1912) and by Lehmann and Trentlein, 1909 (Long, 1912). The metabolism is not deranged. With larger doses by mouth, there are signs of gastro-intestinal irritation, due to the liberation of sulphurous acid (Jacob and Walbaum, 1906). Kionka and Ebstein, 1902, and Harrington, 1904, described hemorrhagic and inflammatory lesions in the kidneys and other organs after long-continued use; but these have not been confirmed by later observers and were probably accidental. The absorbed sulphite is rapidly oxidized to sulphate (Pfeiffer, 1883; Rost and Sonntag, 1904) and it is only when this capacity is exceeded by very large doses or intravenous injection that toxic effects appear. These lower the blood pressure, depressing the central nervous system, especially the medulla, and the cardiac and arterial muscle. Death occurs by paralysis of respiration (Rost, 1914). In man, 1 Gm. produced no effects; 4 to 6 Gm. caused violet colic, diarrhea and circulatory disturbances (Rost; Franz, 1912).

Sodii Sulphis, B.P.; Sodium Sulphite, $\text{Na}_2\text{SO}_3 + 7\text{H}_2\text{O}$.—Freely sol. in water (1:2). Dose, 0.3 to 1.2 Gm., 5 to 20 gr., B.P. Oxidizes in air to sulphate.

SODIUM THIOSULPHATE

This salt is familiar as a reducing agent in photography, under the name of "hypo" or "hyposulphite." It has been employed externally in parasitic skin diseases, similarly to sodium sulphite, and by mouth as a cathartic (1 Gm. in water, every two hours if necessary; Petteys). It is now used intravenously against exfoliative dermatitis, particularly that resulting from the arsphenamines and other arsenicals: and against other manifestations of arsenical poisoning, and of poisoning by metals in general. It appears to be successful against the dermatitis and the arsenical jaundice, but the evidence for the mechanism of its action is not known. Its effectiveness against other phenomena, and especially against other metals is not convincing.

Action in Arsenic Poisoning.—The use of thiosulphate against arsenical and other dermatitis appears to have been introduced by Ravaut, 1920, and it was popularized in the United States mainly by McBride and Dennie, 1923. It was suggested that it converts the arsenic into less harmful compounds, such as the sulphide, but there is no chemical proof for this suggestion. It is rendered improbable by the observation that the acute toxicity of arsenicals is very little decreased by thiosulphate injection. The renal damage is said to be decreased (Kuhn and Reese, 1925); and the excretion of arsenic is sometimes accelerated (C. W. Myers et al., 1925). Since thiosulphate has a similar beneficial effect on non-arsenical and non-metallic dermatitis, it is quite conceivable that the action is not on the arsenic, but that it is perhaps an allergic response to the precipitation of colloidal sulphur. This, however, has also not been tested.

Administration.—In arsenic and other metal poisoning, the thiosulphate is injected intravenously as a 10 per cent. solution in the dose of 0.3 Gm. of the crystallized salt on the first day, repeating the injection daily with increasing doses, namely 0.45, 0.6, 0.9, 1.2 and 1.8 Gm. (McBride and Dennie). At the same time it may be administered by mouth, 2 Gm. twice a day, in 120 to 200 c.c., of normal saline, which is said to diminish the tendency to vomiting (Kuhn and Reese).

Local Injection vs. Neoarsphenamine Irritation.—If neoarsphenamine solution accidentally enters the subcutaneous tissue, the injection of 5 or 10 per cent. thiosulphate solution diminishes the irritation. This is probably due merely to dilution, and the injection of normal saline solution would probably be equally effective.

Thiosulphate against Other Metals.—This has been tried especially against mercury poisoning. Animal experiments indicate that it is ineffective (Haskell et al. 1925, literature); and the difficulty of controlling the clinical conditions renders it difficult to judge its clinical value. However in view of its harmlessness, it should be tried further, but not to the neglect of other measures.

Harmlessness.—Lasch, 1919, states that sodium thiosulphate may be consumed without harm up to 12 Gm. per day. It would, however, produce catharsis, and possibly emesis.

Fate.—The thiosulphate is oxidized and excreted as sulphate.

* *Sodii Thiosulphas* (Sod. Thiosulph.), U.S.P. (Sodium Hyposulphite), $\text{Na}_2\text{S}_2\text{O}_3 + 5\text{H}_2\text{O}$.—Very sol in water (1:0.5). *Dose*, 1 Gm., 15 gr., by mouth or intravenously, U.S.P.

SULPHONATED PETROLEUM DISTILLATES (ICHTHYOL AND SUBSTITUTES; AMMONIUM SULPHOICHTHYOLATE)

Treatment of certain petroleum distillates with concentrated sulphuric acid and subsequent neutralization with ammonia results in tarry products, miscible with water or glycerin, containing considerable quantities of sulphur compounds of alkyl radicals, *i.e.* sulphonic acids (RSO_3H), sulphones (RSO_2R) and sulphur ethers or sulphides (RSR).

The original product, "ichthyol" was introduced into dermatology by Unna, on the basis of a now disproven "reduction-theory." Its use became rather a fad in dermatology, gynecology and proctology, but was not supported by critical control observations; and accordingly, its popularity has waned very greatly. The limited usefulness of these products is due mainly to their physical, demulcent and emollient effects. They are also somewhat astringent for mucous membranes or exposed tissues; and when concentrated, are mildly irritant, and stimulating and antiseptic. In dermatology, they are probably less useful than zinc oxide or tar ointments. Their miscibility with water gives them some advantage for mucous membranes.

Ichthyol was also tried internally, especially against tuberculosis, on the basis of mistaken theories. It is doubtless ineffective.

Origin.—The original "ichthyol" was prepared from a Tyrolian bituminous shale containing the remains of fossil fish. Sulphonated oils have a long, although not prominent history in medicine; for instance "*Harlem oil*," *i.e.*, linseed oil, saturated with sulphur.

Composition.—This varies considerably for the various products, and even for different samples of the same product. All, however, contain the three classes of sulphur compounds. The individual constituents have not been isolated. The total sulphur content of commercial "ichthyol" is about 10 per cent., of which about half consists of sulphides (sulphur ethers and mercaptans). The addition of acid to the ammonium salt precipitates a tarry mixture, "sulphoichthyolic acid."

Theories of Local Actions.—Unna, 1882, classed ichthyol with pyrogallol and chrysarobin amongst reducing agents, which he credited with producing keratinization, vasoconstriction, analgesia and antiseptis, when applied to the skin. This reduction theory has little to recommend it; especially as glucose would surpass ichthyol as a reducing agent. Later, Unna seems to have shifted his ground, attributing the effects to albumen precipitation. This, *i.e.* simple astringency, is a much more reasonable explanation; although the tarry and sulphur compounds may be somewhat irritant.

Internal Uses.—Zeulzer, 1886, claimed that the oral administration of ichthyol to men causes some sulphur and nitrogen retention, but his data are not impressive; only a third of his patients gained in weight in three months. Larger doses produce gastrointestinal irritation and diarrhea.

Ichthyol, N.N.R. (*Ammonium Sulpho-ichthyolate*).—A mixture prepared by sulphonating the tar-like distillate obtained from bituminous shales found in Tyrol, and which contain the fossil remains of fishes. A dark brown syrupy liquid of characteristic empyreumatic odor and burning taste; of faintly acid reaction. Miscible with glycerin, with water (not truly soluble; Hostmann, 1915) and with oils, or fats; incompletely soluble in alc. *Dose*, internally, 0.2 to 2 c.c. (3 to 30 minims) mostly in simple suspension in water, or peppermint water, sometimes in the form of pills or capsules; locally, in vaginal, uterine or rectal suppositories; in 0.06 to 0.18 c.c. (1 to 3 minims) bougies or 1 to 3 per cent. solution for gonorrheal treatment.

IRRITANT VOLATILE OILS AND RELATED DRUGS

General Statement.—Most volatile (or “essential”) oils are complex mixtures, generally containing terpenes and oxidized aromatic derivatives. The balsams and resins, which contain volatile oils, may be included in the group. These oils occur in numerous plants, and determine their use as flavors, aromatics, carminatives, antiseptics and irritants. Their chief application is for their local effects, consisting in deep irritation with a minimum of tissue destruction. The sensory stimulation is followed by some anesthesia. They exert a favorable influence on chronic inflammations; partly by their mild antiseptic and irritant action, and partly by chemotactic attraction of leucocytes. In acute inflammations they are more apt to do harm. Their antiseptic action is, in practice, relatively weak, since they are but slightly soluble in water.

After their absorption they are excreted mainly in combination with glucuronic acid. They irritate the kidneys and produce diuresis.

Central effects are only seen in poisoning, and agree broadly with those of camphor, which really belongs to this group. These effects are more or less convulsive, followed by narcosis; on direct application, stimulation of cardiac muscle; and curare action on the muscle-nerve endings.

The Flavoring and Aromatic Oils are considered in another place.

Composition.—A convenient tabulation of the constituents of volatile oils is given by Rippetoe and Wise, 1912. The terpenes are aromatic, cyclic compounds of the general empirical formula, $C_{10}H_{16}$. Related to them are the semi-terpenes (C_8H_8); sesqui-terpenes ($C_{15}H_{24}$); and di-terpenes ($C_{20}H_{32}$). Other constituents are oxidation products of these and aromatic phenols, ketones, aldehydes, acids and their compounds.

The Antiseptic Effects.—These have been investigated especially by Kobert, 1906; Bruning, 1906; Geinitz, 1912; and Rippetoe and Wise, 1912.

Antiseptic Action of Aromatic Fumes.—The smoke of burning wood has been used since antiquity for “purifying” or “curing” meat; the smoke of aromatic resins, incense, etc. for “purifying contaminated air.” Macht and Kunkel, 1920, confirmed that these fumes are feebly antiseptic. It is improbable, however, that concentrations which would be inhaled without injury to the mucosa would be directly injurious to bacteria.

Fungicidal Action.—This is not necessarily proportional to the antibacterial action (H. B. Myers and Thienes, 1925). Thymol is especially effective against yeast, and is being used clinically against fungal infections of the skin and mouth.

Chemotactic Action.—The value of volatile oils (particularly those enumerated as urinary antiseptics) in various subacute and chronic inflammations seems confirmed by clinical observations and laboratory experiments. They are also said to lessen aseptic inflammations at points remote from the site of their application, by decreasing the formation of exudates and by hastening their absorption. The explanation may be chemotactic attraction for leucocytes (Lémière, 1891; Borissow; Hamburger, 1912). In this way they withdraw these cells from the inflamed area into the blood (Winternitz, 1901).

Excretion.—Terpenes are for the most part excreted in the urine in combination with glucuronic acid (Matzel, 1905), sometimes after partial oxidation.

Systemic Actions of Volatile Oils.—The principal central effects of volatile oils are reflex. With the ordinary doses, no direct action whatever can be observed. Large doses act on the nervous centers, especially the brain and medulla. These are first stimulated, then depressed. The details have been investigated especially by Rimini, 1900; Hildebrandt, 1901 and 1902; Matzel, 1905; and Geinitz, 1912. The degree of stimulation varies for the different oils. Turpentine has scarcely any effect, whilst absinthe, thujon, fenchon, carvon and camphor produce violent epileptic convulsions. The depression is more uniform: The majority (valerian, fennel, chamomile, eucalyptus, mint, rosemary, sabinol, citral, turpentine) diminish the reflex excitability, so that large doses entirely prevent strychnine convulsions in rabbits. The effective doses are, however, entirely too large to make it possible to employ this action in man.

The *Curare*-actions have been studied by Hildebrandt and by Matzel; the *cardiac* effects by H. Schwall, 1912.

According to d'Ormea (1903), the intravenous injection of volatile oils causes a peculiar dilation of the *cerebral vessels*, the volume of the brain increases, whilst the pressure in the circle of Willis falls. This effect is strongest with absinthe, weak with anise or lemon. Camphor has a similar effect. The general blood pressure also falls in most cases, but quite independently of the changes in the cerebral circulation.

If volatile oils are injected **hypodermically**, they produce at first the reflex action, in a more marked degree than when they are applied to the surface of the skin. Later their systemic, and still later the renal, actions take place.

Isolated Intestinal Segments are stimulated by oil of anise, turpentine and chenopodium, in concentrations of 1:50,000 to 1:25,000. Higher concentrations of all volatile oils depress the movements (Muirhead & Gerald, 1916).

Hemolytic Action of Terpenes.—Ishizaka, 1914, found that this varied mainly with the surface tension; but that the alcohol or ketone character also has an influence. Some form methemoglobin.

OLFACTORY STIMULANTS

Odorous substances produce pronounced reflex effects. Pungent and aromatic drugs cause in this way a prompt medullary stimulation, increasing the respiration and blood pressure, and slowing the pulse. They are especially useful in fainting. They are employed by inhalation. *Tinctura Lavandulæ Composita* (U.S.P., B.P.) and Aromatic Ammonia are used for this purpose. Any pungent substance will answer in an emergency; the burning of a feather under the nose of the patient is a standard household measure.

Substances which produce sneezing (*sternutatoria* or *errhines*) act in a similar manner, but have passed out of fashion. They are sometimes useful as local counterirritants in nasal catarrh (snuff).

HYSTERIC SEDATIVES OR ANTISPASMODICS

Actions and Uses.—Asafoetida, valerian, and some other malodorous drugs have been used since antiquity as sedatives in hysterical and similar nervous conditions. They are often effective, presumably by olfactory and psychic reflexes. Asafoetida is also carminative, and has been used by mouth and enema (emulsion) in tympanites; but it imparts its odor to the excreta and eructations. Very large doses ($\frac{1}{2}$ ounce) have been taken without other noticeable effects. Large doses of valerian produce systemic action, but it is very doubtful whether these occur with the ordinary doses. Valerian was formerly used as a perfume, and as a spice for meat, and asafoetida is said to be similarly employed in Persia.

PREPARATIONS

* *Asafoetida* (Asafoet.), U.S.P.; *Asafoetida* (Asafoet.), B.P.; Asafoetida.—The gum-resin obtained by incising the rhizome and roots of *Ferula Asafoetida*. Characteristic odor; bitter and acrid taste; forms milk-white emulsion when triturated with water. *Constituents*: 3 to 9 per cent. volatile oil; 20 to 30 per cent. gum; 45 to 70 per cent. resin. The alcoholic preparations yield turbid mixtures with aqueous liquids. *Dose*, 0.4 Gm., 6 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.; best as pills.

Pil. Asafoet., U.S.P.—0.2 Gm., 3 gr. *Dose*, 2 pills, U.S.P.

Emuls. Asafoet., U.S.P. (Milk of Asafoetida, Asafoetida Mixture).—Made by rubbing 4 parts of asafoetida with 100 parts of water. *Dose*, 1.5 c.c., 4 drachms, U.S.P. Used especially as enema against tympanites.

Tr. Asafoet., U.S.P.; *Tr. Asafoet.*, B.P.—20 per cent. *Dose*, 1 c.c., 15 minims, U.S.P.; 2 to 4 c.c. $\frac{1}{2}$ to 1 drachm, B.P.

Sp. Ammon. Fet., B.P.—An alcoholic distillate of Asafoetida, mixed with Ammonia, *Dose*, 1.2 to 2.5 c.c., 20 to 40 minims, repeated; single, 4 to 6 c.c., 60 to 90 minims, largely diluted, B.P.

Valeriana (Valer.), U.S.P.; *Valer. Rhiz.*, B.P.; Valerian.—The dried rhizome and roots of *Valeriana officinalis*. *Dose*, 0.75 Gm., 12 gr., U.S.P. Contains $\frac{1}{2}$ to 2 per cent.

volatile oil, valeric and other organic acids; tannin and resins. The oil consists of esters of valeric (valerianic) acid, especially with borneol. These are the bearers of the action, free valeric acid and its salt being quite ineffective. The fresh root is also ineffective, the esters being formed only during drying, by the action of oxidases (Kochmann, 1904). The juice of the fresh plant also produces different effects from the dried valerian (Pouchet and Chevalier, 1905). The esters again deteriorate by oxidation on keeping. Certain synthetic esters are said to be more stable (Kionka, 1902).

The Injection of Valerian.—This produces the usual effects of volatile oils (Pouchet and Chevalier; Kionka, 1904); in small doses, psychic exaltation and rise of blood pressure from cardiac and vasomotor stimulation; in larger doses, central sensory and motor depression.

Excised Uterus.—This is stimulated by Valerian oil (Pilcher, 1916).

Excised Intestine.—The contractions are depressed by valerian oil (Delzell, Burman and Pilcher, 1916).

Tr. Valer., U.S.P.—20 per cent. *Dose*, 4 c.c., 1 drachm, U.S.P.

* *Tinctura Valerianæ Ammoniata* (Tr. Valer. Ammon.), U.S.P., B.P.—20 per cent.; with Sp. Ammon. Arom., U.S.P.; with ammonia and aromatics, B.P. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Valer. Ind. Rhiz., B.P.—From Valeriana Walachii.

Tr. Valer. Ind. Ammon., B.P.—*Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Synthetic Valerian Esters (N.N.R.)—Amyl valerate Bornyval (borneol isovalerate); and Valyl (valeryldiethyl-amine). Side actions, Seifert, *Nebenwirk.*, 1915, p. 99.

Valerates (Valerianates).—These have very little value. They are given in doses of 0.06 to 1 Gm. (1 to 15 gr.), generally in capsules. They are colorless crystals of a valerianic odor, readily soluble in water; Zinci Valeras, U.S.P., B.P.; Ammonii Valeras.

Minor Drugs of This Group.—Sumbul (Musk-root), Moschus (Musk), Castoreum Cataria (Catnip); and Symplocarpus (Skunk-cabbage).

Moschus; Musk.—The dried secretion from the preputial follicles of Moschus moschiferous. *Dose*, 0.25 Gm., 4 gr. *Tr. Moschi.*—5 per cent. *Dose*, 4 c.c., 1 drachm.

Sumbul (Musk-root).—The rhizome and roots of Ferula Sumbul. *Dose* 2 Gm., 30 gr.

OIL OF TURPENTINE

Actions and Uses.—Applied to the skin, this produces simple reddening and burning, and is used as a counterirritant; undiluted, or mixed with 1 to 5 parts of oil in liniments. It is often used as "stupes," *i.e.*, flannel wrung out of hot water, and then out of warm turpentine, and applied for ten to thirty minutes. In susceptible individuals it may cause severe eruptions, and if left on for several hours, blistering.

Oil of turpentine is used externally in bronchitis, neuralgic and rheumatic pains, and to relieve meteorism. It causes more severe irritation on mucous membranes.

Inhaled or taken internally it diminishes bronchial secretions (Rossbach and Fleischmann). It was used for this purpose (a teaspoonful inhaled from a pint of hot water) in chronic bronchitis. It is now displaced by the more pleasant terpene hydrate by mouth and pine-needle or eucalyptus oil for inhalation. Its use as anthelmintic (2 to 15 c.c.) and as diuretic and urinary antiseptic have also been discontinued.

Turpentine Abscess.—The injection of oil of turpentine produces localized aseptic abscess. Pehu and Pillon, 1914, propose such abscesses, formed by its hypodermic injection into the abdominal wall, in the treatment of all sorts of infections—pneumonia, whooping cough, measles, etc. This is somewhat analogous to the obsolete "setons."

Absorption, Fate and Excretion.—Oil of turpentine is readily absorbed from the skin, lungs and intestines. It circulates for a time unchanged in the blood, and is excreted mainly in the urine as terpenals, paired with glycuronic acid. The urine has the odor of violets. Neither turpentine, nor eucalyptol nor menthol, is excreted by the lungs or sputum (Falk, Hofbauer, 1915).

Systemic Actions.—These do not occur with small doses.

Turpentine Poisoning.—Half an ounce has been fatal to children, 6 ounces to adults. The symptoms in man are those of gastro-intestinal irritation; nausea and vomiting,

colic and diarrhea, wild excitement and delirium, ataxia, painful micturition, hematuria, albuminuria, glycosuria, skin eruptions, coma.

Treatment.—This comprises evacuation, demulcents and coffee.

Inhalation.—Fatal poisoning has been reported from inhalation of varnish in a confined space (Drescher, 1906); largely by exclusion of air (Wolf, 1911). There is rapid breathing, palpitations, vertigo, stupor, convulsions, and other nervous disturbances; pain in chest, bronchitis and nephritis. The latter may also occur on chronic exposure.

PREPARATIONS—TURPENTINE

Oleum Terebinthinæ (Ol. Tereb.), U.S.P.; Oil of Turpentine (Spirit of Turpentine). The volatile oil recently distilled with water, below 100°C., from the concrete oleoresin (Turpentine) obtained from *Pinus palustris* and from other species. It consists mainly of pinene, $C_{10}H_{16}$, with small quantities of other terpenes and traces of organic acids. A thin, colorless liquid, of characteristic odor and taste, becoming stronger and more unpleasant by age and exposure to air. Practically insol. in water; sol. in 3 vol. of alc. and in all proportions of oils. The rectified oil should be employed for internal use.

* *Ol. Tereb. Rect.*, U.S.P.; *Ol. Tereb. Rectif.*, B.P.—Rectified (by distillation with NaOH, U.S.P.). *Dose*, 0.3 c.c., 5 minims, U.S.P.; 0.12 to 0.6 c.c., 2 to 10 minims, B.P.; anthelmintic dose, 12 to 15 c.c., 3 to 4 drachms, B.P.

Emuls. Ol. Tereb., U.S.P.—15 per cent. *Dose*, 2 c.c., $\frac{1}{2}$ drachm, U.S.P.

Lin. Tereb., B.P.—Ol. Tereb., 65 per cent.; Camphor, 5 per cent.; Sap. Moll. and water.

Lin. Tereb. Acet., B.P.—Ol. Tereb., 53 per cent.; Lin. Camph., 45 per cent.; Ac. Acet. Glac., 11 per cent.

Ol. Pini Pumilionis (Ol. Pin. Pumilion.), U.S.P., Oil of Dwarf Pine Needles; *Oleum Abietis* (Ol. Abiet.), B.P., Oil of Siberian Fir.—Colorless or faintly yellowish volatile oil, of pine-needle odor, distilled with steam from the fresh leaves of *Pinus montana*, U.S.P.; of *Abies sibirica*, B.P. Contains l-pinene, other hydrocarbons and esters. Resembles oil of turpentine, but has more agreeable odor, and is employed as inhalant in bronchial affections.

Terebinthina Canadensis (Tereb. Canad.), B.P.; Canada Turpentine.—An oleoresin obtained from *Abies balsamea*.

TERPIN HYDRATE

This is used to diminish cough and expectoration in phthisis and in chronic bronchitis, acting similarly to oil of turpentine, and being less irritant, less disagreeable and less toxic. It is also sometimes employed as diuretic and urinary antiseptic, but is not very effective.

Lepine, 1887, claimed a diuretic effect from 0.2 to 0.4 Gm. Matzel, 1905, took 4 Gm. daily without any effect; the urine was not albuminous. It was excreted as paired glucuronic acid.

PREPARATIONS

* *Terpini Hydras* (Terpin. Hyd.), U.S.P.; Terpin Hydrate, $C_{10}H_{18}(OH)_2 + H_2O$.—Prepared by hydrating oil of turpentine with alcohol and nitric acid. Colorless prisms, odorless, of slightly aromatic and somewhat bitter taste. Slightly sol. in water (1:200); freely sol. in alc. (1:13). *Dose*, 0.25 Gm., 4 gr., U.S.P., 0.1 to 1 Gm., $1\frac{1}{2}$ to 15 gr., in powders or capsules. The N.F. Elixir contains 1 gr. to the drachm, in a vehicle of alcohol and glycerin.

Terebenum (Tereben.), U.S.P., B.P.; Terebene.—Dipentene and other hydrocarbons, obtained by the action of concentrated sulphuric acid on oil of turpentine. Colorless, thin liquid; rather agreeable odor; aromatic, somewhat terebinthinate taste. Slightly sol. in water; freely sol. in alc. (1:3). *Dose*, 0.25 c.c., 4 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P., on sugar; or by inhalation.

EUCALYPTOL

Eucalyptol (Cineol, Cajeputol), $C_{10}H_{18}O$, is obtained chiefly from oil of eucalyptus, but occurs also in other volatile oils, such as cajuput. It is a mild local irritant, used especially in bronchitis, as inhalation (teaspoonful in hot water), or internally (5 to 10 drops on sugar); and in

coryza (spraying with 3 to 5 per cent. solution in liquid petrolatum). The oil of eucalyptus may be substituted.

Eucalyptol imparts to the *urine* the same violet odor as does oil of turpentine, which it closely resembles in action. It has been used in malaria but is greatly inferior to quinine.

Toxicity.—Large doses of eucalyptol or the related *Myrtol* produce fatal collapse. Death occurred in about $\frac{1}{3}$ of the human subjects who had taken between 10 and 30 c.c. Idiosyncrasy toward small doses is manifested by skin eruptions (L. F. Barker and Rowntree, 1918; experimental and clinical bibliography).

PREPARATIONS

Eucalyptus, U.S.P. (Blue Gum Leaves).—The dried leaves of *Eucalyptus Globulus*. Dose, 2 Gm., 30 gr., U.S.P.

Fldext. Eucalypt., U.S.P.—*Dose*, 2 c.c., 30 minims, U.S.P.

**Ol Eucalypt.*, U.S.P., B.P.—A volatile oil distilled from the fresh leaves of *Eucalyptus* species, yielding not less than 70 per cent. of eucalyptol. Colorless or pale yellow liquid. *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Ung. Eucalypt., B.P.—10 per cent. of the oil.

Eucalyptol, U.S.P.; *Eucalyptol* (Cineol), $C_{10}H_{18}O$.—An organic compound obtained from the volatile oil of *Eucalyptus Globulus* and from other sources. A colorless liquid; characteristic, aromatic and distinctly camphoraceous odor; a pungent spicy taste, and producing a cooling sensation in the mouth. Very sol. in alc. or oils; practically insol. in water. *Dose*, 0.3 c.c., 5 minims, U.S.P.

Oleum Cajuputi (Ol. Cajup.), U.S.P., B.P.—A volatile oil distilled from the fresh leaves and twigs of several varieties of *Melaleuca Leucadendron*. Used mainly as counterirritant. *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Sp. Cajup., B.P.—*Dose*, 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

RUBEFACIENT VOLATILE OILS

A large number of drugs, containing volatile oils have been used as ingredients of liniments. With some of the tinctures (arnica, witch hazel) used in domestic medicine, the alcohol is perhaps the main active ingredient. Thymol, menthol, and camphor, and some of the volatile oils that are discussed in other connections could be classed with the rubefacients.

The oils of cloves, cinnamon, and creosote are employed in *dentistry* to destroy the nerves and to disinfect the cavities of carious teeth.

PREPARATIONS

Arnicae Flores, B.P.; *Arnica*.—The dried flower-heads of *Arnica montana*. Contains a volatile oil, small quantities of volatile acids, and an acrid bitter principle (Arnica). Used externally.

Intravenous injections tend to produce lasting rise of blood pressure (E. D. Brown et al., 1918).

Tr. Arnic. Flor., B.P.—10 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Caryophyllus, U.S.P., B.P.; *Cloves*.—The dried flowerbud of *Eugenia aromatica*. *Dose*, 0.25 Gm., 4 gr., U.S.P.

Inf. Caryoph., B.P.—2.5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Ol. Caryoph., U.S.P., B.P.; *Oil of Clove*.—The volatile oil, consisting mainly (82 per cent.) of eugenol. *Dose*, 0.1 c.c., $1\frac{1}{2}$ minims, U.S.P.; 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Eugenol, U.S.P.—An unsaturated, aromatic phenol ($C_6H_3.C_3H_5.OCH_2OH$) obtained from oil of cloves and from other sources. *Dose*, 0.2 c.c., 3 minims, U.S.P.

Ol. Cedrelae.—Cedarwood Oil.

Liquor Hamamelidis, B.P.; *Hamamelis Water*, Solution of *Hamamelis* (Witch Hazel, Extract of Witch Hazel).—A saturated aqueous distillate obtained by distilling with steam or water the bark, twigs and smaller stems of *Hamamelis virginiana* and adding about 15 per cent. of alcohol. Clear or colorless or slightly yellowish liquid having a characteristic aroma and taste.

- Ol. Origani*.—Origanum oil.
Ol. Pimentae.—Oil of Allspice.
Ol. Rosmarini (Ol. Rosmar.), U.S.P., B.P.; Oil of Rosemary.—Distilled from the fresh flowers of *Rosmarinus officinalis*. Dose 0.1 c.c., 1½ minims, U.S.P.
Sp. Rosmarin., B.P.—10 per cent.
Ol. Succini.—Oil of Amber.
Ol. Thymi; Oil of Thyme.—Distilled from the flowering plant of *Thymus vulgaris*.

LINIMENTS

Cutaneous irritants are usually employed in the form of liniments; *i.e.*, in solution or suspension in oil or alcohol. The proportions in which they are used are about the following:

Ammonia Water	} 1:5
Tr. Aconite, Belladonna, Iodine or Opium.	
Spirits Camphor, Chloroform or Ether	
Tr. Cantharides or Capsicum	
Turpentine	} 1:10
Sp. Sinapis	
Essential Oils	
Croton Oil	} 1:50
Creosote	

JUNIPER OIL

This is closely allied to turpentine (containing pinene, $C_{10}H_{16}$, and cadinene, $C_{15}H_{24}$); but it has a more agreeable flavor. It is distilled from the "berries," the fruit of the conifer, *Juniperus communis*. In the form of "Holland Gin," it is an old-fashioned diuretic (Cow., 1912) in cardiac and hepatic dropsies. It is supposed to act by mild irritation of the kidneys. Its use in nephritis therefore requires caution. It also has some reputation as emmenagogue. Overdoses produce poisoning, similar to Savin.

PREPARATIONS

Ol. Juniperi (Ol. Junip.), U.S.P., B.P.; Juniper Oil.—Distilled from the ripe fruit of *Juniperus communis*. Dose, 0.1 c.c., 1½ minims, U.S.P., 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Sp. Junip., B.P.—10 per cent. Dose, 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

ECBOLIC AND TOXIC VOLATILE OILS

Actions.—Many volatile oils are popularly employed as emmenagogues and ecbolics: turpentine, juniper, savin, rue, pennyroyal, tansy and apiol. They produce pelvic congestion through intestinal irritation. A mild degree of this action may be useful in delayed and painful menstruation, as after exposure to cold. Abortion occurs only with toxic doses; indeed fatal doses are not always effective. Prochnow, 1911, also finds a slight direct action on the excised uterus. Macht, 1913, finds the contraction inhibited, never stimulated.

Savin (*Sabina*) and **Arbor Vitae** (*Thuja*) contain volatile oils similar to turpentine but much more toxic. Savin oil contains pinene, cadinene and sabinol, $C_{10}H_{16}OH$. Thuja contains pinene, fenchon, and thujon (isomers of camphor, and having similar actions (Hildebrandt, 1902; Matzel, 1905). Poisoning has often occurred from their use as abortifacients.

Excised Uterus.—This is not stimulated by the oils of juniper, pennyroyal, rice, savin, or tansy. Low concentrations have no effect; active doses produce relaxation and inhibition (emulsions in Ringer's solution; human uterus; Gunn, 1921).

Toxic symptoms from oil of savin are those common to volatile oils: Burning, nausea, vomiting, colic and diarrhea, sometimes bloody; severe congestion of the pelvic organs, increased menstrual flow and sometimes abortion; hematuria and painful micturition; unconsciousness, convulsions and coma. Death may occur in a few hours, but more often after several days. Six drops are said to have produced toxic effects (Lewin).

Fatty degeneration of the liver and of other organs (Heffter, 1895; Lindemann, 1899) is produced by large doses of these oils, especially by pulegon, the active constituent of pennyroyal; and also by the oils of sassafras, rosemary and thyme.

Apiol.—Two drugs are known under this name: "Green Apiol," or Oleoresin of Parsley Seed (Oleores. Apii), a green oily liquid. *Dose*, 0.3 to 1 c.c., 5 to 15 minims; and "Apiol" proper, "Crystallized Apiol," "Parsley Camphor," a crystalline aromatic derivative extracted from the oleoresin, *dose*, 0.1 to 0.3 Gm., 2 to 5 gr. It has been studied by Heffter, 1895. Overdoses (0.6 to 0.8 Gm.) produce arrhythmia, incoördination, digestive disturbances and fever. Fatal poisoning, with intestinal symptoms, icterus and uremia, is reported by Brenot, 1916.

The Apiols are administered in capsules, as emmenagogues and antipyretics. The actions of the different apiols do not seem to be identical (Lutz, 1920). Their usefulness is doubtful.

Tansy.—The leaves and tops of *Tanacetum vulgare* have been used mainly as anthelmintic against *Ascaris* and *Oxyuris*, internally, 0.5 to 2.5 Gm. as infusion, twice a day; or as enema of 15:200. Half an ounce to an ounce of the oil (which contains thujon) has produced death after two to four hours, with convulsions and unconsciousness.

Pennyroyal.—The leaves and tops of *Hedeoma pulegioides* are used as carminative, 5 to 10 Gm., 1 to 2 ounces, as infusion. *Ol. Hedeoma* (U.S.P.), 0.2 c.c., 3 minims; a teaspoonful has produced convulsions. Its active constituent, *pulegon*, $C_{10}H_{16}O$ has been studied by Lindemann, 1899; Falck; and Matzel, 1905.

Absinthe.—The herb *Artemisia Absinthium*, contains a volatile oil, whose chief constituent is *thujon*, $C_{10}H_{16}O$. This produces effects similar to camphor (Hildebrandt, 1901 and 1902; Matzel, 1905). The liqueurs "*absinthe*" and "*vermouth*" contain this oil and also anise, fennel, and others; it is doubtful what part each of these and the alcohol (50 per cent.) plays in the toxic complex.

Absinthe Convulsions.—In mammals, intravenous injection of absinthe oil (1 to 3 drops for a cat) produces unconsciousness and general convulsions, clonic and tonic, of epileptiform type (Magnan, 1871). The clonic spasms are due to stimulation of the motor areas, for they become tonic if the cerebral arteries are clamped (Leonard Hill). The tonic spasms are medullary.

In man overindulgence causes similar effects and is also said to lead to mania.

The symptoms and the literature are discussed by I. L. Meyers, 1916.

Nutmeg Poisoning.—This is by no means rare. In man severe symptoms have occurred from one to one and one-half nutmegs, or from a teaspoonful of powdered mace. The effects appear in one to six hours, and are mainly narcotic, varied by excitement and delirium, with some motor stimulation and local irritation; they usually end in recovery in twenty-four hours. Nutmeg is also ecboic. Similar effects occur in animals. Hepatic necrosis has been demonstrated in cats (Dale, 1909). Cushny and Wallace, 1908, showed that the narcotic effect is produced by "*myristicin*," the high-boiling portion of the volatile oil. The oil has been investigated chemically by Power and Solway, 1908.

Myristica, U.S.P., B.P.; (Nutmeg).—The ripe seeds of *Myristica fragrans*. *Dose*, 0.5 Gm., 8 gr., U.S.P.

Ol. Myrist., U.S.P., B.P.—Distilled from the preceding. *Dose*, 0.1 c.c., 1½ minims, U.S.P.; 0.03 to 0.18 c.c., ½ to 3 minims, B.P.

Sp. Myrist., B.P.—10 per cent. *Dose*, 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

Senecio.—The alkaloids (*senecine* and *senicionine*) of *S. Jacobea* and vulgaris produce in cattle toxic effects resembling those of volatile oils: Hemorrhages in abdominal organs, especially the liver; fatty changes, necrosis, congestion, and hepatic cirrhosis (Cushny, 1911; Willmot and Robertson, 1920). The fluidextract (10 to 20 drops) has been used as emmenagogue. It has a slight depressant effect on the excised uterus (Pilcher, 1916).

Helenium Autumnale.—This contains a neutral bitter principle (Reeb, 1910), which is strongly irritant to mucous membranes. Systemically, it stimulates respiration and directly paralyzes cardiac and other muscle. It is not hemolytic (Lamson 1913).

Spewing Sickness.—A sheep disease of Utah, is due to the eating of *Dugaldia hoopesii*, a composite plant, allied to *Helenium* and probably containing similar active principles. It produces also similar gastro-intestinal and cardiac symptoms (D. D. Marsh, 1916).

Eupatorium Urticifolium (*Ageratoides*).—The feeding on the green plant is said to be the cause of one form of "trembles" or "milk-sickness" of sheep; the symptoms consist in weakness and ataxia, ending in death (Curtis, 1917). Marsh and Clawson, 1917). The toxic principle is extracted by 95 per cent. alcohol (Sackett, 1919).

Other species of *Eupatorium* (Bonaset) are used as diaphoretic tea.

VOLATILE OILS AND OLEORESINS EMPLOYED IN URETHRITIS AND CYSTITIS

Members and Uses.—The oil of Sandalwood and the oleoresins of Copaiba and Cubeb, and Matico are used mainly as urinary antiseptics in subacute and chronic urethritis, as adjuvants to local treatment, to diminish the pain and the discharge, and to hasten healing. Santal oil is generally preferred. It is best administered in capsules, on a full stomach, so as to minimize gastric irritation. Buchu is used as a diuretic in catarrhal cystitis, Cubeb is sometimes employed in bronchitis.

Manner of Action.—The oleoresins are natural mixtures of resins and volatile oils rich in terpenes and terpene alcohols. The terpenes are excreted as glycuronic compounds, which have a slight but distinct antiseptic action on the urine. This is much less than that of methenamine; but it has the advantage that it is not affected by the reaction of the urine (Jordan, 1911); and probably they are specifically more effective for certain bacteria. The gonococci are not killed (Bruck, 1913); but the control of the putrefactive bacteria presumably puts the mucous membrane in a better position for resistance. The terpenes and resin-acids are mildly irritant. The urinary passages are thus kept under the continuous influence of the antiseptic terpenes, and stimulated to repair by the irritation. The combination seems to be more effective than either the oils or the resins administered separately.

Experimental Pleurisy.—Winternitz, 1901, and Pohl, 1912, found that the oral administration of various balsams, santal oil, etc., appeared to have favorable effects on experimental aseptic pleurisy (alcuroniat, etc.) in rabbits. However, their doses are so much larger than the clinical, that the applicability of the experiments is doubtful.

Side Actions.—The gastro-intestinal tract is also irritated, resulting in anorexia, colic, eructations, and diarrhea. These unpleasant effects are less with santal oil, which therefore deserves preference; and they may be further avoided by the use of the santalol esters, which are only dissolved in the intestines. Skin eruptions, scarlatinal rashes, etc., occur in some patients, either directly or from the digestive disturbance. Excessive doses of the oils produce more pronounced irritation of the entire urinary tract, with kidney pain, albuminuria, and vesical tenesmus. Albuminuria may be simulated by the precipitation of the resin-acids with nitric acid; to be distinguished by the addition of alcohol, which dissolves the resins. Glycosuria may also be simulated by the glycuronic acid.

PREPARATIONS

Buchu, U.S.P.; *Buchu Fol.*, B.P.; *Buchu*.—The dried leaves of *Barosma betulina* (also of *B. crenulata* and *B. serratifolia*, U.S.P.). Contains volatile oil, glucoside, bitter principle, etc. *Dose*, 2 Gm., 30 gr., U.S.P.; best as infusion.

Inf. Buchu, B.P.—5 per cent. *Dose*, 30 to 60 c.c., 1 to 2 ounces, B.P.

Fldext. Buchu, U.S.P.—*Dose*, 2 c.c., 30 minims, U.S.P.

Tr. Buchu, B.P.—20 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Copaiba (Copaib.), U.S.P., B.P. (Balsam of Copaiba).—An oleoresin derived from South American species of *Copaiba*. Contains volatile oil and resin (copaivic acid). Pale yellow to brownish yellow, more or less viscid liquid, either without fluorescence or with only a slightly greenish fluorescence; having a peculiar aromatic odor, and a persistent, bitter and acrid taste. Insol. in water, partly sol. in alc., freely sol. in oils. *Dose*, 1 c.c., 15 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.; in capsules or pills (with magnesia). The various "Lafayette," "Chapman" and similar mixtures are undesirable.

Ol. Copaib., B.P.—Distilled from the preceding. *Dose*, 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

Cubeba, U.S.P.; *Cubeb. Fruct.*, B.P.; *Cubeb*.—The dried, full-grown, unripe fruits of *Piper Cubeba*. Contains volatile oil and resin (cubebic acid). *Dose*, 2 Gm., 30 gr., U.S.P.; 2 to 4 Gm., 30 to 60 gr., B.P.

Oleores. Cubeb.—An evaporated alcoholic extract. *Dose*, 0.5 Gm., 8 gr.

Ol. Cubeb., B.P.—The distilled oil. *Dose*, 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

Tr. Cubeb., B.P.—20 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Troch. Cubeb.—0.02 Gm., 3 gr.

Kava Rhiz., B.P.—From *Piper methysticum*.

Ext. Kava Liq., B.P.—*Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Matico.—The leaves of *Piper angustifolium*.

Sabal (Saw Palmetto).—The partially dried, ripe fruit of *Serenoa serrulata*. Statements as to presence of alkaloids and volatile oils are contradictory. Has been used as nutritive tonic, alterative, in respiratory diseases, digestive disturbances, as aphrodisiac, etc. Of very doubtful value. *Dose*, 1 Gm., 15 gr.

**Oleum Santali* (Ol. Santal.), U.S.P., B.P.; Santal Oil.—Distilled from the heart wood of *Santalum album*. A pale yellow, somewhat thick liquid; peculiar aromatic odor, spicy taste. Readily sol. in alc. It often disturbs the stomach; and sometimes causes vesical and renal irritation, with dysuria. *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.3 to 1.8 c.c., 5 to 30 minims, B.P.

Santal Oil Derivatives.—Santal oil consists chiefly (90 per cent.) of santalol, $C_{16}H_{26}O$, a mixture of two sesquiterpene alcohols. This may be used in the form of its carbonic ester and of its salicylic ester (*Santyl*, N.N.R.). These are oily liquids, almost without odor or taste. *Dose*, 0.5 c.c., three times daily.

BALSAMS

Balsams (Peru, benzoin, tolu, storax) are oleoresins containing cinnamic and benzoic acids. The oils act as antiseptics; the oils and resins are mildly irritant, stimulating repair; and the resins furnish local protection and thus allay inflammation. The balsams are therefore employed in chronic inflammations of mucous membranes (bronchitis) and of the skin (eczema and pruritus); and to promote the healing of ulcers and wounds. Myrrh acts similarly. The balsams are also used locally against scabies, destroying the acarus and their ova. Peru balsam is employed locally and internally for tuberculosis (for intravenous use, see "Cinnamic Acid"). Its internal administration is of doubtful utility, as is also the internal use of other balsams in bronchitis. Even large doses of the balsams do not produce albuminuria (Stockman, 1891).

PREPARATIONS—BALSAMS

Benzoinum, U.S.P., B.P.; Benzoin (Gum Benjamin).—A balsamic resin obtained from *Styrax Benzoin* and other species growing in the East Indies. *Dose*, 1 Gm., 15 gr., U.S.P.

Tr. Benz., U.S.P.—20 per cent. *Dose*, 1 c.c., 15 minims, U.S.P.

**Tinctura Benzoini Composita* (Tr. Benz. Co.; Tr. Benzoin. Co.), U.S.P., B.P.; Compound Tincture of Benzoin (Friars' Balsam, Turlington's Balsam).—10 per cent. of Benzoin, with Aloes, Storax, and Tolu, in alcohol. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P., as stimulant expectorant; as inhalant, teaspoonful to cup of boiling water; externally, mixed with glycerin or water, as lotion for chapped hands. The original formula was much more complex; and the present formula is still needlessly complicated and expensive. When used as inhalant, the steam contains a trace of oil and benzoic acid (Peacock and Deg, 1919), which would be deposited on the mucous membranes. The same results would probably be secured more simply by substituting the official Tr. Tolu.

**Balsamum Peruvianum* (Bals. Peruv.), U.S.P., B.P.; Balsam of Peru.—A balsam obtained from *Toluifera Pereira*, Central America (not from Peru); often adulterated. Dark brown, viscid liquid of agreeable vanilla odor and persistent bitter acrid taste. Freely sol. in alc. *Dose*, 0.3 to 1 Gm., 5 to 15 minims, B.P. Externally on lint; in scabies, inunction of 2 to 3 Gm., four to six times in the day.

It is used generally diluted with 2 parts of castor oil as a stimulant to indolent ulcers.

It is said to promote healing without stimulating granulation; but it is sometimes irritating.

Styrax, U.S.P.; *Styrax Praep.*, B.P.; Storax.—A balsam obtained from the wood of *Liquidambar orientalis* (Levant Storax), or *L. styraciflua* (American Storax), U.S.P. *Dose*, 1 Gm., 15 gr., U.S.P.

Tolu, U.S.P.; *Balsamum Tolutanum* (Bals. Tolut.), B.P.; Balsam of Tolu.—A balsam obtained from *Toluifera Balsamum*. A yellowish-brown or brown, plastic solid,

becoming brittle when old, dried, or exposed to cold; pleasing, aromatic odor, resembling that of vanilla; mild, aromatic taste. Sol. in alc. *Dose*, 0.3 to 1 Gm., 5 to 15 gr., B.P.

Tr. Tolu., U.S.P.—20 per cent. in alcohol. *Dose*, 2 c.c., 3 minims, U.S.P.

Tr. Tolu., B.P.—10 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Syr. Tolu., U.S.P., B.P.; see Index.

PREPARATIONS—AROMATIC RESINS

Ammoniicum, B.P.—Gum resin exuded from stem of *Dorema* species. *Dose*, 0.3 to 1 Gm., 5 to 15 gr., B.P.

Mist. Ammoniaci, B.P.—3 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Galbanum.—Gum-resin from *Ferula galbaniflua*. *Dose*, 0.3 to 1 Gm., 4 to 15 gr., B.P.C.

Mastiche, Mastic.—Resinous exudation from *Pistacia Lentiscus*.

Mastic Varnishes.—These have been used in surgery to fix the skin-bacteria on the hands and operative area. They are brushed on, and allowed to dry. The skin may first be treated with iodine. Various formulæ have been published (Merck's Rep. 27: 324; 28: 279; 1914). Borchardt's consists of mastic 40 Gm.; benzene 60 Gm., castor oil 20 drops; filter. The basis of Heubner's is rosin, of Dietrich's dammar.

Myrrha, U.S.P., B.P.; *Myrrh*.—Gum-resin from *Commiphora Myrrha* and other species. *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P., as carminative. Was used by the ancients as incense in religious ceremonies; and by the Egyptians in embalming, in combination with spices.

* *Tr. Myrrh.*, U.S.P., B.P.—20 per cent. in alcohol. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P. Used especially as mouth wash (1:25) in stomatitis and pharyngitis; as a lotion, 1:5 or 10.

PREPARATIONS—RESINOUS DRUGS

Echinacea.—The root of *Echinacea angustifolia* (Purple Cone Flower). It contains resins, and no alkaloids (Heyl and Staley, 1914). Several proprietary preparations have been praised for sialagogue, diaphoretic, antiseptic, stimulant, and general alterative effects (Lloyd, 1904; Madden, 1905); but no good evidence of its value has been published and the claims appear extravagant (J.A.M.A., Nov. 27, 1909). *Dose*, 1 to 2 Gm., 15 to 30 gr.

Grindelia, B.P.—The dried leaves and flowering tops of *Grindelia camporum*. Contains an amorphous resin (probably the active principle), sugars, proteins, tannin, and a very small quantity of volatile oil, no saponin or alkaloid (Power and Tutin, 1905). It is said to relax the muscular coats of the bronchi and diminish the excretion of mucus. It is therefore used in asthma and bronchitis.

Ext. Grindel. Lig., B.P.—*Dose*, 0.6 to 1.2 c.c., 10 to 20 minims, B.P. Also employed locally in ivy poisoning, but probably without value.

Pyrethri Radix; *Pyreth. Rad.*, B.P. (Pellitory).—The dried root of *Anacyclus Pyrethrum*. Chewed as sialagogue and against toothache.

Tr. Pyreth., B.P.—20 per cent.

INSECTICIDES

Certain volatile oils, or drugs containing them, as also poisons belonging to other groups, are used to kill or repel noxious insects, such as *Mosquitoes*, *Roaches*, *Flies*, etc. "Insect Powder" (the powdered flowers of *Pyrethrum* species—Persian Powder—and of *Chrysanthemum cinerariæfolium*—Dalmatian Powder); *Eucalyptus*, *Menthol*, *Erigeron*, *Cedar*, and *Lavender* may be cited. (Roach powders commonly contain sodium fluoride or borax; arsenic is effective, but dangerous; White Hellebore is also poisonous.) Naphthalene and Camphor are used against *moths*.

The physical properties, volatility, spreading power, etc. are important, as well as the chemical toxicity (W. Moore and Graham, 1918; bibliography).

Pediculosis.—The experiences of the war greatly revived the interest in insecticides against these parasites. Mercury, staphisagria, phenol, etc., are effective against limited infections; but they are too toxic and irritant for extensive application. Naphthalene and volatile oils stupefy and paralyze the parasites, but they are likely to recover subsequently. Acids are definitely fatal. Sulphur dioxide is effective (Knaffl-Lenz, 1915).

Oiling of underwear destroys the lice mechanically (1 c.c. of oil per 4 square inches of medium weight underwear).

Of chemical substances, the most promising appear to be creosote and especially heliotropin (piperonal). The latter must be applied in theobroma oil solution (W. Moore, 1918).

House-flies.—The toxicity of organic compounds is generally proportional to their volatility (W. Moore, 1917).

Mosquitoes.—Nearly all volatile oils when mixed with fat tend to protect up to 2 hours. Presumably they obscure the human odor (Bacot and Talbot, 1919).

MUSTARD OIL

Actions and Uses.—The volatile oil which is developed from black mustard on contact with water, produces a more prompt, more violent, and more penetrating irritation than the other volatile oils. Mustard preparations are extensively used for counterirritation, but care must be taken to stop the application when marked tingling is felt, or there may be vesication and even ulceration. Internally, mustard is used as a condiment; larger doses (1 to 4 teaspoons of powdered mustard in a tumbler of warm water) produce vomiting; still larger doses cause violent gastro-intestinal irritation. Boiling water prevents the development of the oil by destroying the ferment.

Composition.—Volatile oil of mustard (allyl iso-thiocyanate, C_3H_5NCS) is derived from *black mustard* by the action of a ferment, *myrosin*, on the glucoside *sinigrin* (potassium myronate). The latter itself is not irritant. Mustard seed also contains about 25 per cent. of bland fixed oil.

White mustard contains a similar ferment and glucoside, *sinalbin*, which yields an analogous oil, acrinyl iso-thiocyanate. Much less volatile oil is liberated than with black mustard. White mustard seeds have a cathartic action, due to the liberation of H_2S on contact with water. Large doses may produce sulphide poisoning, with cyanosis, etc. (van Leersum, 1916).

Similar sulphur-containing oils are formed in other cruciferous plants, such as horseradish, radish, cress; and in onion, garlic, etc.

Plants containing mustard oil (*Bursa pastoris*) stimulate the contractions of the excised uterus (Groeber, 1915).

PREPARATIONS

Armoracia Radix, B.P.—Fresh Horseradish Root.

Sp. Armor. Co., B.P.—Dose, 4 to 8 c.c., 1 to 2 drachms, B.P.

Sinapis Alba (Sinap. Alb.); White Mustard.—The ripe seeds of *Sinapis alba*.

Dose, as emetic, 10 Gm., $2\frac{1}{2}$ drachms, of the powder, in tepid water.

Sinapis Nigra (Sinap. Nig.), U.S.P.; Black Mustard.—The ripe seeds of *Brassica nigra* (and *B. juncea* and varieties, U.S.P.) Dose, an emetic, 10 Gm., $2\frac{1}{2}$ drachms, U.S.P., of the powder, in tepid water. Powdered mustard is applied as a *poultice*, mixed with 5 to 10 parts of flour and enough water to make a paste; it may also be sprinkled on the surface of the ordinary linseed poultice. It is used in *footbaths* for preventing colds (1 to 2 ounces to a gallon); and in general baths for infantile coma (large tablespoonful to small bath).

* *Emplastrum Sinapis* (Emp. Sinap.), U.S.P.; Mustard Plaster (*Charta Sinapis*, Mustard Paper).—A mixture of de-fatted black mustard and rubber, uniformly mixed and spread on paper, cotton cloth or other fabric. Mustard plaster is moistened thoroughly with warm (not hot) water, and applied to the skin for fifteen to thirty minutes.

Oleum Sinapis Volatile (Ol. Sinap. Vol.), U.S.P., B.P.; Oil of Mustard.—A volatile oil produced synthetically or obtained from the seed of *Brassica nigra*, consisting chiefly of allyl iso-thiocyanate (C_3H_5SCN). Colorless or pale yellow, strongly refractive liquid, having a very pungent and acrid odor and taste. Dose, 0.008 c.c., $\frac{1}{8}$ minim, U.S.P. It may be used as counterirritant in $\frac{1}{10}$ to 2 per cent. solution in 50 per cent. alcohol (Herzfeld, 1909).

Mustard oil is more irritant in aqueous than in oily vehicles (Sollmann). A 2 per cent. suspension in 3 per cent. tragacanth paste represents an effective counterirritant, equal to a 3 per cent. ointment (Ewe, 1920).

Lin. Sinap., B.P.—3.5 per cent. of Ol. sinap., 5.5 per cent. of Camphor.

THIOSINAMINE

Uses.—This is allyl-sulphocarbamide, prepared by heating volatile oil of mustard (allyl thiocyanate) with alcoholic solution of ammonia. It was introduced by Hebra

and Unna, 1892, and has been credited with causing the absorption of exudates, lymphatic swellings, scar-tissue, etc.; and with the cure of lupus. The administration must be continued for weeks, and combined with massage and other adjuvant measures. It is therefore difficult to judge whether it has any value. The clinical opinions are contradictory, and no satisfactory explanation has been offered for its reputed effects. Its restricted use indicates that it probably does little, if any good, and it may produce toxic systemic effects, although it is usually well borne, except for the bitter taste and garlic eructations.

Thiosinamine has been injected intravenously in arspenamine dermatitis, in place of sodium thiosulphate (Greenbaum, 1924); but it does not appear to have found favor.

Toxic Effects.—In man, 1 Gm. or 0.2 Gm. on repeated use, have caused headache, nausea, vomiting, lassitude and fever (J.A.M.A., 56: 835, 1911; Charteris, 1910; Seifert, *Nebemwirk.*, 1915, p. 182). These may set in suddenly after it has been used for a time uneventfully. In animals, Tyrode, 1910, found impaired respiration, eventually cessation, and death; sometimes pulmonary edema and hyperemia (Lange, 1892). The circulation is not affected in mammals, but high concentrations paralyze the frog's heart. Smaller doses produce severe changes in metabolism, with loss of nitrogen and rapid emaciation; and fatty generations of parenchymatous organs, especially the heart and kidneys. Normal connective tissue showed no changes.

Other Allyl Compounds.—Allyl acetic acid, allyl urea and dimethylallylamine are indifferent; allyl iodide is strongly irritant; allyl formate produces necrosis of the liver and kidneys; allyl amine is highly toxic. The effects are described by Piazza, 1915.

PREPARATIONS

Thiosinamina, N.N.R.; Thiosinamine (Rhodamine, Allylthiourea); $(\text{NH}_2)\cdot\text{CS}\cdot\text{NHCH}_2\cdot\text{CH}:\text{CH}_2$.—Colorless crystals, of slight garlic odor and bitter taste. Slightly sol. in water, with decomposition; dissolves in alc. or glyc. The oral dose is 0.03 to 0.1 Gm. in capsules. It is usually administered by hypodermic injection (which need not be made at the site of the lesion), daily to every third day, 0.05 to 0.2 Gm., in 15 per cent. alcohol or 10 per cent. glycerin. Since the solvents produce local irritation, *Fibrolysin* may be substituted (Mendel, 1905).

Fibrolysin, (Liq. Thiosinam. Sodio-salicylatis).—15 per cent. of a double salt of thiosinamine and sod. salicyl. Dose, a 2 c.c. vial, corresponding to 0.2 Gm. of Thiosinamine.

DICHLOR-DIETHYL-SULPHIDE, "MUSTARD-GAS"

General Statement.—This substance acquired great importance as the "blistering-gas" of the war. It was also known as "Yperite," "Yellowcross shells" and as thiodiglycol chloride. It has the formula

It is an oily fluid of sharp odor, but not related to "mustard oil."

"Mustard gas" differs from the older war "gasses" in that its serious effects are not confined to the respiratory tract. Pulmonary lesions, when they occur, are indeed the most fatal manifestations; but there are also very important actions on the eyes and skin; and sometimes fairly severe gastric disturbances. Even direct systemic effects occur (Lynch, *et al.* 1918) although these are only faintly indicated in field or factory intoxications.

Contact with the fluid or its vapor does not produce any immediate effect whatever; but after a latent period of some hours, intense inflammation develops at the site of contact, even after minute traces. This leads to vesication, followed by local necrosis with very slow healing. The lesions, however, are superficial and extend but little beyond the actual contact. Secondary infections are common, as the resistance is lowered.

The local phenomena have been attributed to the intracellular hydrolysis of the substance, with liberation of hydrochloric acid. The toxic effect would thus be due to intracellular acidosis. This explanation, however, does not appear adequate.

The intoxication is usually strictly local, involving the skin, the eyes, the respiratory and sometimes the alimentary mucosæ, according to the method of application. Systemic intoxication usually occurs only by intravenous injection.

The treatment of the local lesions is mainly by cleanliness and emollients, similar to that of burns. Oils also protect the skin, but only very slightly. If the patient is seen immediately after exposure, the poison may be partly removed by scrubbing with kerosene; but the penetration is so rapid that this treatment is not successful if delayed for 15 or 30 minutes.

Historical.—The substance and its toxic effects were discovered by Victor Meyer in 1886 (Ber. deut. chem. Gesell., 1886, v. 19, p. 3259, v. 20, p. 1729).

Military Use.—"Mustard Gas" was first used on a large scale by the Germans at Ypres, July 12 and 13, 1917. At first it scored heavily, since its peculiar properties were not at once appreciated. It differs from the other gases in two essential respects: (1) its effects are delayed several hours, so that effective protection is apt to be neglected; and (2) it is very persistent, so that areas that have been shelled with it are infective for several days.

This persistence is due to the limited volatility of the liquid at ordinary temperatures. When atomized by the explosion of the shell, it spreads as a mist, which condenses as a liquid film on any solid substance, leaves, cannon, the ground, etc.; and thus forms deposits that are dangerous both by direct contact, and because their slow evaporation keeps up a prolonged saturation in the air with the poison. This holds especially for valleys, trenches, etc., where the air is stagnant.

When occupying an area which has been heavily shelled with mustard, respirators must be worn almost continuously; this and the insidious course of the poisoning are a severe test of morale. However, since its dangers have been fully recognized, they are greatly diminished.

Physical Properties.—Dichlorethylsulphide is a colorless or pale yellow, heavy, oily liquid of neutral reaction.

When pure, it has a faint but penetrating odor, reminiscent of stale ether and of mustard oil. This is the source of its popular name, "Mustard Gas," for it is not derived from true mustard oil. The odor of the crude product is more pronounced and similar to garlic. It is due mainly to contamination with ethyl sulphide.

Toxic concentrations of mustard gas can generally be smelled in the air. However, there is considerable difference in individual sensitiveness. Further, the odor is sometimes disguised by adding other substances.

Solubility.—Dichlorethylsulphide is generally soluble in fats and fat-solvents and alcohol, but is only very slightly soluble in water (0.07 per cent. at 10°C., E. F. Hopkins). Its solubility increases with the temperature, but it is rapidly hydrolyzed.

Chemical Properties.—The toxic action of dichlorethylsulphide is intimately connected with its constitution, particularly with the presence of the two chlorine atoms. If these are either diminished or increased, the activity is destroyed. This may be accomplished, and the "mustard gas" may be "killed" by hydrolysis, chlorination, and by reducing agents evolving nascent hydrogen; less efficiently by oxidizing substances.

Hydrolysis.—Dichlorethylsulphide is hydrolyzed by water, probably mainly according to the equation:

The hydrolysis starts promptly and proceeds fairly rapidly for the dissolved substance. The undissolved substance is not hydrolyzed, of course. For this reason, and because of the limited solubility of the substance, the hydrolysis of any excess of dichlorethylsulphide proceeds very slowly.

Hydrolysis Theory of Toxic Action.—It has been suggested that the dichlorethylsulphide penetrates as such into the cells, and is there slowly hydrolyzed, resulting in a liberation of free acid within the cells; and that in this free acid is really the toxic agent (Lynch, Smith and Marshall, 1918, J. Pharmacol, 12: 265).

The plausible assumption would explain the delayed effects, and is in consonance with most the facts so far as known. It is established that the substance is hydrolyzed before it is excreted; and, there is proof that this hydrolysis may occur within the cells at the place of application, at least in the cells that have been examined. The most direct evidence is furnished by invertebrates, especially star-fish ova (Lillie, Clewes *et al.*, 1918, 1919); when these are exposed for say 8 minutes to the solution and then washed, cleavage progresses normally for 2 hours, when changes start. This coincides with the appearance of free acid; *i.e.*, the effect appears only when enough acid is developed to neutralize all buffer substances.

Further evidence is furnished by intracellular injection: Eggs injected with water are not materially injured. Those injected with fresh dichlorethylsulphide solution show no immediate effects, but are killed later. Those injected with hydrolyzed dichlorethylsulphide solution are injured immediately, about to the same degree as eggs injected with hydrochloric acid of the same acidity.

The proof, however, is not conclusive. On the other hand, it has been pointed out that related substances, such as dichloro-diethylsulphide, which practically do not produce acid, are nevertheless vesicant; while dichloro-dimethylsulphide, which produces acid more readily than the "mustard gas," is not vesicant (Flury and Wieland, 1921; Peters and Walker, 1923). This does not altogether disprove the acid-theory, since cell penetration and other factors may enter; but it suggests that the "mustard-gas" action may be due to the substance as such, in analogy to cantharidin, true mustard oil, etc.

Destruction of "Mustard Gas."—This may be accomplished by chlorination or dechlorination; or less efficiently by other chemical changes.

Chlorination.—Free chlorine, as gas or dissolved in carbon tetrachloride, introduces a third chlorine atom into the dichlorethylsulphide, forming "monochloro-mustard gas" which is nonirritating. Sulphur dichloride, pure or dissolved in carbon tetrachloride, is also highly effective, and is used to "kill" the gas. It is, however, corrosive to organic matter.

Dry hypochlorites chlorinate and destroy the substance readily, with evolution of heat. "Bleaching powder" is very useful as a "kill."

Chloramine and dichloramine also react vigorously with "mustard." With these, the reaction appears to be more complicated; but the irritative qualities are destroyed.

All chlorinating agents must be applied as concentrated and especially as dry as possible; else the immiscibility of "mustard" with water prevents intimate access of the chemicals.

Development of Symptoms.—The variations introduced by differences in concentration and other conditions will be discussed later. The following represents the usual order of the phenomena as they occur under field conditions without protection:

No effects are felt *immediately* on exposure, except in high concentrations, when there may be tendency to sneeze, with or without smarting of the eyes. Hemorrhage, especially from the nose, is a common early symptom (Berghoff, 1919).

The first definite symptoms are generally from the eye, starting 2 or 3 hours after exposure, with the smarting and watering; proceeding to reddening, pain, edema and all the phenomena of acute conjunctivitis. The nose also reacts early with increased secretion and sneezing. The throat likewise becomes sore.

In 4 to 16 hours after exposure, these symptoms have become much more marked and distressing. The eyes are discharging and very painful; the nasal discharge is more purulent; the voice is husky or suppressed.

Nausea, retching and vomiting, associated with epigastric pains, occur in a large proportion of cases and may recur at frequent intervals for several hours. In severe cases, they may become very intense and prolonged. Diarrhea may set in, but is rather exceptional.

Skin-rashes also show in this period, as a dusky erythema of the exposed parts of the body, and in the axilla, crotch and genitals.

At the end of 24 hours, the eye-symptoms have assumed a very characteristic form in the severer cases. They are very painful, with the lids swollen almost shut, and oozing tears. There is photophobia and blepharospasm, and generally frontal headache.

The exposed skin is further reddened and swollen and may be itching.

The nose discharges freely. The throat feels raw and burning. Aphonia may be complete. A dry harsh cough may develop. The respiration is fairly normal.

Death practically never occurs during the first day.

During the second day, the skin erythema may have developed into blisters, sometimes of large size, with the scrotum and penis especially painfully swollen. (The further course of the skin lesions will be discussed later.)

The eyes become somewhat less painful, although the acute inflammation may persist for several days.

This is also the time when the inflammation of the respiratory tract becomes conspicuous in severe cases. The expectoration becomes abundant, muco-purulent, sometimes with large sloughs of tracheal mucosa. This is complicated by secondary infection of the necrotic respiratory membranes. Fever sets in, with rapid pulse and respiration. The infection may terminate in broncho-pneumonia, with death anywhere between the second day to the fourth week.

Milder cases, fortunately, are of a milder type; especially as the troops acquire familiarity with the gas and apply the protective measures more stringently. In the opening of the 1918 campaign, the mustard mortality was slight. There were very few actual blisters, although minor rashes were common. The conjunctivites were less severe; the laryngites fairly mild, but almost universal. Most mustard field cases have only slight respiratory catarrh. Only about 10 per cent. are burns (Underhill, 1918).

During the hot months, there is an increase of the pulmonary lesions; perhaps because of the greater volatilization.

In factory poisoning, most of the burns were of the hands, arms and fingers (Young, 1918).

Toxicity for Animals.—This is fairly uniform for different species, there being less variation for species than there is for individuals (Marshall *et al.*, 1918; Lynch, Smith and Marshall, 1918; Reed, 1918, 1920).

Air saturated with dichlorethylsulphide at ordinary temperature would hold about 0.5 mg. per liter. This would be fatal if breathed for 7 minutes.

Concentrations of 0.01 to 0.02 mg. per liter have a 50 per cent. mortality with a 2 hour exposure, and 60 per cent. with 4 hours.

Less than 0.01 mg. per liter (1:700,000 by volume) is not fatal even with 8 hours exposure, but produces slight symptoms from the mucosæ (conjunctiva, nose), and loss of appetite.

Slow Course.—The delayed start of the action has been attributed to gradual hydrolysis. This could scarcely explain the delay of over a day. More likely, it is merely the expression of the sluggish character of the inflammation.

Precipitation of proteins by dichlorethylsulphide is also very slow. Excised skin, muscle and mucous membrane are not grossly altered.

Lesions in Upper Respiratory Tract.—The corrosive effects on the epithelium are identical with the corrosion of other epithelial surfaces. Their intensity diminishes from the mouth and nose toward the lungs. The bronchi are involved only in the severest cases. Sub-epithelial edema is much less than in the skin or conjunctiva (Warthin and Weller, 1919).

The primary action is followed by local catarrh or diphtheritic lesions from the nose to the bronchi, even in the mildest cases. In the more severe, there is a marked pseudomembrane formation, secondary purulent bronchitis and broncho-pneumonia (Warthin and Weller).

The rhinitis, laryngitis, tracheitis and bronchitis play a conspicuous part in the minor as well as in the severe intoxications of mustard gas. Their symptomatology has been sufficiently outlined. The anatomic changes consist in intense congestion, often hemorrhage. In the severer grades this passes into necrosis and desquamation of the mucosa, often in large masses. These may interfere with respiration; but more commonly the lesions become infected, ending either in pneumonia or in slow healing.

The congestion is visible early in the nose and mouth, the pharynx, epiglottis and larynx, and extends through the trachea into the finest bronchioles. *Epistaxis* is a common early symptom (Berghoff, 1919).

In the *trachea* and *bronchi* the necrotic mucosa, and the purulent exudate, form a continuous thick, pale yellow false membrane, which is easily detached in large strips.

This false membrane formation extends into the bronchioles, where it may occlude the lumen. Incomplete occlusion of a bronchial branch results in emphysema of its ramifications. When the occlusion becomes complete, the air is absorbed, and the corresponding lung area collapses. Thus, emphysema and atelectasis may occur in different portions of the same lung.

The alveoli are but little affected directly, presumably because most of the substance is bound and absorbed before it can reach them. Consequently there is no acute pulmonary edema, in the early stages, and no fluid or froth in the air tube; although there may be considerable congestion and some epithelial desquamation.

However, the serious cases become infected by bacteria, and then change to an intensive broncho-pneumonia, with its ordinary phenomena, which may bring about a secondary edema.

In case of recovery, the ulcers of the mucosæ heal slowly. Ulceration of the trachea may be followed by constriction of its lumen.

Treatment of the Respiratory Lesions.—The *rhinitis* is treated along the usual lines; by frequent spraying or instillation of a few drops of 1 per cent. sodium bicarbonate, followed by a liquid petrolatum. When the condition is not too painful, a few drops of 2 per cent. dichloramine T in chlorosane may be introduced several times daily.

The mouth and throat may be gargled with a weak Dakin's or $\frac{1}{2}$ to $\frac{3}{4}$ per cent. chloramine T solution.

For *aphonia and mild bronchitis* steam inhalations may be used, with or without compound tincture of benzoin. An ice-bag may be applied to the larynx.

The severe bronchitis and pneumonia are treated as in ordinary practice.

Eye Lesions from "Mustard Gas."—The cornea and conjunctiva are highly sensitive to the "mustard" irritation, and present the earliest and often the most serious symptoms after unprotected exposure to the vapor. Identical effects are produced by contact with the liquid poison. A previous eye burn increases the susceptibility.

Light cases may heal in 2 or 3 days. In severe poisoning the inflammation is intensely painful for several days, and ocular symptoms may persist for several weeks. Fortunately the deeper structures of the eye are not affected, except under extreme conditions. Consequently, nearly all cases recover without permanent injury, except at most some reduction of vision from cicatrization of the cornea. Severe eye injuries resulted in only about $1\frac{1}{2}$ per cent. of the gassed (Tenlières, 1918).

The course and pathology of the lesions has been studied in detail on rabbits and are essentially the same as for skin lesions, the difference being merely quantitative. The healing process is also similar (Warthin and Weller, 1918).

Sensitivity of the Eyes.—This is fairly uniform for different species and individuals, if uniform access of the poison is assured; the results naturally differ according to whether the eyes are kept open or shut during exposure to the gas.

For Human Subjects, Reed, 1920, reported that 1:10,000,000 (0.0006 mg. per liter of air) produced visible ocular reaction with exposure of less than an hour. The skin was sometimes affected in highly susceptible individuals. 1:5,000,000 (0.0012 mg. per liter) for 45 minutes caused quite severe reaction of the mucous membranes, and itching and desquamation of the skin. The eye-sensitivity of *animals* was reported by Marshall *et al.*, 1918, and Hess and Barba, 1916.

Treatment of the Eye Lesions.—The conjunctiva should be kept clean by frequent irrigation with saturated boric acid, or with 1 per cent. sodium bicarbonate, followed by a few drops of oil. Light-weight cold compresses of saturated boric solution should be applied continuously for 12 to 24 hours, or longer if needed, to relieve the pain and discomfort, reduce the congestion and protect the eyes against light. Pressure on the eye-lids must be avoided.

This treatment also tends to prevent adhesion of the eyelids. If they do become glued together, they must be soaked in boric or bicarbonate solution until they can be opened without force. Forceful opening is liable to do harm.

Organic silver protein salts have been used, but are probably undesirable. They might cause permanent staining. Cocaine is also inadvisable since it could only give temporary relief.

Dichloramine, 0.5 to 1 per cent. in oil, has been recommended, but would probably be quite painful. Dakin's solution is too irritant.

In corneal ulcers produced by vapor in dogs, Hess and Barba, 1918, found that irrigations with the following solutions, every 4 to 24 hours, had no influence whatever on the natural course of healing: Saline; sodium bicarbonate, 1 per cent.; boric acid, 3 per cent.; potassium permanganate, 0.1 per cent.; sodium carbonate, $2\frac{1}{2}$ per cent.; chloramine, 0.1 per cent.

If liquid "mustard" is splashed into the eyes, this should be washed at once with the 1 per cent. dichloramine solution.

Skin Burns.—The "mustard gas" burns resemble X-ray and drug dermatitis rather than simple heat burns.

In principle, they do not differ from the course of other toxic dermatitis; but they differ in detail: (1) in the length of the latent period, and (2) in the absence of all pain until the ulceration stage has set in. That is, not only are mustard burns imperceptible when first received, but they remain painless until the blisters break, about the 3d or 4th day. This is not due to anesthesia.

In the mild rashes, the skin edema causes intense itching about the same time.

The very tedious and slow healing of the necrotic lesions is due to injury of their blood vessels. Moreover, they generally become somewhat infected, but only superficially. There is little or no fever. The lymph-nodes, however, are swollen and painful quite early.

Dichlorethylsulphide penetrates the skin very rapidly. The effects of the liquid or vapor are absolutely identical, differing only in extent and intensity; vapor burns being usually more extensive but less severe. The susceptibility varies considerably in different individuals, and is also influenced by temporary conditions.

The burns range in intensity from simple rubefaction, through edema, vesication and necrosis. Although severe, the inflammation remains confined to the skin, perhaps because the circulation prevents its accumulation in the deeper structures.

Bibliography.—The phenomena are described by Warthin and Weller, 1918, Marshall; Smith and Lynch, 1918; Sollmann, 1919.

Course.—The inflammation has a rather striking course. There is a latent period, of $\frac{1}{2}$ hour to 2 days, before any sign of inflammation can be seen or felt. Then the inflammation gradually increases, then remains stationary, and slowly heals. The duration of these stages depends on the severity of the exposure. Light burns appear late and heal early; severe lesions appear early and heal late.

Skin Rashes.—Erythema occurs as the first stage of all "mustard" lesions. Vapor burns and dilute solutions (*i.e.*, saturated watery solution) do not usually progress beyond this stage. In such cases the entire course is confined to the "rash." Practically everyone who works with or around mustard gas is liable to the frequent occurrence of these rashes; and they are probably the most common form of "burns" in the field.

The rashes present varieties of intensity and duration, according to the dose, location and susceptibility.

Rashes also commonly surround the blister-burns for considerable distances. A splash of liquid mustard on the skin will produce a circumscribed blister of the underlying skin by direct contact; but the excess of the dichlorethylsulphide evaporates from the cloth, and the vapor spreads between the clothing and skin, until it is confined by a belt, garter, gaiter, etc. The axilla and groins are especially affected.

Severer grades may develop minute military blisters. These may give the skin the appearance and feel of pebbled oilcloth. The edema is confined to the epidermis and papillary layer.

The inflammatory phenomena persist for several days, and then gradually subside, within a week or two, leaving generally some pigmentation, and hypersusceptibility to irritation.

Pigmentation.—This may take various forms. It may have the red appearance of weather-exposure; or be more or less "tanned" as by the sun. In severe burns, the pigmentation is sometimes almost black, but confined to the superficial desquamating epidermis.

Erythema Preliminary to Vesication.—Erythema also constitutes the first stage of the blister-burns. In that case it appears much earlier, is more sharply localized, and undergoes vesication after one or two days.

Prognostic Significance.—The time when the erythema first becomes noticeable is of prognostic value:

If the skin shows pink or livid spots within $1\frac{1}{2}$ hours after exposure, the burn will develop into a deep blister, and probably undergo ulceration and scarring.

If the pink spots start between 2 or 3 hours after exposure the blisters will be superficial, and will probably heal without ulceration, and without real scarring.

If the rash is delayed for 12 to 48 hours, it will not develop into blisters.

Blister Burns.—When strong vapor or especially when liquid dichlorethylsulphide comes in contact with the skin, the erythema passes into vesication. The first noticeable change is a silvery appearance of the skin, produced by loosening of the epidermis. This is then raised by the accumulation of fluid; the blister is usually well developed in 12 hours, and reaches its maximum size in about 24 hours.

The blisters at first are very tense, often an inch or more high, and may be up to 3 or 4 inches in diameter. They are filled with a transparent gelatinous material, *i.e.*, practically coagulated plasma. If they are opened at this time, the contents stand up like a jelly, and require to be pushed or scooped away.

Between the second and third day the serum begins to separate from the clot. The "skin" of the blister becomes very thin and wrinkles as the serum is absorbed, and opaque balls or shreds of the fibrin are seen within the blister. Generally the blister breaks, and the serum, as it separates, drips in a continuous slow stream from the wound. This gives the patient a very distressing and uncomfortable appearance, especially

if the genitalia are involved. In fact, however, the process is absolutely painless up to this time, and this without any anesthesia.

If the blister is undisturbed, it may be a week before it is fully collapsed.

About 3 days after exposure, the blister begins to become painful, especially on exposure to air, and on mechanical contact, or when treated with chemicals. This sensitiveness increases rapidly to the fifth or sixth day, and the pain becomes very severe. This hypersensitiveness lasts for 2 or 3 weeks, or even longer if ulceration develops. However, the lesions become painless long before the ulcers are healed.

With relatively small doses, the blisters are confined strictly to the area that was in contact with the gas, and are surrounded by a narrow zone of erythema. In more serious burns the blisters themselves extend somewhat, but not much farther, and the erythematous area may be extensive, but this is largely due to the evaporation producing a vapor burn, as explained.

The size of the blisters is not an indication of the severity of the lesions: the largest blisters may be healed in 2 or 3 weeks, while another smaller blister, nearby, goes through a tedious ulceration that is healed only by scarring after 6 or 8 weeks. In fact, the severest lesions (the gangrenous form) do not blister at all.

When a simple "mustard" blister collapses or is opened, and the detached skin removed, the exposed stratum mucosum has a clean red appearance, perhaps with some shreds of fibrin. With the deeper burns, it is covered with a greyish-yellow coating, presumably largely necrotic tissue mixed with some pus cells.

The coating may be removed by soaking in saline or Dakin's solution, thus exposing a raw, granulating surface beneath; but it rapidly forms again. The process, however, remains rather superficial. It apparently involves the corium more or less, although it does not often destroy the epithelium so deeply that it cannot re-cover the wound. Even in severe cases, it does not extend materially below the corium. Statements that it "corrodes to the bone" have no foundation.

For a couple of weeks, this condition of the wound remains practically stationary. Toward the end of 2 to 4 weeks, further necrosis ceases quite noticeably, about the same time that the hypersensitiveness diminishes. A pale pink ring of epithelium starts from the periphery to cover the wound, which meanwhile may form very exuberant granulations.

Toward the end of the fifth or sixth week, practically all wounds are essentially healed, with or without cicatrization. The new skin over the burned areas appears shiny and often pigmented, as in X-ray burns.

Burns of the genitalia differ somewhat from the type. When the scrotum is involved, the testicles become very sensitive. The condition clears about the same time as the skin lesions.

Blisters of the penis may come on quite slowly, and turn into tedious ulcers, which heal much more slowly than other lesions. Infection of the meatus may cause a urethral discharge.

The most severe burns (the gangrenous type) differ from the blister type from the start. Smarting and burning are felt within an hour after receiving the burn. The skin at that time is intensely blanched. By the next day, the burn proper is of a livid, cadaveric color. It does not vesicate but forms a depression, surrounded by a continuous ring of blister. After a week or so, it breaks down into an ulcer, and the entire thickness of the skin may be removed in a mass. The wound remains painful for 3 or 4 weeks. Healing occurs after 5 to 7 weeks, by cicatrization.

Systematic Reactions of Mustard Burns.—Dichlorethylsulphide applied to the skin does not reach the circulation in sufficient amount to produce any systemic lesions; nor are the mustard-burns, even when extensive and deep, accompanied by the acute toxic phenomena of fire-burns. The temperature remains practically normal. However, extensive burns may produce temporary collapse, mainly if not entirely of psychic origin. Later on, the pain is likely to interfere with sleep. The urine should be watched.

Secondary Furunculosis.—Mustard burns lower the resistance of the skin to infection. The blisters are usually followed by a crop of furuncles or pustules, generally on and around the burned area. Men who work with mustard commonly have this complaint even when they have only had superficial rashes.

Increased Susceptibility of the Skin.—Healed mustard burns are definitely hypersusceptible to the poison, and also to mechanical injury. A light contusion may result in a blister. This hypersensitivity, however, is confined to the burned areas and does not extend to the remainder of the skin.

Microscopic Changes in Mustard Burns.—These have been described in detail by Warthin and Weller, *loc. cit.* Briefly, the dichlorethylsulphide produces slow but severe

destructive changes in the epidermis and corium, and especially in the endothelium of the blood vessels.

Even minute quantities penetrate rapidly and deeply. The hair follicles, and sebaceous and sweat glands evidently facilitate the penetration.

The epithelium shows hydropic and other degenerative and necrotic changes within 2 hours. The edema in the early stages is confined to the epidermis and papillary layer, and does not extend much more deeply.

In severe burns, the vessels in the affected area are greatly damaged and collapsed. This results in local anemia in the earlier stages, with marked exudation and leucocyte migration. The vascular lesions are non-hemorrhagic and non-thrombosing.

The slowly progressive character of the necrosis is partly explained by contraction and death of the vessels, and the resultant loss of blood-supply.

Skin Lesions in Animals.—Blistering does not usually occur in any of the experimental animals, including monkeys. Otherwise the lesions are essentially the same as in man.

There are some differences in the degree and rapidity of the primary erythema. In dogs, this is visible in 5 to 15 minutes. Most other animals do not show reddening. Monkeys react by blanching.

Protection against secondary infection being more difficult in animals, the sloughing is often much more severe.

When tested by the paraffin oil method, dogs and goats were found to be about as susceptible as man; but there were considerable differences in individuals. With 0.1 per cent. solution, about $\frac{1}{3}$ of the dogs and goats reacted; $\frac{1}{5}$ of the rats; $\frac{1}{6}$ of the mice. Rabbits, guinea pigs and monkeys required 1 per cent. solutions (Marshall and Williams, 1918).

Susceptibility to Skin Burns.—The susceptibility of different individuals varies more than a hundred times, *i.e.*, to produce a visible reaction requires in the case of "tolerant" individuals a concentration more than a hundred times greater than will produce results in a hypersensitive. Negroes are notably tolerant. The individual susceptibility is easily determined by rapid and convenient methods, and may be of considerable practical importance, since the natural tolerance is much greater than what can be conferred by ointments.

The tolerance, for a given person, does not change greatly with time, if other conditions are uniform. It is also fairly alike for the skin of the entire body, with the exception of a few special regions. The axilla and crotch are hypersusceptible (largely because of their moisture), the thick-skin palmar surface of the hand and fingers is relatively insusceptible. The area of a previous burn is hypersusceptible; but it is doubtful whether the susceptibility of the unburned areas is changed. So far as present observations go, hypersusceptibility appears not to be especially frequent among those who have worked constantly with "mustard" and who have received severe and extensive burns (Sollmann, 1919).

Moisture of the skin and perspiration very definitely increase the susceptibility—an important hint for prophylaxis.

The presence of moisture also increases the susceptibility to other irritants that are more soluble in oil than in water, *f.i.*, phenol or true mustard oil. In all these cases, the insolubility in water would favor the penetration into the more solvent skin. Marshall, Lynch and Smith, 1918 (*Journal Pharmacology*, 12:291), explain susceptibility along similar lines: They assume that the outer layers of the skin (the stratum corneum?) have considerable affinity for the poison, and thus delay its passage into the deeper, living tissues. On this assumption, the solution affinity of the outer skin layer would be less when this layer is rich in water, and greater when it is rich in fat.

Smith, Clewes and Marshall, 1919, believe that the intracellular threshold of toxicity would probably be the same in all individuals, and that the differences in toxicity are due entirely to absorption. They believe that the poison is rapidly absorbed by the skin-surface. A part passes rapidly into the deeper layers and cannot be removed. A greater part, however, remains in the upper layer and is removable for 10 minutes. A large part of this in the superficial layer evaporates, in fact, more than passes inward.

A resistant skin absorbs much more than a sensitive, and on contact with sensitive skin, the resistant takes up the poison.

Removal of "Mustard Gas" from the Skin.—When the dichlorethylsulphide has penetrated the cells of the skin, the damage has been done, and treatment is only palliative. It is therefore imperative to remove the poison as completely as possible before it has penetrated and combined. Unfortunately, the penetration is very rapid; if a small drop is placed on the skin, it is absorbed so rapidly that even the odor has disappeared within 2 minutes. The fixation within the skin is almost as rapid, so that the

efficiency of removal treatment is limited within 5 minutes, and almost nil after 10 to 20 minutes.

This, combined with the fact that most burns are not noticed until several hours after they were received, emphasizes the desirability of prophylaxis, of protection against exposure and contact.

The first step in the treatment of a mustard burn is the removal of the contaminated clothing.

The removal from the skin may be attempted by chemical means or by solvents. The solvents have given better results, presumably because of their better penetration. Any convenient solvent may be used with almost equal results: alcohol, acetone, gasoline, kerosene, turpentine, oils or grease, petrolatum and somewhat less efficiently, soap, "green soap" being better than soda soaps. For practical reasons, chiefly economical, kerosene is generally preferred.

The solvent treatment is materially more efficient if it is combined with rubbing; presumably because this presses some of the poison out of the gland ducts.

Chemical Removal.—Chlorinated lime and the chloramines neutralize the poison if they are applied immediately; but they fail to reach any that has penetrated. This renders them rather inferior to the kerosene treatment. In any cases, they would be useless 5 or 10 minutes after exposure.

Treatment of Mustard Burns.—The various treatments that have been proposed involve mainly three principles:

1. *Attempts at Chemical Destruction of the Poison within the Skin.*—These have been uniformly unsuccessful, since the poison is rapidly fixed within the cells and is thus out of reach of most, if not all, of the chemical antidotes. The outlook in this direction is unpromising, though perhaps not quite hopeless.

2. *Protective Measures.*—These at least add considerably to the comfort of the patient, and may indirectly hasten healing somewhat. It is very doubtful whether the natural course and healing of the burns can be materially influenced for the better by any treatment so far tried; but it can be materially influenced for the worse, by irritation. Protective measures eliminate this additional injury.

As the first step in the protective treatment, the patient should be removed from all chance of exposure to the poison, even to the dilute vapor, or other irritant vapors, until the burns are healed. Irritant dressings must also be avoided.

3. *Antiseptics.*—The extensive raw surface, the lowered vitality, and the presence of necrotic tissue in the blistered burns offer excellent opportunity for infections. On the other hand, the infection remains superficial and is easily kept in bounds by antiseptics, and even by ordinary cleanliness. Most burns probably heal about the same whether antiseptics are used or not.

However, the antiseptic should be given the benefit of the doubt. Antiseptics of the chlorine group have been found most serviceable, and should be used whenever possible (Warthin *et al.*, 1918). They are especially useful toward the end of the necrotic stage. Perhaps their benefit here may be referred partly to the solution of the necrotic tissue.

The comparison of different methods of treating the burns is not easy, partly because it is difficult to judge the severity of a burn, and its presumptive course, especially if it was not followed through all its stages. Several adjacent blisters that look practically alike at the height of vesication may really be of a different depth; one may heal smoothly within two weeks, the other may undergo necrosis and require four weeks.

Another source of error is the rather abrupt turning point when spontaneous improvement sets in. Without any treatment a necrotic surface that has been practically stationary for a week or more, starts to improve over night, almost visibly. If a treatment has been instituted within a few days of this turning point, it would very naturally, but very erroneously receive the credit (Sollmann, 1919).

Details of the treatment were discussed in the Second Edition of this Manual.

Treatment of the Gastric Symptoms.—Nausea and vomiting are seen in a proportion of the intoxications by inhalation. Recovery generally follows without other treatment than a light diet. Occasionally, however, the vomiting is very severe and prolonged. Such cases should be treated with alkalies and bismuth and a milk diet, essentially like gastric ulcer.

There seems to be a general lowering of the resistance after mustard gas poisoning; and therefore increased susceptibility to infections, influenza, bronchitis, pneumonia and tuberculosis (Warthin and Weller, 1919).

Direct Systemic Actions.—The local actions of dichlorethylsulphide are so conspicuous that they rather obscure the systemic actions. These

have been studied by direct injection. They affect mainly the heart and nervous system. Heartblock is particularly characteristic.

Fairly small doses are fatal in dogs, less than 6 mg. per Kg. (Lynch, Smith & Marshall, 1918).

Effect of Subcutaneous and Intravenous Injections.—There is latent period of 10 to 20 minutes, during which no effects of any kind are disclosed. At the end of this period, salivation sets in, followed by increased nervous irritability, excitement, diarrhea, and sometimes convulsions. The excitement soon gives place to coma.

The pulse becomes slow and irregular, with 2 or 3 auricular beats for each ventricular contraction. Toward death the heart becomes very rapid, but does not respond to vagus stimulation. Finally, heart-failure is the apparent cause of death.

Warthin and Weller, 1919, studied the effects of fatal doses on rabbits (0.6 c.c. per kg.) and dogs (0.03 c.c. per kg.). If death occurs quickly, the symptoms are referable to the central nervous system; and is probably direct. When death is slower, there is severe diarrhea (catarrhal enteritis).

The nervous symptoms consist in extreme restlessness, incoordinated movements, etc.; but no definite paralysis or convulsions (Pappenheimer; 1919; rabbits, 5 to 10 mg. per kg.; is M.F.D.).

Lesions.—The necropsy fails to show either gross or microscopic changes in the heart. The only consistent lesion is an intense congestion, sometimes hemorrhagic, of the intestinal mucous membrane, particularly in the duodenum.

Intestinal Changes.—They consist of severe mucoid, desquamative and necrotic enteritis. They suggest that excretion of the substance or irritant derivatives occurs partly by the intestines (Lynch *et al.*, 1918). These results have been confirmed by Warthin and Weller, 1919, for hypodermic injection. They also found similar degeneration inflammatory changes in the intrahepatic bile ducts and gall-bladder, so that the excretion may occur partly by the liver. There is no evidence that the poison is excreted by these channels.

Direct Gastro-intestinal Lesions.—These occur by the ingestion of the substance with the food or saliva. Animals that survive several days after being "gassed" in chambers generally have acute gastric-intestinal catarrh. The lesions are similar to those produced by local contact in other locations: superficial necrosis, followed by ulceration of the mucosa (Warthin and Weller, 1919). The gastro-intestinal symptoms in man are probably chiefly reflex, from respiratory irritation and shock.

Kidneys.—These do not show direct changes, even with intravenous injection. Secondary involvement (cloudy swelling and hyaline casts) may occur during infection or extensive necrosis in severe local lesions (Warthin and Weller, 1919).

Such cases may show diminished urine output, increased concentration, diminished urea and chloride. The condition improves on forced liquid regimen. Mild skin burns show no changes in the urine or blood (Hermann, 1918).

Blood.—Human inhalation casualties show initial *leucocytosis*, followed by more or less extreme *leucopenia* (Giensa, 1919), associated with severe lesions in the bone-marrow (Krumbhaar, 1919; Pappenheimer and Vance, 1919). This usually persists even during bronchopneumonia, and probably contributes to the high mortality of bronchopneumonia, and probably contributes to the high mortality of this complication. The formation of *red cells* and of the *platelets* is also diminished. The *coagulation time* is decreased in the earlier stage, lengthened in the later stages of severe cases (Krumbhaar, 1919, J.A.M.A., 72:39). Hermann, 1918, noted that the maximum of the blood change coincides with the height of the secondary infections, and believes these responsible, rather than direct action. Pappenheimer and Vance, however, found the same changes after intravenous injections.

Systemic Symptoms from Inhalation.—The characteristic effects on the pulse and the nervous system are also seen in animals poisoned by inhalation, and indeed even after the application of large amounts to the skin. The substance must therefore be *absorbed* fairly readily (Lynch *et al.*, loc. cit.).

Fate.—Dichlorethylsulphide is evidently rapidly hydrolyzed for the urine contains products of hydrolysis, probably dihydroxyethylsulphide, with all methods of administration. This is not irritant but by artificial chlorination it can be re-converted into the toxic substances (Lynch *et al.*, loc. cit.).

Protection of the Skin against Mustard Gas.—The very limited success of treatment makes prophylaxis especially important. The poison, like other fat-soluble irritants, is more injurious when the skin is moist; whilst oiling of the skin confers a certain degree of protection. Unfortunately, this protection is quite limited. It may be fairly complete for short exposure to low concentrations; and with high concentrations it at least

increases the efficiency of removal-treatment. For long exposures, however, there is practically no protection by oils.

Extensive experiments with different oils, ointments and admixtures have revealed quantitative differences; but they are not sufficiently great to affect the practical results materially (Sollmann, 1919).

Other Skin Irritants.—Hanzlik *et al.*, 1919, give a survey of the results from a large number of substances.

NON-VOLATILE ORGANIC IRRITANTS

A number of fixed organic drugs act as local irritants. The most important of these is cantharidin. Capsicum, euphorbia, poison ivy, and croton oil, the "acrid principles" of certain fresh plants, especially of the family of Ranunculaceæ, etc., may be counted in this group. They owe their activity to neutral, resinous, or oily principles. Some benzol derivatives—chrysophanic acid, resorcin, pyrogallol, etc.—have a similar action, so also do some of the toxins and the poison of bees (Faust, 1910).

CANTHARIDIN

Actions and Uses.—Cantharides (Spanish Flies) are used for vesication and for prolonged counterirritation in pleurisy, neuralgic and rheumatic pains, etc. The irritation is active, but the penetration slow, so that the effects are gradual, with only moderate pain, and without involvement of the deeper layers of the skin. The blisters therefore heal readily and without scar. On mucous membranes and open wounds, the effects are more severe, leading to local necrosis, and slowly healing, suppurating ulcers. Internally, cantharis is highly toxic by gastroenteritis and nephritis; even the absorption from a large blister may cause severe irritation of the kidneys and urinary passages. It is therefore contraindicated in nephritis, and should never be used internally, although it was formerly employed as a diuretic.

For vesication, the cantharides may be employed as the Emplastrum Cantharidis, U.S.P., which is prepared by spreading cantharides cerate upon rosin plaster, leaving a margin around the edges. Each square centimeter of spread plaster should contain 0.1 Gm. of cantharides cerate. It requires from six to ten hours to raise a blister, according to the thickness of the skin, its content in fat, and probably also individual susceptibility. The plaster adheres very poorly, and must usually be fixed with adhesive plaster. When the blister has appeared, the plaster should be carefully removed without rupturing the vehicle. The latter is then pierced and dressed with an ointment. This prevents further pain, irritation, or infection. By a "flying blister" is meant a series of small blisters raised along the course of a nerve by the application of successive plasters.

Other Vesicants.—When cantharis is contraindicated—e.g., in cases of inflammation of the urinary passages—it is usually replaced by ammonia water or chloroform, which vesicate if their evaporation is prevented, as by covering the point of application by a thimble. These are rather more rapid in action, but much more painful than fly blister, and are, therefore, avoided, if possible. Iodine, croton oil, and mustard have also been used, but act too deeply,

Contraindications to Vesication.—Blisters in general are *contraindicated* in people of feeble condition, since they may then lead to ulceration. When they are employed for counterirritation, they should not be applied directly over the inflamed part, but at some distance from it. They might otherwise render the inflammation more violent.

Origin of Cantharidin.—Cantharidin is a crystalline principle, the anhydride of cantharidic acid. It combines readily with alkalies, forming soluble salts. These produce the same local and systemic actions. Cantharidin is contained in a number of insects, especially beetles. A similar substance exists also in some caterpillars. It is present in varying amount, even in the same species. It was isolated by Robiquet in 1812 from the Spanish "Fly" (a beetle—*Cantharis* or *Lytta vesicatoria*). It is contained in the soft parts, particularly the blood.

Cantharis was recommended by Hippocrates in dropsy and amenorrhea; it was very popular in the days of heroic medication.

Absorption and Excretion.—Cantharidin is readily absorbed from all surfaces, even from the skin. It is excreted mainly by the kidneys (Eliasschoff); but since it irritates the gastro-intestinal tract when injected hypodermically, some must be excreted by this channel.

Symptoms of Poisoning.—When cantharis is taken by mouth, it produces successively: burning in the mouth, thirst, difficulty in swallowing, swelling and blistering of the tongue; salivation, nausea, vomiting, colic, and sometimes bloody diarrhea and tenesmus. The gastro-intestinal symptoms may be less pronounced in rapid poisoning. Kidney pain, burning in urethra, frequent micturition, albuminuria, casts, hematuria, painful erections, abortion. Weak and slow pulse, chill, syncope and collapse. Recovery may occur in about five days, the urine returning to normal. Toxic effects have been produced by 0.6 Gm.; death by 1.5 to 3.0 Gm., but recovery has also occurred from much larger doses. Of cantharidin, 10 mg. is said to be fatal.

Central Actions.—When injected into the circulation, cantharidin affects the *central nervous system*, producing short stimulation, excitement, and increased reflexes, followed by paralytic symptoms, coma, etc.

This central action is not often seen, being obscured by gastroenteritis or nephritis.

The Treatment of Poisoning.—This consists of gastric lavage, demulcents, opiates, alkalies and plenty of fluid, heat to the gastric and renal region, and warm baths. No oils or fats should be given by mouth; but the Arab physician Rhases advised washing the bladder with oil, through a catheter and this would probably diminish the tenesmus.

Cantharidin Nephritis.—The kidneys are highly sensitive to cantharidin. Small doses act entirely on the glomeruli, which are greatly dilated; numerous leucocytes are found in Bowman's capsule. The urine becomes albuminous within half an hour after subcutaneous injection. The smaller doses increase its amount, while larger doses diminish it. The epithelium of the convoluted tubules is only affected by large doses, and rather late in the course of the poisoning. The interstitial tissue escapes entirely in the acute intoxication, and is but slightly changed even in the subacute form (Mürset, 1886; Lyon, 1904; Richter and Roth; Schlayer and Hedinger, 1907; Pearce, 1913). The excretion of pthalein is delayed (Eisenbrey, 1913); the non-protein nitrogen of the blood is increased (Folin, Karsner and Denis, 1912).

Hepatic Changes and Edema.—These are seen in dogs, with fatal doses. Opie, 1912, found fibrinous clots in the lymph nodes of the hepatic region, around the injured cells, and considers their obstruction responsible for the edema. In their absence, the lymph flow is increased independent of the renal changes.

Polycythemia.—This occurs after acute clinical or experimental poisoning. It sets in slowly and is rather persistent (Lipsitz and Cross, 1917; Morgulis and Muirhead, 1919).

Racial Tolerance.—The hedgehog, chicken, and duck are remarkably tolerant to the nephritic action (Ellinger, 1900). This is not due to differences in the absorption, nor to destruction of the poison, for the cantharidin is found in the urine, just as it is in susceptible animals. Nor are these animals immune to other nephritic poisons. The immunity to cantharides is also only partial; even a single injection of a large dose causes chronic nephritis. But taking the fatal dose for man (30 mg. by stomach) as the unit, that for the same weight of hedgehog lies about 3,000. For the dog and cat it is about 2.5 (1 mg. per kilo); for the rabbit, about 45.

This immunity to the nephritic action does not confer immunity to the local action on the skin. In this respect, the hedgehog is even more susceptible than the rabbit, which latter animal is almost immune to the cutaneous action. The nephritic action is lessened by rendering the urine alkaline (Ellinger, 1905). In the rooster, cantharidin

causes changes in the comb, analogous to those produced by ergot. Frogs are not susceptible.

Vesication in Animals.—Animals respond to irritation of the skin by cutaneous edema, rather than by vesication. This is probably due to anatomic differences. Of the experimental animals, the horse alone seems suited to test the action of vesicants (Ewe, 1920).

Alopecia.—Cantharis is used in the treatment of baldness, in the form of tincture, very greatly diluted with alcohol.

Treatment of Impotence.—Many drugs have been employed for this purpose, but with questionable results. *Cantharis* produces erection through reflex irritation from the urethral mucous membrane. It is, however, quite dangerous, since effective doses may set up nephritis. Many *essential oils* act in the same manner, and are at once less dangerous and less active. Here belong, e.g., *damiana*, *ginseng*, *mint*, *garlic*, etc., and possibly *camphor*. *Strychnine* was thought to be effective by raising the tone of the spinal centers, but is probably useless; as also *phosphorus*; and *arsenic*. *Alcohol*, *morphine*, *cannabis*, and other narcotics may act as aphrodisiacs by stimulating the imagination. *Yohimbine* has a special action on the blood vessels. The best treatment for impotence consists, of course, in the removal of the cause and improvement in the general health of the patient by appropriate hygiene.

PREPARATIONS

Cantharis (Canthar.), U.S.P.; Cantharides (Spanish Flies, Russian Flies).—The dried beetle, *Cantharis vesicatoria*. Contains cantharidin, 0.4 to 1 per cent. (not less than 0.6 per cent., U.S.P.) volatile and fixed oil, etc. Maximal dose, 0.05 Gm., 1 gr.

Cerat. Canthar., U.S.P. (Blistering Cerate).—35 per cent. of Cantharides.

Emplastrum Cantharidis (Emp. Canthar.), U.S.P.; Cantharides Plaster.

Collod. Canth. (Blistering Collodion, Vesicating Collodion).—6 per cent. Cantharides in Flexible Collodion.

Tr. Canthar., U.S.P.—10 per cent. *Dose*, 0.1 c.c., 1½ minims. Maximal, 0.5 c.c., 8 minims. May be added to liniments to prolong their local action; in hair lotions, 1:50.

Cantharidinum, B.P.; $C_{10}H_{12}O_4$.—Obtained from various species of *Cantharis* and of *Myiobris*. Colorless, glistening crystals; no odor. Very slightly sol. in water or alc., more sol. in chlorof., ether or oils. Cantharidin, 0.05 to 1 mg. in a drop of oil, and covered with simple plaster, may be employed as a blister.

The cantharidal preparations of the B.P. are now made of Cantharidin. The proportions are adjusted on the basis that 1 part of Cantharidin is equivalent to about 200 parts of *Cantharis*; so that the activity of the new preparations is about the same as that of the old.

Acet. Cantharidin, B.P.—0.05 per cent. (equiv. to 10 per cent. of *Cantharis*).

Collod. Vesic., B.P.—0.4 per cent. (equiv. to 50 per cent. of *Cantharis*).

Emplastrum Cantharidin (Emp. Cantharidin), B.P.—0.2 per cent. (equiv. to 35 per cent. of *Cantharis*). See "Emp. Canthar."

Emplastrum Calefaciens (Emp. Calefac.), B.P.; Warming Plaster.—0.02 per cent. (equiv. to 4 per cent. of *Cantharis*).

Liquor Epispasticus (Liq. Epispast.), B.P.; Blistering Liquid—0.4 per cent. (equiv. to 50 per cent. of *Cantharis*), in acetone menstruum.

Tr. Cantharidin, B.P.—0.01 per cent., equiv. to 1¼ per cent. of *Cantharis* (¼ of U.S.P.). *Dose*, 0.12 to 0.3 c.c., 2 to 5 minims, B.P.

Ung. Cantharidin, B.P.—0.33 per cent., equiv. to 7 per cent. *Cantharis* (⅔ of the old preparation).

Capsicum, U.S.P.; *Capsic. Fruct.*, B.P.; Capsicum (Cayenne Pepper, African Pepper).—The dried ripe fruits of *Capsicum frutescens*, U.S.P.; *Capsicum minimum*, B.P. The action is due to about 0.02 per cent. of a crystalline neutral principle, *capsaicin* (1:100,000 produces lasting burning of the tongue, Nelson, 1910). Capsicum is used internally as a condiment and carminative, and externally to produce prolonged counter-irritation for rheumatism, etc. (20 per cent. ointment; or equal parts of tincture and of soap-liniment). *Dose*, 0.06 Gm., 1 gr., U.S.P.

Emp. Capsic., U.S.P.; Capsicum Plaster.—Prepared by brushing oleoresin of capsicum upon the surface of rosin plaster so as to form a thin coating, leaving a margin around the edges.

Oleores. Capsic., U.S.P.—Evaporated ethereal extract. *Dose*, 0.015 Gm., ¼ gr., U.S.P.

Tr. Capsic., U.S.P.—10 per cent. *Dose*, 0.5 c.c., 8 minims, U.S.P., diluted.

Tr. Capsic., B.P.—5 per cent. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

* *Ung. Capsic.*, B.P.—25 per cent.

Euphorbium.—The dried juice of *Euphorbia resinifera*, consists of a gum-resin. The active constituent is the resinous euphorbon which resembles the active resin of croton oil (Boehm, 1915). The drug is rarely used (in liniments, 10 per cent.; plasters, 3 per cent.).

Mezereum.—The dried bark of *Daphne* species. The active constituent is the anhydride of mezerinic acid. There is also a glucosid daphnin. The fluid extract is rarely used as an addition to liniments or plasters; also in *Fldext. Sarsap. Co.*

Piper; Black Pepper.—The dried unripe fruit of *Piper nigrum*. (White pepper is the ripe fruit, deprived of its outer pericarp.) Contains the crystalline alkaloid piperine, a volatile oil, and a pungent resin. *Dose*, 0.5 Gm., 8 gr.

Piperine (piperyl-piperidine).—Has been used as an antipyretic and carminative, 0.1 to 0.5 Gm., 2 to 8 gr., in capsules.

Pulsatilla.—The herb of *Anemone Pulsatilla* and *A. lirata*; Europe. Should not be kept over one year. Active ingredient, anemonin. The drug is very irritant, and is almost obsolete, but has been used against asthma, hemicrania, etc., in *doses* of 0.1 to 0.4 Gm. It has a depressant action on the excised uterus (Pilcher, 1916).

Anemonin.—This is the active irritant constituent of fresh plants of the buttercup family; for instance, the marsh-marigold, *Caltha palustris* (Kobert, 1917). It exists in *Ranunculus sceleratus* mainly as a mother substance, proto-anemonin, which is volatile with steam. The structure of this and of anemonin have been determined and confirmed by synthesis (Asahina and Fujita, 1920).

Arisaema (Indian Turnip; Jack-in-the-pulpit).—The fresh corm of this plant is very irritating or "acid" when chewed. This is probably due to the mechanical effect of its sharp calcium oxalate crystals (Lazenby, 1915; E. D. Brown and Anderson, 1918).

CHRYSAROBINUM

This is strongly irritant to the skin and mucous membranes. It is employed as ointment (5 to 25 per cent. daily) against psoriasis and parasitic skin diseases, ringworm, etc. It stains the skin (keratin) and linen a brownish-violet color. This can be removed by chlorinated lime or benzol (Mankiewicz, 1916). Caution must be used lest it reach the eyes and produce violent conjunctivitis (or rather keratitis; Igersheimer, 1912) and corneal opacity. It is absorbed from the skin, and excreted partly as chrysophanic acid, which is easily formed by its oxidation, especially in alkaline solutions. The urine is, therefore, colored red by alkalis. A part is excreted unchanged, and causes renal irritation, casts and albuminuria. By mouth, 0.18 Gm. produces vomiting, diarrhea, renal pain and hematuria.

Chrysarobin has a strong affinity for oxygen, abstracting it from the tissues. This has been suggested as the basis of its action, the oxidation product, chrysophanic acid, being relatively inactive. The oxidation occurs only in watery suspensions in the presence of alkali. Fats, therefore, diminish its activity (Schamberg, Raiziss and Kolmer, 1915).

PREPARATIONS

Araroba, B.P. (Goa Powder, Crude Chrysarobin).—A substance found in cavities of the trunk of *Andira* (Vouacapoua) *Araroba*.

* *Chrysarobinum* (Chrysarob.), U.S.P., B.P.; Chrysarobin.—A mixture of neutral principles extracted from Goa powder; chiefly chrysophanolanthranol, $C_{16}H_{12}O_3$. An orange-yellow, microcrystalline powder, tasteless, odorless, and irritating to the mucous membrane. Very slightly sol. in water, slightly sol. in alc. (1:385); partially sol. in fats. A saturated ethereal solution of chrysarobin is used in the treatment of warts. It is painted on daily, the dead tissue being pared off. *Dose*, 0.03 Gm., $\frac{1}{2}$ gr., U.S.P.

Ung. Chrysarobin, U.S.P.—6 per cent. in Hydrous Wool Fat.

Ung. Chrysarobin, B.P.—4 per cent. in Soft Paraffin.

POISON IVY

Contact with certain species of *Rhus*, common along roadsides, on fences, in woods and swamps, etc., produces typical dermatitis (Captain John Smith, 1609) passing through the successive stages of hyperemia and itching, to violent vesication, edema, and suppuration, according to the specific sensibility of the individual; many persons are practically immune, although a sufficient quantity of the isolated toxicodendrol has never failed to produce the dermatitis.

The active ingredients of all the species is a phenolic oily resin, *toxicodendrol*, contained in the sticky sap of the plants, which exudes when the plant is injured. It is identical or very similar in all the toxic *Rhus* species (McNair, 1916, 1923). It is so highly active that $\frac{1}{1,000}$ mg. has caused severe vesication (Pfaff). Toxicodendrol is not volatile, but it may be conveyed to some distance on the soot in the smoke of burning plants, and perhaps on dust (E. D. Brown), and by insects alighting on injured plants. None is present in the pollen (Warren, 1913; McNair), as had been claimed. It may be conveyed by the hands or clothing from one person to another, as if it were contagious.

The dermatitis begins after a latent period of one-half to nine, usually four or five, days, probably depending more on the sensitiveness and thickness of the skin than on the quantity of the poison. The toxicodendrol may penetrate directly through the epidermis for it may infect portions of the skin that are devoid of glands; but where these are present, the infection is usually more severe. The dermatitis does not spread beyond the area of contact.

The cutaneous reaction begins with rubefaction, swelling and itching, and passes through the stages of macule, papule, vesicle and pustule, with leucocytic infiltration of the skin. There is also some systemic reaction: severe leucocytosis, febrile symptoms, and slight renal irritation (McNair, 1916). The attack generally subsides in four to six days. Internally and hypodermically it produces gastric and intestinal irritation, proctitis, vulvitis and nephritis, but the systemic toxicity is relatively low.

Bibliography.—McNair, "Rhus dermatitis," Chicago University Press, 1923, is the most comprehensive work and gives extensive references. A critical bibliography is also given by Ford, 1913.

Toxic Species.—The most important are: *Rhus vernix*, synonym. *venenata* (Poison Sumach, the most powerful); *Rhus Toxicodendron* (Poison Oak); *Rhus radicans* and *diversiloba* (Poison Ivy); *Rhus pumila* (a Southern species)—all common in North America; the Japanese lacquer tree (*Rhus vernicifera*). Other toxic species are mentioned by L. E. Warren, 1909, and by McNair, 1916. The common sumach, *Rhus glabra*, does not have this action.

Nature of the Toxicodendrol.—Pfaff, 1897, showed that the toxicity is not due to a volatile alkaloid, as claimed by Khittel, 1858; nor to a volatile acid (Maisch, 1860); but that it is caused by a fixed oily substance. Acree and Syme, 1907, isolated this as a tar or wax, and claimed it to be a glucoside (Acree, 1916), but McNair was unable to obtain glucose. It is soluble in alcohol and oils and is precipitated by lead acetate and other metallic salts. It is not destroyed by heating an hour at 100 C. (v. Adeling, 1912, 1913). On exposure to the air it becomes gradually oxidized, blackens, and loses its activity. It is non-nitrogenous and has phenolic groups, gives the blue-green reaction with iron, and absorbs bromine readily. McNair names the corresponding constituent of *Rhus diversiloba* "*Lobinol*," it is closely related, if not identical, with toxicodendrol.

Differential Diagnosis.—Toxicodendrol dermatitis does not differ essentially from other dermatoses. The principal differential features are the relatively rapid course; the situation of the lesions on thin skin that would come into contact with the poison;

the sharply defined margin. A dark color may develop on touching with 1 per cent. NaOH.

Congenital Tolerance.—The congenital variations in susceptibility are very marked, many persons being immune to ordinary contact, although the immunity is probably never absolute. Krause and Weidman, 1925, found half the subjects clinically immune to application of the plant to the intact skin; this was reduced to a fourth immune if the skin was scarified. They found no definite difference between blondes and brunettes, or obese and thin. Children are probably more susceptible than adults. There exists a "consensus of clinical opinion" that American Indians are less susceptible; but the actual test gave the same proportion of susceptibility as with white people (Deibert, *et al.*, 1923). The tolerance varies from time to time, and is sometimes lost, and one attack seems to leave the skin more sensitive to others; but Ford mentions that Syme gradually acquired tolerance. Perspiration seems to facilitate infection. Animals in general are relatively or quite insusceptible (Krause and Weidman).

Treatment of Ivy Poisoning.—Susceptible persons should avoid exposure to the plant, *f.z.*, by wearing rubber gloves. As soon as possible after contact, the area should be scrubbed thoroughly with soap and brush, followed by alcohol, to remove the unabsorbed poison. This may be supplemented by the frequent washing with a ferric chloride lotion (one part of the tincture to two of water). This inactivates any toxicodendrol that is still on the surface, and at the same time tends to diminish irritation through the astringent effect. When the dermatitis has developed, its course is not materially influenced by treatment. The iron lotion or lead-acetate (saturated alcoholic solution), or permanganate (1 to 4 per cent.) give some symptomatic relief; but the paraffine-film treatment, as for burns, is probably most effective (McNair). If the skin becomes infected with bacteria, the Carrel-Dakin treatment may be applied. Salves should be avoided, especially in the early stages, since they might spread the area of infection by dissolving the toxicodendrol. A large number of other measures have been tried, but without advantage (Addelung; McNair). They may be grouped as astringents (metallic salts, iodine, bromine, tannic extracts); analgetics (phenol, quinine); protective ointments and resins (grindelia); detergents (soap-paste dressing); alkalies (bicarbonate, borax, lime-water); nondescript (expressed juice of "Touch-me-not," *Impatiens fulva*).

Artificial Immunization.—It has been claimed that this could be produced by the internal administration of *Rhus* extracts. Critical experiments, however, indicate that this is clinically unsuccessful and not harmless (Krause and Weidman, 1925).

Warren, 1919, who reviews the literature of the subject, mentions that immunization by the chewing of the leaves was claimed by Dakin in 1829. Ford, 1907, reported that repeated hypodermic injections of increasing doses of the fluidextract induced resistance to the local necrosis and to the nephritis; and that the serum of these animals conferred passive immunity on others. v. Adelung, 1913, was not successful in producing immunity to the isolated toxicodendrol.

Attempts at clinical immunization were made by Schamberg, 1919, and developed especially by Strickler, 1921 to 1923. Other clinicians were favorably impressed, but critical tests with adequately controlled exposures appear to show definitely that the clinical method confers no protection whatever, and that it appears sometimes to even increase the susceptibility (Krause and Weidman, 1925). On the other hand, the injections are followed by persistent pain and induration. The oral administration may lead to pruritus ani and aggravation of hemorrhoids. A fatality from chewing the leaves in attempting immunization has been reported (Alumbaugh, quoted by McNair).

Other Plants Producing Dermatitis.—These comprise a number of tropical trees belonging to the same family—*Lithrea caustica*; *Anacardium* (active principle, cardol, an oily substance); *Semecarpus*. *Primula*, *chrysanthemum*, *arbor vitae*, and many other plants (*Vanilla* beans, Claveric, 1908); the fruit of the ornamental Ginko tree (Starr, 1913), affect sensitive persons in the same manner.

Tomato-vine juice has apparently produced mild dermatitis in susceptible individuals (Lain, 1918).

Primula Dermatitis.—This is caused by direct contact with the common Chinese house plant, *Pr. obconica*, and a few other species. Nestler describes toxic crystals in the resinous secretion of the leaves. The treatment consists in cleansing with alcohol or ether, and the application of Zinc Ointment (O. H. Foerster, 1910; Rost, 1914). Primrose dermatitis has also been studied by Simpson, 1917.

Hypericum.—Ray, 1914, stated that cattle feeding on a Tunisian species (*H. crispum*) develop dermatitis of non-pigmented portions of the skin, and inflammation of the mucous membranes exposed to light. The phenomena are due to a fluorescent substance. Rogers, 1914, claims analogous effects for the common St. John's wort, *Hypericum perforatum*. Similar symptoms are also said to be sometimes produced by buckwheat.

PHYSICAL COUNTERIRRITANTS

Irritation of the skin is easily produced by physical agencies, which are often preferred to the chemical irritants. The effects and indications are similar. They can only be enumerated here: *heat and cold*, in the form of applications, baths, heated air, or cautery. *Friction*, generally combined with massage. *Electricity*, *radiotherapy* and *phototherapy*.

Antiquated are: *Acupuncture* (pushing needles through the skin to the underlying organs, said to be popular with the Chinese); *scarification* (small incisions with knife or needle); *setons* (a string carried through a fold of skin and left to suppurate).

Venesection, cupping and leeches also act by altering the distribution of the blood.

DRUGS EMPLOYED FOR THEIR LOCAL EFFECTS ON THE ALIMENTARY CANAL

STOMACHICS

Bitter, aromatic and "sharp" drugs have been used since antiquity as "tonics," and in functional dyspepsias. They were supposed to increase the appetite and improve digestion, and thus favor nutrition. About a tenth of the medicines mentioned by Hippocrates belong to this class, and they have always played a prominent rôle in folk medicine.

Classification.—*Simple bitters* generally contain some "*bitter principle*"—neutral substances, often crystalline, non-nitrogenous, sometimes glucosidal, and without pronounced systemic actions. In *aromatic bitters* these are mixed with volatile oils. The *astringent bitters* contain tannin. *Condiments*, which also contain aromatic oils or other sharp principles, form the transition to *carminatives*. These are employed to secure the expulsion of gas from the alimentary canal.

Modern scientific investigations (Moorhead, 1915) have confirmed that the bitters may improve deficient appetite, and the flow and quality (acidity) of the gastric juice, in conditions of poor health (anemia); although they have no effect on normal individuals (Carlson and co-workers, 1914 and 1915).

The mechanism of the action of the "bitters" has not been demonstrated. They are always administered shortly before meals, and it is conceivable that they act as a sort of chemical dinner bell, setting up a "conditioned reflex" of appetite.

The aromatics and condiments probably act by mild direct irritation of the gastric mucosa, the beneficial effects being due to the hyperemia and motor stimulation.

Effect in Experimental Cachexia.—In dogs provided with a Pavlov gastric pouch, and rendered cachectic by repeated large hemorrhages, Moorhead, 1915, found that the

administration of bitters improved the appetite and the gastric deficiency, although not quite to normal. The animals consumed more food and the gastric juice became more abundant and more acid. The increase of appetite occurred whether the bitters were given by mouth or by stomach; the increase of secretion was confined to oral use. The improvement occurred with the first administration so that it was not due to the establishment of a habit. Possibly the bitter taste enhances the taste of food, by contrast.

Experiments on Normal Individuals.—Carlson and co-workers, 1914 and 1915, could find no beneficial effects in normal men or dogs. Therapeutic doses of bitters, however given, have no immediate or delayed effect on gastric secretion. When taken by mouth (or large doses introduced directly into the stomach) they inhibit the normal hunger contractions and the sensations of hunger, just as do other irritant or disagreeable substances.

Gastric Secretion.—Carlson, 1915, tested the effects on a man with gastric fistula, and on dogs with Pawlow miniature stomachs. The bitters were placed in the mouth, or directly in the stomach, before, with, or without food, etc. However the experiments were varied, the results were uniformly negative. This disposes of the rather contradictory results of older investigators as to direct secretion (Buchheim and pupils, 1849; Reichmann, 1888; Korczynski, 1901; Hoppe, 1905) and "psychic juice" (Borisoff, 1904; Bonanni, 1905; Strasheko, 1905).

The introduction of irritant substances into the mouth also fails to provoke gastric secretion in man (Carlson, 1915).

Absence of "Taste" in the Stomach.—Albertoni and Tullio, 1912, found on a human subject that the direct introduction, through a gastric fistula, of bitter or sweet substances or bouillon, produced only the same immediate sensation as saline; but bouillon, bread or alcohol provoked speedier secretion of acid and, taken with food, afforded a more satisfactory sensation.

Influence of Pancreatic Secretion.—The presence of any irritant in the intestine stimulates the flow of pancreatic juice (Gottlieb, 1894). The effect of bitters is somewhat different: They have no effect on the pancreatic or bile flow; the intestinal juice is first diminished, then increased (Reichmann, 1888; Jodlbauer).

Effect on Absorption.—Bitters are claimed to hasten the absorption of sugar and peptone from the stomach (Brandl, 1893), but seem to delay it somewhat from the intestine (Rieder, 1910).

Sojourn of the Food in the Stomach.—According to Heubner, this is shortened by small, delayed by large, doses.

W. E. Morse found that tabasco sauce does not modify the discharge of water from the stomach.

Effect on Digestive Ferments.—Most of the bitters have no effect on digestion *in vitro*.

Antiseptic Action.—Bitters and aromatics are antiseptic, and may therefore influence digestion favorably by limiting putrefaction and abnormal fermentation.

Leucocytosis.—A further action of stomachics (both bitters and aromatics) which may be concerned in their therapeutic action, is that they *increase the leucocytes* of the blood. (Hirt, 1856; Binz, 1875; Pohl, 1888.) The theory has been advanced that these leucocytes play a rôle in intestinal absorption (Hofmeister, 1887).

Therapeutic Uses of Stomachics.—These are employed:

1. To increase appetite, from whatever cause this be deficient.

Bastedo, 1920, states that bitters increase the appetite in achylia gastrica, although they have no effect on the secretion. He considers them especially valuable in convalescence after acute illness.

2. To improve digestion in all kinds of "atonic" dyspepsias, with motor or secretory deficiency. They tend to remove the anorexia, oppression, constipation, hypochondria, etc. In subacute or chronic gastritis, the astringent bitters may be more useful, otherwise they are rather objectionable. Tannin must be especially avoided when the bitter is to be prescribed with iron, since this makes an unsightly mixture. Tannin-free are the simple bitters and the majority of the aromatic bitters.

3. As tonics in anemia, convalescence, phthisis, etc., to hasten reconstruction.

4. As antemetics.

5. To modify or improve the taste of food or medicincs; also to obscure a "bad taste in the mouth."

Administration.—It is believed that stomachics should be administered within a half an hour, preferable 5 or 10 minutes, before meals. They are generally more pleasant, and therefore more effective, if they are judiciously blended, as in the aromatic and compound bitters (Tr. Gentianæ Co.; Tr. Cardamomi Co.). Overdoses produce nausea and so defeat their object.

Since the effects of bitters depend on the taste, it is useless to administer them in the form of pills and tablets, although this is often done.

SIMPLE BITTERS

These are practically free from aromatic oils or tannin, and can therefore be mixed with water. The tinctures are strongly alcoholic.

Certain pure alkaloids, such as Quinine or Strychnine, may be used as simple bitters.

PREPARATIONS

Berberis, B.P.—The dried stem of *Berberis aristata*. The rhizome and roots of *B. aquifolium* were formerly official in the U.S.P. The pharmacology has been studied by Hildebrandt, 1907.

Tr. Berber., B.P.—10 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Calumba, U.S.P.; *Calumbæ Radix*, B.P.; *Calumba* (Colombo).—The dried root of *Jateorhiza palmata*, U.S.P.; *Jateorhyza Columba*, B.P. Resembles gentian but can be mixed with iron. Contains several alkaloids (Calumbanin, jateorhizin, and palmatin), related to berberine. Biberfeld, 1909, found that these differ only quantitatively in action, paralyzing the central nervous system, especially the respiratory center, and lowering the blood pressure through cardiac and vasomotor depression. *Dose*, 1 Gm. 15 gr., U.S.P.

Inf. Calumb., B.P.—5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Tr. Calumb., U.S.P.—20 per cent. in 60 per cent. alcohol. *Dose*, 4 c.c., 1 drachm, U.S.P.

Tr. Calumb., B.P.—10 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 dram, B.P.

Chirata, B.P.—The dried plant of *Swertia Chirata*.

Inf. Chirata, B.P.—5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Tr. Chirata, B.P.—10 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Gentiana, U.S.P.; *Gentianæ Radix*, B.P.; *Gentian*.—The dried rhizome and roots of *Gentiana lutea*, Switzerland. One of the most useful of the bitters; mentioned by Pliny. The bitter principles are the crystalline glucoside gentiin, and the amorphous gentiamarin. There is also a small amount of tannin, not enough to be astringent, but sufficient to be incompatible with iron. *Dose*, 1 Gm., 15 gr., U.S.P.

Extractum Gentianæ (Ext. Gent.), B.P.—A watery pilular extract, used largely as pill excipient. *Dose*, 0.25 Gm., 4 gr., U.S.P.; 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Inf. Gent. Co., B.P.—1.25 per cent., with Bitter Orange and Lemon peels. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

* *Tinctura Gentianæ Composita* (Tr. Gentian. Co.). U.S.P., B.P.—10 per cent. of Gentian, with Bitter Orange Peel and Cardamom, in 45 per cent. alcohol. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Pareira.—The root of *Chondodendron tomentosum*. Contains bebeerine, isobeeberine, and other alkaloids (studied by Faltis, 1912; Scholtz, 1913). Commercial "Bebeerine sulphate cryst." is isobeeberine. It is isomeric with codeine, and like this, has narcotic actions (Scholtz and Koch, 1915). *Dose* of Pareira, 2 Gm., 30 gr.

Picrorhiza, B.P.—The rhizome of *Picrorhiza Kurroa*. *Dose*, 0.6 to 1.2 Gm.; 10 to 20 gr.; antiperiodic dose, 3 to 4 Gm., 45 to 60 gr., B.P.

Ext. Picrorh. Liq., B.P.—*Dose*, 1 to 4 c.c., 15 to 60 minims, B.P.

Tr. Picrorh., B.P.—25 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Quassia, U.S.P.; *Quassia Lignum*, B.P.; *Quassia*.—The wood of *Picraena excelsa* (also of *Quassia amara*, U.S.P.). *Dose*, 0.5 Gm., 8 gr., U.S.P.

A 1 to 5 per cent. aqueous infusion is used by enema (to $\frac{1}{2}$ pint, retained as long as possible) against oxyuris.

Inf. Quass., B.P.—1 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Tr. Quass., B.P.—10 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Taraxaci Radix (Tarax. Rad.) B.P.; *Taraxacum* (Dandelion).—The fresh root of *Taraxacum officinale*. (Composition, Power and Browning, 1912.)

Succ. Tarax., B.P.—The juice, preserved with 25 per cent. of alcohol. *Dose*, 4 to 8 c.c., 1 to 2 drachms, B.P.

Xanthoxylum (Prickly Ash).—The dried bark of *Xanthoxylum americanum* or *X. Clava-Herculis*. Contains berberine. *Dose*, 2 Gm., 30 gr.

ASTRINGENT BITTERS

With these, tannin is a prominent ingredient, whilst volatile oils are present only in small quantity, if at all. The preparations can be mixed with water.

PREPARATIONS

(* *Tr. Cinchona Co.*, U.S.P., B.P., see Index.)

Cascarilla, B.P.—The dried bark of *Croton Eluteria*.

Inf. Cascarill., B.P.—5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Tr. Cascarill., B.P.—20 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Cimicifuga, U.S.P. (Black Cohosh, Black Snakeroot; *Macrotys*).—The dried rhizome and roots of *Cimicifuga racemosa* (Constituents, Finnemore, 1910). *Dose*, 1 Gm., 15 gr., U.S.P.

Fldext. Cimicif., U.S.P.—*Dose*, 1 c.c., 15 minims, U.S.P.

Condurango.—The bark of *Marsdenia Condurango*. Used as astringent bitter especially in gastric ulcer and carcinoma.

Fldext. Condur.—*Dose*, 1 to 1.5 c.c., 15 to 25 minims.

Cusparia (Angostura Bark).—The bark of *Cusparia febrifuga*. Contains alkaloids, chiefly cusparine (Troeger and Mueller, 1915). *Dose*, 0.6 to 2.5 Gm., 10 to 40 gr.

Serpentaria, U.S.P.; *Serpent. Rhiz.*, B.P.; *Serpentaria* (Virginia Snakeroot).—The dried rhizome and roots of *Aristolochia Serpentaria* or *reticulata*. *Dose*, 1 Gm., 15 gr., U.S.P.

Tr. Serpent., B.P.—20 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

AROMATIC BITTERS

These contain both aromatic oils and bitter principles, but no tannin. Their alcoholic preparations can not be mixed with water without turbidity.

PREPARATIONS

(* *Aurantii Amari, Cortex*, see Index.)

Anthemidis Flores, B.P. (English or Roman) Chamomile Flowers.—The dried flower-heads of *Anthemis nobilis*.

Ol. Anthem., B.P.—The distilled oil. *Dose*, 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Betel, B.P.—The dried leaves of *Piper Betle*.

Calamus (Sweet Flag).—The rhizome of *Acorus Calamus*.

Matricaria (German Chamomile).—The dried flower-heads of *Matricaria Chamomilla*. Volatile oil and bitter principles. Used as infusion, internally as stomachic, carminative, and diaphoretic; externally as counterirritant. *Dose*, 15 Gm., 4 drachms.

Panax, Ginseng.—The root of *Panax quinquefolium*, very highly valued by the Chinese, belongs to this series. Korean ginseng contains a glucoside which is said to lower the level of blood-sugar in various hyperglycemias (Abe and Saito). Other species of *Panax* and *Aralia* are also aromatic bitters.

Numerous other bitters are used in domestic medicine, but are not worth mentioning.

CARMINATIVES

These are aromatic and pungent drugs, which are used in flatulence and colic, to expel gas from the stomach and intestines, and to diminish the "gripping" pains. Given by mouth or by enema, according to the situation of the gas, they may be very promptly effective; in other cases they fail. They have a "warm" taste, and exert a mild irritant action on the digestive tract. Injected into the intestines of unanesthetized dogs,

by a long Thiry-Vella loop, dilute suspensions or saline solutions of the carminative oils increase the tone, rhythm and peristalsis; this would naturally result in the propulsion of any gas. Occasionally the stimulation is followed by decrease of movement, which might be helpful in relaxing spasms. It may explain the clinical use of carminatives to diminish the griping of irritant cathartics.

The carminative stimulation is abolished by cocainization, so that it is perhaps a sensory reflex (Plant, 1920). Excised intestines and those of laparotomized animals are relaxed (Gunn, 1921), but as just explained, this plays a minor part with intact animals. The excised stomach is also relaxed; with laparotomized animals the movements may be either increased or decreased (Gunn). Relaxation of the cardial sphincter may be an important factor in the relief of gastric flatulence. Further observations on gastric fistulae are needed. The aromatic oils also have an antiseptic action, which may be of value in gastric dilation.

The most useful carminatives are the mints, fennel and anise; ginger; and capsicum.

Menthol and Peppermint Oil on Bronchial Foam.—McGuigan, 1921, found that these diminish the foaming of blood, saponin, etc., and suggests that their mechanism in catarrhs consists in breaking down foam in the air passages, and thus enlarging the effective lumen. However, the mucus of catarrh is not always foamy, especially not in rhinitis or pharyngitis in which menthol gives most relief. The benefits are probably due to detachment of adherent mucus by the fresh secretion which follows the counterirritation.

PREPARATIONS

Mentha Piperita, U.S.P.; Peppermint.—The dried leaves and tops of *Mentha piperita*. Dose, 4 Gm., 60 gr., U.S.P.

(* *Aq. Menth. Pip.*, see Index.)

Ol. Menth. Pip., U.S.P., B.P.—The distilled oil. Colorless liquid, characteristic odor, pungent aromatic taste. Dose, 0.1 c.c., $1\frac{1}{2}$ minims, U.S.P.; 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

* *Spiritus Mentha Piperita* (Sp. *Menth. Pip.*), U.S.P., B.P.; Spirit (Essence) of Peppermint.—10 per cent. of the Oil; the U.S.P. is tinged green by maceration with Peppermint. Dose, 1 c.c., 15 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P.; in water.

Mentha Viridis, U.S.P.; Spearmint.—The dried leaves and tops of *Mentha spicata*. Dose, 4 Gm., 60 gr., U.S.P.

(* *Aq. Menth. Vir.*, see Index.)

Ol. Menth. Vir., U.S.P., B.P.—The distilled oil. Dose, 0.1 c.c., $1\frac{1}{2}$ minims, U.S.P.; 0.03 to 0.18 c.c., $\frac{1}{2}$ to 3 minims, B.P.

Sp. Menth. Vir., U.S.P.—10 per cent. of oil, colored by maceration with spearmint herb. Dose, 1 c.c., 15 minims, U.S.P.; diluted.

Zingiber, U.S.P.; B.P.; Ginger.—The dried rhizome of *zingiber officinale*. The chief active ingredient is a volatile oil.

It also contains capsaicin (Nelson, 1920). Dose, 0.5 Gm., 8 gr., U.S.P., as powder or in water.

Similar to Ginger are: *Galanga*, *Zedoaria*, and *Asarum*.

Fldedxt. Zingib., U.S.P.—Strong alcohol. Dose, 1 c.c., 15 minims, U.S.P.

Syr. Zingib., U.S.P., B.P.—3 per cent., U.S.P.; 2.5 per cent., B.P. Dose, 10 c.c., $2\frac{1}{2}$ drachms, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

* *Tinctura Zingiberis* (Tr. *Zingib.*), U.S.P., Tincture of Ginger.—20 per cent. in alcohol. Dose, 2 c.c., 30 minims, U.S.P.

Tr. Zingib.—B.P.; 10 per cent. Dose, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

VEGETABLE CATHARTICS

Manner of Action.—Cathartics or evacuants are drugs which induce defecation. They may do so by simply increasing the bulk of the intesti-

nal contents (petrolatum, agar, etc.); or by preventing the absorption of water (salines); or by irritating the small or large intestine, as most of the vegetable cathartics. The cathartics differ from other irritants in that their irritation is relatively mild and is confined more specifically to the intestines. This may be explained by selective action, or by the alkaline reaction or bile of the intestines favoring their solution or decomposition. This solution must not be too rapid or the drugs will be largely absorbed or decomposed before reaching the lower intestine. The isolated principles are therefore less useful, and sometimes less effective than the galenic preparations in which they are masked as compounds or by the extractives, gums, etc., of the drug.

Liberation and Solution of the Cathartic Constituents.—Castor oil and croton oil become active only when their fatty acids are liberated; croton oil contains some free acid and is, therefore, pustulant also on the skin. The emodin cathartics often contain glucosidal compounds, which must be split before the action occurs. The group of “resins” are insoluble in water, but are decomposed and dissolved by alkalies and bile.

Influence of the Bile on Cathartics.—The *bile* seems to be necessary for the activation of many of the resinous cathartics, the following being relatively or quite ineffective in its absence: gamboge, podophyllum, convolvulin, jalap, and scammonium (Buchheim and Stadelmann). The bile acts presumably by increasing the solubility. Rhubarb, senna and calomel are active in the absence of bile (Valeri, 1910). Aloe seems to act quite well without bile in animal experiments; but clinically it has been claimed that it is ineffective in biliary obstruction.

Efficiency on Hypodermic Administration.—The anthracene and resinous cathartics and the phenolphthaleins also increase peristalsis if they are injected subcutaneously or intravenously; the resin-group is even more active by this channel. The action, however, is even then a local one, the constituents being excreted into the intestine by the bile. The cathartics are not administered in this manner, in practice, since the injection would be painfully irritant; the effects are also more easily controlled when the drugs are given by mouth.

Toxic Effects.—The vegetable cathartics are not corrosive. Even the drastic cathartics do not ordinarily produce inflammation, because they are propelled so rapidly; but if their propulsion is prevented by obstruction, or slowed as by opiates, they may lead to enteritis, especially colitis, and to nephritis. The intestinal irritation may also become cumulatively harmful, if the irritant cathartics are used habitually.

Location of Action.—This is of practical as well as scientific interest, because it often determines the choice of the cathartic. The older investigations have only a limited value, because they generally involve operative procedures which are apt to render the intestinal movements abnormal or to arrest them altogether. Cannon's method of observing these movements in intact animals by means of the Roentgen-rays opened the way for more reliable observations. This method has been applied to pharmacologic problems especially by Magnus, 1909, and by his pupils. Their results have been confirmed in man (*f.i.*, Meyers-Betz and Gebhardt, 1912). Another very fruitful method, which has been applied especially by Lenz, 1923, consists in replacing a part of the abdominal wall by a plate of transparent celluloid, which heals into the wound and serves as a window. These methods have shown that the emodin cathartics (senna, etc.) act

mainly on the colon. Castor oil stimulates peristalsis in the small intestine. Colocynth increases the movements of the small intestine and leads to intestinal effusion. Magnesium sulphate quickens the passage through the small intestines, and prevents the absorption of fluid and the concentration of the contents of the large intestine. Calomel increases peristalsis both in the small and large intestines.

Cathartics on Excised Intestines.—The effects are not related to those produced in life. For instance, the addition of aloin to the bath is inactive; cascara and castor-oil inhibit the contractions; saponified croton-oil stimulates (Meissner, 1916).

Alvarez and Taylor, 1917, obtained more positive results by giving cathartics of all the groups to living rabbits, then excising the intestines. The segments showed irregular irritability; they contracted poorly and fatigued quickly. However, the doses were so high that the significance of the results is doubtful.

Contraction of Intestine at Different Levels.—These exhibit some peculiarities (Alvarez, 1918).

Defecation Reflex.—This is started by the arrival of the mass in the rectum. It is greatly influenced, however, by the sensitiveness of the rectum and by the habits of the patient. It is here that the delay in constipation mainly occurs.

Defecation usually involves a reflex through the spinal cord; but destruction of the lumbar and sacral cord results in diarrhea, lasting several days, followed by normal evacuation of the large intestine at the customary interval (Goltz and Ewald, 1896). The intraintestinal mechanism can therefore control defecation, if necessary (Schüller, 1911). (Review of defecation reactions, Lehmann, 1912).

Effectiveness for Animals.—This differs materially from that in man. The relations are discussed by Fuehner, 1925; as also the evaluation on mice. The response of dogs and cats is much more closely akin to the human than is that of rabbits.

Peculiarities of the Cathartics.—These are largely explained by the mechanism, the location and the severity of the action.

Time of Action.—A cathartic which acts on the large intestine can not produce any effect until it reaches this place. Even then the response will depend on the habits of the patient. These become less important with the more irritant cathartics. The usual time of response, for the more important cathartics, is as follows:

Salines, one-half to one hour on empty stomach; two to four hours if in bed.

Castor oil, one to two hours on empty stomach.

Jalap, three hours or less.

Senna, four to five hours.

Rhubarb or Phenolphthalein, four to eight hours.

Cascara or Aloes, eight to twelve hours.

Podophyllum, ten to sixteen hours.

Colic and "Griping" is proportional to the severity of the irritation. It is due partly to increased peristalsis, partly to direct irritation, as evidenced by abdominal tenderness. It may be mitigated by belladonna and carminatives.

Consistency of the Stools and Elimination of Fluid.—The consistency varies from the soft but formed stools of the milder laxatives, to the watery stools of the "hydragogue" cathartics, the salines and drastics. The more rapid passage of the intestinal contents leaves less time for the absorption of fluid, so that the stools always contain more water. Some of the cathartics also prevent the absorption of fluid by osmosis (salines); or by imbibition (agar); and some perhaps by inhibiting the absorbing power of the epithelium (castor oil, calomel). The fluid in these cases comes really from the food rather than from the body. Even large doses of the

anthracene cathartics (senna, cascara, etc.) do not increase the secretion of intestinal fluid (Thiry, Brieger, Flemming). On the other hand, the irritant cathartics (colocynth, jalap, etc.) actually produce effusion into the small intestine. The practical results, as concerns the water supply of the tissues, is the same in either case; whether these are deprived of fluid by effusion or by non-absorption.

Effects on the Local Circulation.—All catharsis is apt to be accompanied by some hyperemia, were it only by the increased intestinal movement. The irritant cathartics produce a more violent intestinal congestion, which extends also to the pelvic organs, and thus increases the menstrual flow.

The Systemic Circulation.—This is affected indirectly by the splanchnic dilation; and by the withdrawal of fluid from the blood. Both factors tend to lower the blood pressure moderately. The heart rate is slowed reflexly.

C. H. Neilson and Hyland, 1913, made a clinical study of these effects after full doses of salts and compound jalap powder. The latter gave somewhat greater results. The average decrease of the systolic pressure was 17 per cent.; of the diastolic pressure, 8 per cent.; of the pulse pressure, 24 per cent.; of the heart rate, 14 per cent. The conditions generally returned to almost normal within a day. Individual cases, especially of arteriosclerosis, gave much greater falls (from 180 to 100 mm.), sometimes with the appearance of arrhythmias and increased heart rate.

Influence on Dropsies.—Cathartics favor the absorption of dropsies by carrying off liquid from the body; in ascites, the emptying of the intestines also removes some of the pressure from the veins, and thus tends to the removal of the edema by improving the general circulation and the urine flow.

Elimination of Waste Products.—Cathartics are employed in nephritis to relieve the kidneys of a part of their work, by eliminating fluid, and presumably some of the metabolic products, through the stools.

Uric Acid.—Abl, 1913, claimed that cathartics increase the elimination of endogenous uric acid. Stehle, 1915, found no change with laxatives, but only with drugs that stimulate the digestive glands.

Effects of Cathartics on Bile; Cholagogues.—The stools, with moderate catharsis, have usually a darker color, suggesting an increased bile content. This is not due to increased secretion of bile, as was supposed by the older therapeutists; but to the more rapid passage of the intestines, leaving less time for the reabsorption and decomposition of the bile. The dark color of calomel stools is due partly to mercurous sulphide. The only really effective stimulant of bile formation is the administration of bile or bile salts; salicylates (5 Gm. per day) and olive oil are perhaps also very slightly effective.

Experimental Investigations of Cholagogues.—The older experiments on animals with biliary fistulas gave contradictory results, because they did not extend over sufficient time to discount the natural variations in bile flow. Reliable experiments on a human patient were made by Pfaff and Balch, 1897; Van Hengel, 1913; and Ignatowski and Monossohn, 1914. Weinberg, 1911, experimented in Pavlov's laboratory with dogs provided with gastric and biliary fistulas. The subject was also investigated by Okada, 1915; Volborth, 1915; Downs and Eddy, 1919; Downs, 1920, and others.

The changes in bile-secretion vary somewhat for the different investigators, but tend fairly definitely toward the following grouping:

Definite Increase:	No Effect:	Decrease:
Bile Acids	Glycerol	Atropine
Salicylates	Alkalies	
Hydrochloric Acid	Calomel	
Olive Oil	Thyroid	
Chloral	Starch	
Potas. Bitartrate	Egg	
Alcohol, large doses	Gluside	
Epinephrine	Dextrose	
Secretin		
Gland Extracts		
Animal Proteins		
Albumose		
Meat Extracts		
Fat		
Soap		

Evacuation of Gall-bladder.—Klee and Knuepfel, 1914, found that this is stimulated, in animals, by eating, entrance of the chyme into the intestine, injection of Witte's peptone; and especially by the administration of olive oil. No effect was produced by soap or hydrochloric acid. Weinberg, 1911, also observed this effect of oil.

Autonomic Drugs on Gall-bladder.—Lieb and McWhoiter, 1915, found that the muscles of the gall-bladder receive augmentor impulses from the parasympathetic, inhibitory from the sympathetic. The autonomic drugs act correspondingly: Pilocarpine, barium and strophanthin stimulate; atropine, epinephrine, nitrites and bile salts relax. The rhythmic movements are increased during digestion; or by the introduction of acid into the duodenum (Okada, 1915).

Sphincter of Biliary Papilla.—Reach, 1914, states that the tone of this is increased, and the bile flow correspondingly hindered, by morphine, epinephrine, pilocarpine and atropine.

Therapeutic Indications.—Cathartics are used chiefly for the following indications:

To relieve constipation—cascara, rhubarb, phenolphthalein, small doses of salts.

To soften the stools, in hemorrhoidal and other rectal diseases; and to prevent straining in aneurism, hernia, and apoplexy—petrolatum, cascara, podophyllum, sulphur.

To cleanse the intestines in digestive disturbances, diarrheas and other intestinal putrefactions—calomel, castor oil, rhubarb, cascara, aloes.

To facilitate the absorption of dropsies; to relieve the kidneys in nephritis; to lower the temperature in fevers; to relieve internal congestions, especially of the brain—calomel, large doses of salines, compound jalap powder; in emergencies, croton oil or elaterin.

Cathartics are perhaps the most ancient method of internal medication, and were for a long time practically the only method. The Greeks used the same word, *φαρμακειν*, both for internal medication in general and for the use of cathartics in particular. The present English word *physic* is similarly applied.

Contraindications.—All inflammatory conditions of the abdominal organs (peritonitis, gastroenteritis, etc.) contraindicate the administration of intestinal irritants. Pregnancy and menstruation are contraindications to the use of the stronger cathartics, since the hyperemia may lead to abortion or excessive menstrual flow. General debility, tendency to collapse, threatened intestinal hemorrhage, and toxic spasm of the intestine, are further contraindications. Cathartics should not be used in intestinal obstruction or intussusception.

Habitual Constipation.—In this condition ("chronic intestinal stasis"), cathartics should be used rather sparingly; the condition being treated most effectively by the removal of the cause and the cultivation of proper

hygienic and dietetic habits; aided by the mechanical laxatives, petrolatum, agar or enemas. Small doses of salts, cascara or similar aperients may be needed. The irritant cathartics should be avoided.

In using cathartics against habitual constipation, one should always *employ the mildest remedy* which will accomplish the result. One reason for this is that soft, not liquid, stools are desired; but, further, a "habit" is quite readily acquired so that the intestines will require stronger and stronger stimuli, and the usual cathartics gradually lose their effect. If the treatment has been begun with mild measures, stronger ones are left for later use if necessary. The habitual use of very irritant cathartics is also apt to engender chronic enteritis.

Therapeutic Classification.—The cathartics may be classified according to their clinical characters, *i.e.*, mainly by the degree of their effects. This can not be done rigidly, because the effect varies with the dose; moreover, the names are defined somewhat differently by individual authors.

The following table gives a useful clinical classification. The more important agents are in italics.

1. Laxatives or Aperients.—Increase peristalsis only moderately, producing somewhat more frequent stools, of almost normal consistency, and this without causing notable irritation. They are active in *doses* of 10 Gm. or over.

Fruits, Manna, Agar, etc.; mechanical means (massage, *enemas*, etc.); Sulphur, *Magnesia*, Carminatives, Bile, Bland Oils (*Olive*, Cottonseed, *Liquid Petrolatum*, etc.).

(Small doses of Cascara, Senna, Castor Oil, Rhubarb, and Ipecac are also laxative.)

2. Purgatives.—Increase peristalsis actively, causing more frequent soft or semifluid stools.

(A) *Simple Purgatives.*—Active in *doses* of 0.2 to 1 Gm. Full doses may cause more or less colic and irritation:

Aloes, Rhubarb, Senna, *Cascara*, *Phenolphthalein*, Castor Oil, Calomel, small doses of drastics.

(B) *Saline Purgatives.*—Active in doses of about 10 Gm. Rather profuse, watery stools, with practically no irritation or griping:

Sulphate of Magnesium or Sodium, Sodium Phosphate, Magnesium Citrate, Potassium Bitartrate, Rochelle Salt, etc.

3. Drastics.—Produce watery stools, with much irritation. Large doses are apt to set up an enteritis:

Elaterium, Colocynth, *Jalap*, Scammony, Gamboge, *Podophyllum*, Croton Oil, the stronger Mercurials, and Antimony Sulphide.

4. Hydragogues.—All which produce watery stools, *i.e.*, the salines and drastics.

5. Cholagogues.—Were supposed to increase the bile flow:

Aloes, Rhubarb, Mercurials, *Podophyllum*, Euonymin, Sod. Salicylate or Phosphate, Acid. Nitrohydrochlor. Dilut., Bile.

Pharmacologic Classification.—The cathartics may also be divided into the following groups:

1. Those which act mainly on the colon and rectum. This includes the drugs containing emodin and other anthraquinone derivatives: Senna, Cascara, Rhubarb, Aloes, and perhaps also *Phenolphthalein* and Bile.

2. Those which stimulate the peristalsis of the small intestine and inhibit the antiperistalsis of the colon, but without producing much

irritation or effusion. This includes Castor Oil and probably Calomel and Sulphur.

3. Those which, in addition to these actions, cause marked intestinal effusion and irritation. This comprises Colocynth, Jalap, and presumably the other drastic resinous cathartics, Podophyllum, Elaterin, Gamboge, Croton Oil, etc.

4. The saline cathartics, which retain water by osmosis.

5. The colloid cathartics, which retain water by imbibition: Agar, Fruits, Manna, etc.

6. Emollient cathartics, such as Petrolatum or Olive Oil.

7. Enemas and similar local measures.

THE ANTHRAQUINONE OR EMODIN CATHARTICS

Active Constituents.—Senna, Rhubarb, Cascara, Aloes and related drugs contain glucosidal compounds which are themselves inactive. In the alkaline intestine they are hydrolyzed or oxidized, yielding various oxymethyl-anthraquinones (Buchheim; Tschirch and pupils, 1899), which produce the cathartic action. The pure substances would be too irritant, but their action is graded by their slow liberation, and by the presence of colloid extractives. The most common of these substances are emodin and chrysophanic acid. Numerous isomers of these are possible (15 for emodin alone). The special characters of the different drugs is probably due to differences in these isomers; in the stability of their glucosidal combination; and to the presence of other associated substances (tannin in rhubarb). The action of these drugs does not progress to inflammation. They are often more effective when given in divided doses (three times daily) than when given in a single dose.

Emodin is partly absorbed and is excreted into the urine and milk (laxative effects on sucklings).

The structure of these anthraquinones is shown by the following formulas:

Emodin is probably the most important of these principles. It is present in the amount of 0.8 to 1 per cent. in senna; 2.6 per cent. in frangula; 0.6 per cent. in cascara; 0.8 per cent. in Cape aloes; and 1.5 per cent. in rhubarb (Tschirch and Hiepe).

Coloration of Urine.—The drugs containing emodin color the urine yellowish-brown when it is acid, reddish or violet when alkaline. It may be advisable to acquaint the patient with this fact.

Other drugs which change the color of the urine are: *Logwood* (Hematoxylon) does not color acid urine, but produces a reddish or violet color in alkaline urine. *Santonin* gives a yellow color to acid urine, with a yellow foam; if the urine is made alkaline it gives a very pronounced pink. *Picric acid* gives reddish-brown color in both acid and alkaline urine. The various *coal-tar products* give a brownish-black color. *Methylene blue* imparts a green color.

Manner of Action.—The older work (Buchheim; Tappeiner and Brandl, 1889) showed that the action of the emodin group is mainly on the large intestine, which reacts by increased movement also to intravenous injection; and that there is no increase of intestinal secretion. The X-ray experiments (Magnus, 1909, and of Meyer-Betz and Gebhardt, 1912), and the observations through the abdominal window (Lenz, 1923) confirm that ordinary doses of senna do not accelerate the passage through the stomach and small intestine, but solely through the colon. With aloes the lower ileum participates somewhat. Carnot and Glénard, 1913, claim that the movements of perfused small intestines are stimulated when senna infusion is injected in the lumen. Ordinarily, however, the activity of the emodin cathartics is confined essentially to the large intestine.

The normal peristaltic activity of the colon consists in the occasional formation of limited but firm contraction rings, which persist for some time, either stationary, or traveling slowly up or down the intestine. When these cathartics reach the colon, these contraction rings become much more frequent, tend to travel more rapidly downward, stripping the contents into the rectum. The localization of this action in the colon is due partly to selective penetration, for anthrapurpurin, *f.i.*, stains the mucosa of the colon much more intensely than that of the small intestine. It is possible that sensory reflexes participate.

CASCARA SAGRADA

Cascara is used chiefly in habitual constipation. It softens the stools without noticeable irritation. The susceptibility is not lost with use; on the contrary, the establishment of regular habits usually permits it to be gradually withdrawn. By its bitter taste, it acts also as stomachic. It may be given as the fluidextract, 15 drops three times daily; or in a single dose, a half teaspoonful, in the evening. This causes a single soft stool in the morning. In the Aromatic Fluidextract, which is much more pleasant, some of the bitter and cathartic principles have been destroyed (Wenzell, 1886) by an alkali (magnesia). It may be given in twice the dose.

It is generally stated that the fresh bark is emetic, through the presence of a ferment, which gradually disappears as the bark is aged. R. H. True, and Klugh, 1909, did not find any emetic effect from the unaged bark.

In the excised intestine, cascara increases the rate, but lessens the intensity of the contractions (Flury, 1912). The tone is increased by small, and lowered by large doses, also intravenously (Ott and Scott, 1908).

When cascara is administered hypodermically, its constituents are rapidly absorbed and excreted by the kidneys, producing renal irritation, but *not* catharsis (Chistoni, 1914).

Cascara sagrada ("Sacred Bark") was used by the early settlers, but was little known to the profession till introduced by Bundy, 1877. Johnson and Hindman, 1914, review its history, composition and bibliography.

PREPARATIONS

Cascara Sagrada (Casc. Sagr.), U.S.P., B.P.; *Cascara Sagrada* (Cascara; *Rhamnus Purshiana*).—The dried bark of the trunk and branches of the shrub *Rhamnus Purshiana*, stored at least one year. The active principles are: *Cascarin*, which is a cathartic or emodin principle; isoemodin, bitter resins, etc.; no chrysarobin or chrysophanic acid (Jowett, 1904. This author claims that emodin is not the main active constituent.) *Dose*, 1 Gm., 15 gr., U.S.P.

**Ext. Casc. Sagr.*, U.S.P.; *Ext. Casc. Sagr. Sicc.*, B.P.—A powdered extract, 1 Gm. representing 3 Gm. of drug, U.S.P. *Dose*, 0.3 Gm., 5 gr., U.S.P.

**Fldext. Casc. Sagr.*, U.S.P.; *Ext. Cascar. Sagr. Liq.*, B.P.—*Dose*, 1 c.c., 15 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

**Fldext. Casc. Sagr. Arom.*, U.S.P. (Aromatic Cascara).—A watery extract, with the bitter principles partly destroyed by maceration with magnesia; preserved with 25 per cent. of alcohol, flavored with glycyrrhiza, aromatics and saccharin. *Dose*, 2 c.c., 30 minims, U.S.P.

Syr. Casc. Arom., B.P.—40 per cent. of Liquid Extract, flavored with orange, cinnamon and syrup. *Dose*, 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms, B.P.

Frangula, (Buckthorn Bark).—The dried bark of *Rhamnus Frangula*. *Dose*, 1 Gm., 15 gr.

Fldext. Frangul.—*Dose*, 1 c.c., 15 minims.

Rumex Crispus.—Dock-root is said to contain chrysophanic acid about 0.1 per cent. of an emodin identical with that of cascara (Beal and Okey, 1919).

SENNA

The effects are more extensive and more irritant than with the other drugs of the group, so that it is better suited for acute than for chronic constipation. There is considerable griping, which may be corrected by carminatives, or by the previous extraction of the resins with alcohol (as in the Fluidextract).

PREPARATIONS

Cassia Fructus (Cass. Fruct.), B.P.—The ripe fruits of *Cassia Fistula*.

Cassia Pulpa (Cass. Pulp.), B.P.; *Cassia Pulp.*—An evaporated watery extract of the preceding.

**Senna* (Senn.), U.S.P.; *Senna Folia* (Senn. Fol.), B.P.; *Senna*.—The dried leaflets of *Cassia acutifolia* or *angustifolia*. Introduced by the Arabians. Constituents: senna-emodin, senna-isoemodin, senna-chrysophanic acid, and other anthraquinone derivatives (rhein, aloë-emodin), free and in glucosidal combinations; also some salicylic acid (Tutin, 1913, 1914; Tambach, 1913). *Dose*, 2 Gm., 30 gr., U.S.P., infused in a cup of hot water. Many of the laxative nostrums ("Castoria," "Fig Syrup," various "Teas") owe their activity mainly to senna.

Conf. Senn., B.P.—10 per cent. of powdered Senna. *Dose*, 4 to 8 Gm., 1 to 2 drachms, B.P.

Inf. Senn., B.P.—10 per cent., with Ginger. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, repeated; single, 60 c.c., 2 ounces, B.P.

Inf. Senn. Co., (Black Draught).—*Average dose*, 120 c.c., 4 ounces, contains about 7 Gm. of Senna; 15 Gm. of Magnes. Sulph., with Manna and Fennel.

Fldext. Senn., U.S.P.—*Dose*, 2 c.c., 30 minims, U.S.P.

Mist. Senn. Co., B.P.—25 per cent. of Magnes. Sulph. in *Inf. Senn.*, with aromatics. *Dose*, 30 to 60 c.c., 1 to 2 ounces, B.P.

**Syrupus Senna* (Syr. Senn.), U.S.P.—25 per cent. Flavored with coriander.

Dose, 8 c.c., 2 drachms, U.S.P.

**Syr. Senn.*, B.P.—About 40 per cent., with coriander. *Dose*, 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms, B.P.

Tr. Senn. Co., B.P.—20 per cent., with caraway and coriander. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, repeated; single, 8 to 15 c.c., 2 to 4 drachms, B.P.

Pulvis Glycyrrhizæ Compositus (Pulv. Glycyrrh. Co.), U.S.P., B.P. (Compound Licorice Powder).—Greenish-yellow to greenish-brown powder; odor of fennel. *Average dose*, 4 Gm., 1 drachm, U.S.P.; contains about 0.7 Gm. of Senna, 0.3 Gm. of Sulphur and a little Fennel oil. *Dose*, 4 to 8 Gm.; 1 to 2 drachms, B.P.

Senna Fructus (Senn. Fruct.), B.P.; *Senna Pods.*—The dried ripe fruits of *Cassia acutifolia* or *angustifolia*.

RHUBARB

This contains a considerable quantity of tannin as well as cathartic principles. The astringent action predominates with smaller doses (0.05 to 0.3 Gm.) and these are used as astringent bitter in gastric catarrh, and in diarrhea. Larger doses (1 to 5 Gm.) are laxative with little colic. They may be employed in chronic constipation, but the astringent action makes it inferior to cascara. It may cause skin eruptions.

Constituents (Tutin and Clewer, 1911).—The cathartic principles are mainly a resin, non-glucosidal, but yielding on hydrolysis various anthraquinone derivatives, which also exist partly free: rhein, emodin, aloë-emodin, chrysophanic acid, etc. The astringent principles are glucosidal compounds of tannin (rheotannic acid), and gallic acid. There is also a large amount of calcium oxalate.

PREPARATIONS

Rheum, U.S.P.; *Rhei Rhiz.*, B.P.; Rhubarb.—From *Rheum officinale* or *Rh. palmatum* and probably other species growing in China and Thibet. (The species of Rhubarb cultivated in this country are devoid of cathartic properties.) Rhubarb has been used since antiquity in China, and by the Roman physicians. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.2 to 0.6 Gm., 3 to 10 gr., repeated; single, 1 to 2 Gm., 15 to 30 gr., B.P.

Ext. Rhei., U.S.P., B.P.—A powdered extract, 1 Gm. representing 2 Gm. of drug, U.S.P. *Dose*, 0.25 Gm., 4 gr., U.S.P.; 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Fldext. Rhei, U.S.P.—*Dose*, 1 c.c., 15 minims, U.S.P.

Inf. Rhei, B.P.—5 per cent. *Dose*, 15 to 30 c.c., ½ to 1 ounce, B.P.

Mist. Rhei et Sodæ, N.F.—Sod. bicarb., 3.5 per cent.; Fluidext. Rhubarb, 1.5 per cent.; Fluidext. Ipecac, 0.3 per cent.; Sp. Peppermint, Glycerin, and Water. *Dose*, 4 c.c., 1 drachm.

Pil. Rhei Co., B.P.—Pill-mass containing 25 per cent. of Rhubarb, 20 per cent. of Aloes, 14 per cent. of Myrrha. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

Pulv. Rhei. Co., U.S.P., B.P.—25 per cent. of Rhubarb, 65 per cent. Mag. Oxid., 10 per cent. of Ginger, U.S.P.; the B.P. formula is almost the same. *Dose*, 2 Gm., 30 gr., U.S.P.; 0.6 to 4 Gm., 10 to 60 gr., B.P.

Syr. Rhei., U.S.P.—10 per cent. of Fldext. Rhubarb; 1 per cent. of Pot. Carb.; flavored with Cinnamon. *Dose*, 10 c.c., 2½ drachms, U.S.P.

Syr. Rhei., B.P.—7 per cent., with Coriander. *Dose*, 2 to 8 c.c., ½ to 2 drachms, B.P.

**Syr. Rhei Aromaticus* (Syr. Rhei Arom.), U.S.P.; Aromatic Syrup of Rhubarb. —15 per cent. of Tr. Rhei Arom.; 0.1 per cent. Pot. Carb. *Dose*, 10 c.c., 2½ drachms, U.S.P.

Tr. Rhei. U.S.P.—20 per cent.; flavored with Cardamon. *Dose*, 4 c.c., 1 drachm, U.S.P.

**Tinctura Rhei Aromatica* (Tr. Rhei Arom.), U.S.P.—20 per cent. flavored with Cinnamon, Clove and Nutmeg. *Dose*, 4 c.c., 1 drachm, U.S.P.

Tinctura Rhei Composita (Tr. Rhei Co.), B.P.—10 per cent.; flavored with Cardamon and Coriander. *Dose*, 2 to 4 c.c., ½ to 1 drachm, repeated; single, 8 to 16, c.c., 2 to 4 drachms, B.P.

ALOE

General Statement.—The inspissated juice of the leaves of various species of Aloe from the West Indies, Africa, etc., furnishes the commercial varieties of aloes, which differ somewhat in composition and action. They contain anthraquinone derivatives, especially aloins (10 to 16 per cent.). These are glucosides which are probably inactive themselves; but which yield emodin and other active anthraquinone derivatives on cleavage. This cleavage occurs in the intestine; it is favored by alkalies and perhaps also by bile and by iron salts. Aloin may be used as such. Aloe is intensely bitter, so that it must be administered in pills. Very small doses may be used as stomachic. Moderate doses are simply laxative, but somewhat apt to gripe, and are therefore commonly combined with belladonna or carminatives (myrrh, etc.). They do not lose their

efficiency on continued use and would be suited to habitual constipation, but have no advantage over cascara. Aloes are supposed to produce considerable congestion of the pelvic organs and are therefore contraindicated in hemorrhoids, menstruation and pregnancy. On the other hand, they may be used as emmenagogues. They are especially prescribed for correcting the constipative action of iron medication.

Hypodermic Administration.—Aloin is also effective subcutaneously, being excreted into the large intestine; but this method is too painful (H. Meyer, 1890).

Aloin Nephritis.—In rabbits, hypodermic injection (2 c.c. per kilogram of 5 per cent., repeated on two to three successive days) produces a tubular nephritis. The anatomic lesions have been investigated especially by Mürsët (1885); they are practically the same in acute and chronic poisoning, and consist mainly in degeneration of the epithelium of the convoluted tubules. This loses its striations and staining qualities, and the nuclei disappear. The glomerular epithelium is but slightly altered, and the glomerular vessels show no lesions. The urine may be increased or diminished and contains proteins, leucocytes, casts, crystals, and blood.

Metabolism.—There is also an increased protein metabolism, resulting in rise of urea in mammals, of uric acid in birds. The latter may therefore develop gout. Dogs show some fever (Berrar, 1913).

PREPARATIONS

* *Aloe*, U.S.P., B.P.; *Aloe* (Aloes).—The dried juice of the leaves of *Aloe* species: *Aloe Perryi*, yielding Socotrine Aloes; *Aloe vera*, yielding Curaçoa Aloes; *Aloe ferox*, yielding Cape Aloes (Natural history of the commercial aloes, Wilbert, 1903). *Aloe* was used by the Greeks and probably by the Egyptians. Brown, opaque, glassy masses; aromatic odor; nauseous bitter taste. Partly sol. in water; completely sol. in alc. *Dose*, 0.25 Gm., 4 gr., U.S.P.; 0.12 to 0.3 Gm., 2 to 5 gr., B.P.; best as pills.

Dec. Aloes Co., B.P.—1 per cent. of Ext. Aloes, with Myrrh, Aromatics and Liquorice. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 2 ounces.

Ext. Aloes, B.P.—A powdered watery extract. *Dose*, 0.06 to 0.25 Gm., 1 to 4 gr., B.P.

Pil. Aloes, U.S.P.—0.13 Gm., 2 gr. of Aloes with Soap. *Dose*, two pills, U.S.P.

Pil. Aloes, B.P.—58 per cent., with Soap and Caraway Oil. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

Pil. Aloes et Asafet. B.P.—20 per cent., each, of Aloes, Asafet., and Soap. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

(*Pil. Aloes et Ferr.*, see Index.)

Pil. Aloes et Myrrh., B.P.—44 per cent. of Aloes, 22 per cent. of Myrrh. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

* *Aloinum* (Aloin.), U.S.P., B.P.; Aloin.—A pentoside or mixture of pentosides obtained from aloes (usually from Curaçoa, W. Hills, 1908), varying in chemical composition, physical and chemical properties according to the source. A yellow microcrystalline powder, practically odorless, intensely bitter taste. Sol. in water and alc. *Dose*, 0.015 Gm., $\frac{1}{4}$ gr., U.S.P.; 0.03 to 0.12 Gm. $\frac{1}{2}$ to 2 gr., B.P.

Pil. Aloin, Bellad. et Strychnin. (Pil. Laxative Co., U.S.P. VIII).—Each contains: Aloin, 13 mg. ($\frac{1}{5}$ gr.); Strychnine, 0.5 mg. ($\frac{1}{28}$ gr.); Ext. Belladonn., 8 mg. ($\frac{1}{8}$ gr.); Ipecac, 4 mg. ($\frac{1}{16}$ gr.). *Dose*, Two pills.

Nataloin.—This differs from the other aloins in composition, and is more difficultly hydrolyzed (H. Meyer).

Synthetic anthracene derivatives with laxative action have been prepared, but have little practical importance (*purgatin*, anthrapurpurin diacetate; *exodin*, methyl esters of diacetyl-hexaoxy-anthraquinone).

PHENOLPHTHALEIN

This is a mild tasteless purgative, acting probably on the large intestine. It is but little absorbed from the alimentary canal, and is ordinarily non-toxic even in large doses. It may be used in habitual constipation, and has been exploited under several proprietary names (*purgin*, *laxans*, etc.). *Phenoltetrachlorphthalein*, 0.4 Gm. dissolved in 20 c.c. of neutral olive oil, has been suggested as a subcutaneous purgative (Abel and Rowntree, 1909; Rowntree, 1910).

For the phenolphthalein derivatives, their chemical structure and their use in function tests, see Index.

Action.—The purgative effect of this familiar indicator was discovered by v. Vamossy, 1900. It appears to be connected with the quinone structure. It has been investigated experimentally by v. Vamossy, 1902; Tunncliffe, 1902; Fleig, 1908; Abel and Rowntree, 1909, etc.; and clinically by Dornblueth, 1903, and many others. Animals are rather less susceptible than man. Ott and Scott, 1908, found evidence that it acts directly on the muscle of the excised intestine. Fleig and others attribute the action to increased intestinal secretion, but the evidence is not satisfactory. It acts also on hypodermic or intravenous administration, reaching the intestine through the bile. The blood pressure is scarcely affected, even when large doses are injected into a vein (Tunncliffe; Abel and Rowntree, etc.); the kidneys are not irritated, nor are there any other systemic effects. Phenolphthalein itself does not produce local irritation, but its soluble salts are highly irritant. It is not bactericidal (Abel and Rowntree).

Absorption, Fate and Excretion.—Phenolphthalein is insoluble in acids, but gives a pink solution with alkalis. It passes the stomach unchanged. It is partially dissolved in the alkaline intestine, but very little is absorbed, almost the entire quantity (over 85 per cent.) appearing unchanged in the feces (Vamossy). After large doses, traces are found in the urine (Fleig; Elmer, 1909), which is then colored violet-red by alkalis (Gruebler, 1906).

After hypodermic administration, it is excreted by the urine, feces, saliva, tears, etc. The excretion is very rapid, beginning within fifteen minutes and ending in twelve to eighteen hours. In the urine it exists partly free, partly conjugated. The body-fluids dissolve it more readily than water (Fleig). It is excreted into the intestine mainly by the bile, and is to some extent reabsorbed in the large intestine (Abel and Rowntree). The fate of the phthaleins is also discussed by Kastle, 1906.

Toxic Effects.—Only a few doubtful cases are on record (Holz, 1905; Best, 1906; Zabel, 1911; Orland, 1913, etc.). These presented phenomena of intestinal irritation, always ending in recovery. Hydrick, 1914, claims that even 0.05 to 0.15 Gm. produce quite constantly a slight albuminuria, lasting one to three days. On the other hand, very large doses have often been given without bad effects; to man, several grams by mouth, 0.5 Gm. subcutaneously; to dogs, 1.25 Gm. per kilogram.

Administration.—Phenolphthalein may be taken in the evening, as powder, capsules, or lozenges, in doses of 0.1 to 0.2 Gm., $1\frac{1}{2}$ to 3 gr.; for bed-ridden patients, 0.5 Gm., 8 gr.; for children, 0.03 Gm., $\frac{1}{2}$ gr. These smaller doses soften and regulate the stools for several days, with little or no colic. Large doses are hydragogue.

PREPARATIONS

* *Phenolphthaleinum* (Phenolphthal.), U.S.P., B.P.; Phenolphthalein (Dihydroxyphthalophenone), $(C_6H_4OH)_2CO.C_6H_4CO$.—White crystalline powder, odorless and tasteless. Almost insol. in water, sol in alc. (1:13). *Dose*, 0.06 Gm., 1 gr., U.S.P.: 0.12 to 0.3 Gm., 2 to 5 gr., B.P.

BILE

The administration of bile or bile salts (sodium glycocholate and taurocholate) stimulates the secretion of bile (Pfaff and Balch, 1897), increases peristalsis (Stadelmann, 1896); acts as an indirect antiseptic (Limbourg) by evacuating the intestines, and facilitates the digestion of fat. They have been advocated in obstructive jaundice, and in biliary fistulas; but their effects are not very pronounced. Added to enemas, bile is used as a laxative against impacted feces and against ascaris, but has little advantage over soap.

The pharmacologic actions of bile-salts are similar to those of saponins. Like these, they lower surface tension, hemolyze blood, dissolve fats and resins, etc.

Relative Cholagogue Effects of Bile Constituents.—By oral administration to dogs with biliary fistulæ, the following results were obtained (C. W. Hooper, 1917; Hooper and Whipple, 1917):

	Volume of Bile	Output of Bile Pigment
Taurocholic Acid	Great increase	Little effect
Glycocholic Acid	Moderate increase	Marked diminution
Cholic Acid	Little increase	Slight diminution
Bile Fat	No increase	Strong diminution
Entire Bile	Marked increase	Diminished ¹

¹ This indicates that the bile pigment is not absorbed as such.

Peristalsis.—On excised small or large, intestines, bile or bile salts produce mainly depression (Ott and Scott, 1909, d'Errico, 1910; C. Schwarz and Magerl, 1924); but the large intestines may be stimulated (Schuepbach, 1910). In man, evacuation is assured especially by enemas, but also by oral administration (Glaessner and Singer, 1910).

Excised Uterus.—Bile and bile salts, in moderate concentrations, increase the contractions of the pregnant, not of the virgin uterus. High concentrations inhibit (Cantoni, 1914).

Motor-nerve.—Frog's nerve is at first stimulated, then depressed by immersion in solution of fresh bile (Perichanjan, 1921).

Clotting of Blood.—This is delayed by the addition of bile, apparently by interference with the reaction between fibrinogen and thrombin (Hoessler and Stebbins, 1919).

Autolysis.—Bile salts and whole bile activate autolytic processes, and are thus cytolytic (Tatum, 1916).

Toxic Actions.—Bile is non-toxic by mouth, but when injected into the circulation (Meltzer and Salant, 1905, 1906; Bunting and Brown, 1911) it produces severe nervous and cardiac depression (Brandenburg, 1903; Glur, 1909) and hemolysis. It is also directly toxic to muscle and nerve.

J. H. King and H. A. Stewart claim that the pigments are mainly responsible for the circulatory effects. High toxicity of the bile pigments has been affirmed and denied (bibliography, Merck's Report, 1914, 28:13).

Bile-acids are highly toxic. Small doses stimulate the vagus center; larger doses depress the heart directly, with slow irregular pulse and low blood-pressure. They also produce depression of the medullary centers, coma and paralysis; and hemolysis and cell destruction. They have a local vasoconstrictor action (Samelson).

Toxic Symptoms of Biliary Retention (Obstruction).—These consist in dullness, delirium, convulsions, fever, generally fatal in a few days. It is not at all certain that the effects are due entirely to bile acids or pigments; possibly more complex poisons are concerned.

Bile Salts in Gonorrhea.—Loehlein, 1909, introduced the local injection of bile salts in the acute stage for destroying the gonococci. V. Hofmann, 1912, found that 1 to 2 per cent. had little effect; 5 to 10 per cent. gave better but only temporary results. These were improved by following with silver injections, or by using a soluble silver-bile acid compound.

PREPARATIONS

Fel Bovis, U.S.P.; Ovgall.—The fresh bile of *Bos taurus*.

Fel Bovinum Purificatum (Fel Bov. Pur.), B.P.; Purified Ox Bile.—An evaporated alcoholic extract. Dose, 0.3 to 1 Gm., 5 to 15 gr., B.P.; as enema, 1:50.

Extractum Fellis Bovis (Ext. Fel. Bov.) U.S.P.; Extract of Ovgall (Purified Ovgall).—An alcoholic extract of bile, evaporated and mixed with starch; 1 Gm. representing 8 Gm. of Ovgall. Very bitter yellow powder. Dose, 0.4 Gm., 6 gr., U.S.P., in pills or formaldehyde-hardened capsules. As enema 2 per cent.

Bile Salts, N.N.R.—The various commercial preparations are used as pills, generally 0.05 to 0.5 Gm., ½ to 1 gr.; or as suppositories, in the same dosage.

Sodium Cholale (not to be confused with sodium cholalate) is a misnomer for "Plattner's Bile," a preparation of impure bile salts. Laxative dose 0.3 Gm.; or by enema, 0.2 to 0.5 Gm.

CASTOR OIL

This consists mainly of the triglyceride of an unsaturated fatty acid, ricinoleic acid. The neutral fat is not active, but becomes so when it is saponified in the intestine. The cathartic effect is due mainly to motor stimulation of the small intestine. The intestinal secretion is not

increased, the fluid character of the stools being due to the quicker passage of the feces.

With the usual dose, $\frac{1}{2}$ to 1 ounce, the response is certain and complete, resulting in a few hours in one or two extensive semifluid stools, with but slight hyperemia or irritation, there being little or no colic. The evacuation is so complete that there may be some after-constipation. It is especially suited to the treatment of acute constipation or acute diarrhea from dietetic errors, ptomaine and other poisoning, etc. It is not used continuously, since this may produce gastric disturbance. There is some pelvic congestion, so that it is avoided during menstruation and pregnancy.

Mechanism of Action.—This has been studied with X-ray by Magnus, 1908, and his observations have been confirmed on man. The pure oil delays slightly the passage through the *stomach* (as do other neutral oils). Rancid oil hastens the gastric expulsion. In the *small intestine*, the segmenting movements and peristalsis are greatly increased, so that the expulsion may be completed in two hours instead of the normal eight hours. In the *colon*, the normal antiperistalsis is allayed, so that the feces escape concentration. The propulsive movements of the colon are not much increased, but the passage of the fecal material is hastened by its thinner consistency.

In China it is used as an article of diet. The properties of Castor Oil were known to Herodotus; but Croton Seeds were first described in the middle of the sixteenth century.

Castor oil is said to be an active poison for flies (Boyes and Gurjot, 1919).

Administration.—It is best given on an empty stomach an hour before breakfast. The taste may be somewhat disguised by wetting the mouth with hot coffee or milk, and giving the well-cooled oil floating in these liquids, so that it will not be so adherent. The after-taste may be mitigated by peppermint or bread. It is sometimes preferred in *emulsions*: N.F., 33 per cent.; B.P. (*Mistura*), 40 per cent., flavored with orange flower and cinnamon. The *soft gelatin capsules* are tasteless, but since the ordinary size contains only 1 c.c., it is difficult to administer an effective dose. (For other methods, see J.A.M.A., 60:1174.)

PREPARATIONS

**Oleum Ricini* (Ol. Ricin.), U.S.P., B.P.; Castor Oil.—A fixed oil expressed from the seed of *Ricinus communis*. An almost colorless viscid oil, of faint but characteristic odor and extremely disagreeable taste. Sol. in an equal volume of alc. *Dose*, 15 c.c., 4 drachms, U.S.P., 4 to 30 c.c., 1 to 8 drachms, B.P.; for infants, a teaspoonful. Also used as hair tonic, diluted with 1 to 10 vol. of alcohol.

Mist. Ol. Ricin, B.P.—A 37.5 per cent. emulsion. *Dose*, 30 to 60 c.c., 1 to 2 ounces, B.P.

RICIN

Occurrence, Clinical Symptoms and Treatment.—This toxin is contained in the castor seeds, but does not pass into the oil. Similar phyto-toxins occur in croton seeds (*Croton*); and in jequirity seeds (*Abrin*); in the bark of the locust tree, *Robinia pseud-acacia* (*Robin*); and in the seeds of some leguminous plants (*Phasin*). The last is but weakly toxic (Review of Literature, Ford, 1913). The ricin is responsible for the toxic effects on eating the castor seeds; five or six of these are fatal to a child, twenty to adults; three or four seeds may cause violent gastroenteritis, with nausea, headache, persistent vomiting, colic, sometimes bloody diarrhea, thirst, emaciation, and great debility. The symptoms usually do not set in until after several days. More severe intoxications cause small frequent pulse, cold sweat, icterus, and convulsions. Death occurs in six to eight days, from the convulsions or from exhaustion. The fatality is about 6 per cent. This small fatality is due to the destruction of the poison in the alimentary canal. The *treatment* would be evacuant and symptomatic. Three to ten days are required to complete recovery (Critical Review and Bibliography, Ford, 1913).

Effects of Animals.—The actions can be best studied on rabbits, by hypodermic or intravenous injections. Even with the latter, there is an incubation period of at least twelve to eighteen hours before symptoms appear. These correspond to those described for man. They are partly local—gastroenteritis; and partly central—paralysis of the

respiratory and vasomotor centers. The local inflammation also occurs on other mucous membranes to which the poison may be applied, especially the conjunctiva.

The *autopsy* findings are very characteristic. They consist in swelling and reddening of Peyer's Patches and mesenteric lymph glands, internal hemorrhages and diffuse nephritis. Cruz, Flexner, Mueller and others have shown that these lesions are not due to thrombosis, but to direct action on the tissues. The site of the injection is boggy.

Frogs have a much higher resistance than mammals. The phytotoxins have no direct effect on muscle or nerve.

Action on Blood.—*In vitro*, ricin hemolyzes and agglutinates the corpuscles of nearly all warm-blooded animals (Stillmark, 1888). The agglutination does not seem to occur in the body, but is of great importance as an immunity phenomenon. Leucocytes, epithelial and other cells (except those with thick membranes, as yeast) are also agglutinated; as likewise the stroma of laked corpuscles (Elfstrand). The presence of serum hinders the effect.

The agglutination has been referred to precipitation of the nuclealalbumins (Stasano) or other proteins, such as those of serum (Kraus, 1902). All kinds of colloid precipitates carry down ricin, and it is adsorbed by solid proteins and lipoids.

Nature of Ricin.—This appears to be a true protein; for a preparation of ricin has been obtained, which is a typical albumin, and which is so active that 0.0005 mg. is fatal to a kilogram of rabbit; *i.e.*, 1 part of the ricin is fatal to 2,000,000 parts of rabbit; the fatal dose for man would therefore be about 0.035 mg., or $\frac{1}{2,000}$ grain (Osborne, Mendel and Harris, 1905; Osborne, 1909). The agglutinating action is also very powerful.

The attempt has been made to separate the agglutinin (which is adsorbed by blood corpuscles) from the cytotoxin, which is destroyed by peptic digestion. Jacoby, 1902, believes that they have certain groups in common.

Antiricin.—Injections of the phytotoxins produce typical antitoxins, so that an immunized animal can survive 5,000 ordinary fatal doses of ricin. Some of the basic work of Ehrlich was done with ricin and abrin. He showed (1891) that the immunity starts in five to six days, and lasts six or seven months. The resistance of the corpuscles is unchanged, the antiricin being contained in the pseudoglobulin fraction of the serum (Jacoby, 1902). It contains antitoxin, antiagglutinin (probably identical) and precipitin. Madsac and Walbum found that this combination obeys the same laws as diphtheria antitoxin. The toxicity of ricin is modified rather complexly by lecithin (Lawrow, 1913).

ABRIN AND JEQUIRITY

Abrin, a toxalbumin from Jequirity bean (*abrus precatorius*), resembles ricin so closely in its action that the difference was established only when it was noticed that immunity against one did not constitute immunity against the other. Hausmann, 1902, has studied it by the methods of Jacoby. The literature was reviewed by Ford, 1913.

Poisoning.—When the whole beans are swallowed, no toxic effects result, since the shell is so hard that the poison does not dissolve. But if the powder is taken, it produces effects similar to ricin. Its toxicity is greatly increased by heating the animals (Lesne and Dreyfus, 1913).

Use in Ophthalmology.—The action on the eye is much stronger than with ricin, producing ophthalmitis. It has been used therapeutically (Wecker, 1882), to clear corneal opacities. This is dangerous, unless standardized preparations are used, and excessive effects checked by an antiserum.

CATHARTIC RESINS

General Statement.—Jalap, Colocynth, Podophyllum, Elaterin and similar drugs contain active principles which are for the most part resinous (*i.e.*, soluble in alcohol, but slightly soluble in water), often glucosides. On chemic manipulation (probably hydration) these yield resinous acids which are much less active.

The effects of these resins are highly irritant, producing considerable colic (sometimes vomiting), and several watery stools, in one or two hours with jalap and most of the others, but with podophyllum only after twelve to twenty-four hours. They are used especially in dropsics (Compound Jalap Powder); small doses of podophyllum also as laxative

in habitual constipation. The others tend ultimately to produce constipation. Colocynth, and presumably the others, stimulate peristalsis in the small intestine, inhibit antiperistalsis in the colon, and lead to the effusion of fluid from the whole intestinal canal.

The resins require the presence of bile, which renders them soluble. They are therefore less active in obstructive jaundice. They produce griping, and are therefore often prescribed with belladonna and aromatics. If they are not removed by catharsis, they may cause severe enteritis.

The principles are *not as effective when given pure* as when they are mixed with extractive, as in the crude drugs and "resins" (alcoholic extracts precipitated by water), or as preparations of the crude drug. This is due, in some cases, to their being somewhat soluble, and therefore absorbed in the stomach.

Subcutaneous Administration.—This produces diarrhea with podophyllin and colocynthin, but is not available because it also produces nephritis, local irritation and abscesses.

Mechanism of Action.—This has been studied on colocynth by the X-ray method by Padtberg, 1909, under Magnus. Similar observations have been made with jalap on man: The gastric movements may be slightly increased but often remain normal. In the *small intestine* the peristalsis is so much quickened that the contents may be completely expelled in half an hour instead of the normal eight hours. This is accompanied by the effusion of considerable fluid into the lumen. In the *large intestine* the propulsion is only slightly increased; but the stools are rendered still more liquid by the inhibition of antiperistalsis, and by the secretion of additional mucus. Padtberg, 1911, found that the colocynth peristalsis and effusion are arrested by morphine and opium, although these do not ordinarily act directly on the intestine, but on the stomach.

Other Actions.—Convolvulin and jalapin appear related to saponin and agaricin. They are hemolytic in neutral solution. This has been suggested as an index of the intestinal action, but the relation requires confirmation (G. Heinrich, 1918). They are destroyed by alkalis, not by acids.

JALAP

This is perhaps the mildest member of the group. It produces watery stools within three or four hours, with little intestinal irritation, without gastric disturbance or much prostration. It has little taste and is therefore easily administered. It is used in ascites, cerebral congestion, hypertension; and as adjuvant to anthelmintics. *Scammony* and its equivalent *Ipomea* are closely related to jalap.

Constituents.—These have been studied by Power and Rogerson, 1909 and 1912. The "*resin*" is a complex substance, which can be separated by solvents into several glucosidal portions: Jalapin (convolvulin, jalapurgin) and Scammonin (orizabin).

PREPARATIONS

Ipomœa (Ipom.), U.S.P.; *Ipomœa Radix* (Ipom. Rad.), B.P.; Orizaba Jalap Root (Mexican Scammony Root).—The dried root of *Ipomœa orizabensis*.

Resina Ipomœæ, U.S.P.—Prepared by precipitating an alcoholic solution with water. Dose, 0.2 Gm., 3 gr., U.S.P.

Jalapa, U.S.P., B.P.; Jalap.—The dried tuberous root of *Exogonium Jalapa*. At least 7 per cent. of resin, U.S.P.; 10 per cent., B.P. Dose, 1 Gm., 15 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

**Pulvis Jalapæ Compositus* (Pulv. Jalap. Co.), U.S.P.; B.P.; Compound Jalap Powder—1 part of Jalap, 2 parts Pot. Bitart. (flavored with Ginger, B.P.). Dose, 2 Gm., 30 gr., U.S.P.; 0.6 to 4 Gm., 10 to 60 gr., B.P., stirred into water.

Tr. Jalap., B.P.—1.5 per cent. of resin. Dose, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Tr. Jalap. Co., B.P.—8 per cent. of Jalap, 1.5 per cent. Scammon. Res., 1 per cent. Turpeth. Dose, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Resina Jalapæ (Res. Jalap.), U.S.P.; *Jalap. Res.*, B.P.—Prepared by precipitating an alcoholic extract of Jalap with water. Dose, 0.125 Gm., 2 gr., U.S.P.; 0.12 to 0.3 Gm., 2 to 5 gr., B.P. Maximum dose, 1 Gm., 15 gr.

Kaladana, B.P. (Pharbitis Seeds).—The dried seeds of *Ipomœa hederacea*. Dose, 2 to 3 Gm., 30 to 45 gr., B.P.

Pulv. Kalad. Co., B.P.—Similar to *Pulv. Jalap. Co.* Dose, 0.6 to 4 Gm., 10 to 60 gr., B.P.

Tr. Kalad., B.P.—20 per cent. Dose, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Kalad. Res., B.P.—Dose, 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Scammonii Radix (Scammon. Rad.), B.P.; Scammony Root.—The dried root of *Convolvulus Scammonia*, yielding not less than 85 per cent. of resins. Used by the ancients. The constituents are similar to Jalap. They have been investigated by Power and Rogerson, 1912.

Pulv. Scammon. Co., B.P.—Scammon. Res., 50; Jalap., 35; Ginger, 15. Dose, 0.6 to 1.2 Gm., 10 to 20 gr., B.P.

Scammon. Res., B.P.—Prepared by precipitating an alcoholic solution with water. Dose, 0.25 to 0.6 Gm., 4 to 8 gr., B.P.

Turpethum, B.P.; Turpeth.—The dried root and stem of *Ipomœa Turpethum*. Dose, 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

RESIN OF PODOPHYLLUM

This acts very slowly, generally only after twelve to twenty-four hours or longer, producing several soft stools. Larger doses (20 mg., $\frac{1}{3}$ gr. or more) act as a hydragogue cathartic; but it is chiefly employed in small doses (5 to 10 mg., $\frac{1}{10}$ to $\frac{1}{6}$ gr.) as a laxative in chronic constipation, often combined with aloes or calomel, 0.3 to 0.5 Gm. has been fatal.

PREPARATIONS

Iris (Blue Flag).—The rhizome and roots of *Iris versicolor*. Power and Salway, 1911, could not find any active principle, although the drug and the resinoid "iridin" were formerly considered cathartic and diuretic. Dose, 1 Gm., 15 gr.

Iridis Rhizoma (Orris Root).—The rhizome from several cultivated species of iris, has a violet odor. It is used in sachets and tooth powders.

Juglans (Butternut).—The root bark of *Juglans cinerea*, collected in autumn. Used as rather mild laxative. Dose of extract, 1 to 2 Gm., 15 to 30 gr.

The fluidextract of the root, 5 to 20 minims, is said to be a gentle and prolonged laxative similar to rhubarb, and was used in chronic constipation.

Leptandra (Culver's Root).—The rhizome and roots of *Veronica Virginica*. Contains an amorphous bitter principle, and not a crystalline glucoside, as formerly reported (Power and Rogerson, 1910). "Leptandrin" is a resinoid. The preparations are pharmacologically inert, but were supposed to be cholagogue without producing intestinal irritation. Dose, 1 Gm., 15 gr.

Podophyllum, U.S.P.; *Podoph. Rhiz.*, B.P.; *Podophyllum* (Mandrake, May Apple Root).—The dried rhizome and roots of *Podophyllum peltatum* (yielding not less than 3 per cent. of resin, U.S.P.). Active constituents, resin and a crystalline principle, podophyllotoxin. *Podophyllum* was used by the Indians.

Tr. Podoph., B.P.—3.65 per cent. of resin. Dose, 0.3 to 1 c.c., 5 to 15 minims. B.P.

* *Resina Podophylli* (Res. Podoph.), U.S.P.; *Podoph. Res.*, B.P.; Resin of *Podophyllum* (Podophyllin).—Prepared by precipitating an alcoholic extract of *Podophyllum* with acidulated water. Amorphous greenish-yellow powder, of slight peculiar odor and faintly bitter taste. Very irritating to mucous membranes, especially of the eyes. Sol. in alc. Dose, 10 mg., $\frac{1}{6}$ gr., U.S.P.; 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P.; as pill. Maximum dose, 0.1 Gm., $1\frac{1}{2}$ gr.

Podoph. Ind. Rhiz., B.P.—The dried rhizome and roots of *Podophyllum Emodi*, an East Indian species. This contains a resin closely resembling that of *P. peltatum*, so that the clinical activity of the two resins is said to be indistinguishable, but the resin content of *Emodi* is nearly twice as high; Literature, Scoville, 1909. The preparations are used in the same dosage.

Tr. Podoph., Ind., B.P.

Podoph. Ind. Res., B.P.

Stillingia (Queen's Root).—The dried roots of *Stillingia sylvatica*. Contains pungent resin and volatile oil. Used mainly in domestic medicine in purgative mixtures, also as nauseant and emetic. Dose, 2 Gm., 30 gr.

COLOCYNTH, ELATERIN AND BRYONIA

A number of plants of the cucumber family (Cucurbitacæ) yield these drastic drugs. They are of complex composition, each containing several

active principles, resinous and alkaloidal. They produce continuous watery stools, with intense irritation and hyperemia (mechanism described above). They are less used than formerly, when they were frequently employed to reinforce the action of other purgatives as in the Compound Cathartic Pills. Colocynth is excreted by the kidneys and milk, and should therefore not be used by nursing women. Elaterin is one of the most powerful cathartics, sometimes used in uremia. Large doses cause dangerous prostration.

The toxic dose of Colocynth is 0.6 to 1 Gm.; fatal, 4 Gm. Of elaterin, the toxic dose is 5 mg.; fatal, 0.6 Gm.

PREPARATIONS

Bryonia.—The root of *Bryonia alba* and *dioica*. Bryonin and bryonidin are complex mixtures. The purgative action is due to non-glucosidal resins and alkaloids (Power, 1912). Dose, 0.6 to 4.0 Gm. (10 to 60 grains).

According to Jensen, 1915, the fresh root is much more poisonous than the dried. The toxic principles are more abundant in the autumn. At that time the root contains two glucosides: bryonin, soluble in water, inactive; and bryonidin, insoluble in water, paralyzing the nervous system on peritoneal injection. The introduction of bryonia into the pleural cavity of animals is said to produce more or less fibrous effusion.

Cambogia, U.S.P.; Gamboge.—A gum-resin obtained from *Garcinia Hanburyi*. The resin (70 to 80 per cent.) contains garanolic acids, which form readily soluble compounds with alkalies, and thus become active in the intestine. The effects resemble those of colocynth; 4 Gm. are fatal. It is rarely used in pills. Dose, 0.125 Gm., 2 gr., U.S.P.

Colocynthis, U.S.P.; *Colocynthis Pulpa* (Colocyn. Pulp), B.P.; Colocynth (Bitter Apple).—The dried pulp of the unripe fruit of *Citrullus Colocynthis*. The action is due to at least two constituents, an alkaloid and a resin. Colocynthin and colocynthinidin are merely impure mixtures (Power and Moore, 1910). Dose, 0.1 Gm., 1½ gr., U.S.P., in pills. Maximum dose, 0.4 Gm., 6 gr.

Ext. Colocyn., U.S.P.—A powdered extract, 1 Gm. representing 4 Gm. of drug. Dose, 0.03 Gm., ½ gr., U.S.P. Maximum dose, 0.06 Gm., 1 gr.

Ext. Colocyn. Co., U.S.P.—*Ext. Colocyn.*, 16 per cent.; Aloes, 50 per cent.; Scammon. Res., 14 per cent.; Cardamon, 5 per cent. Dose, 0.25 Gm., 4 gr., U.S.P.

Ext. Colocyn. Co., B.P.—A dry extract from Colocynth, Aloes, Scammony and Cardamon. Dose, 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Pil. Colocyn. Co., B.P.—Colocynth, 20 per cent.; Aloes, 35 per cent.; Scammon. Res., 35 per cent. Dose, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

Pil. Colocyn. et Hyoscy., B.P.—*Pil. Colocyn. Co.*, 2; *Ext. Hyoscy.*, 1. Dose, 0.2 to 0.5 Gm., 4 to 8 gr., B.P.

Pilulae Hydrargyri Chloridi Mitis Compositae, (Pil. Hydrarg. Chlor. Mit. Co.), U.S.P. (Compound Cathartic pills; Pil. Catharticae Co.).—Each pill contains: Comp. Ext. Colocynth, 0.08 Gm.; Calomel, 0.06 Gm.; Jalap Resin, 0.02 Gm.; Gamboge, 0.015 Gm.; a total of seven active ingredients. Dose, two pills, U.S.P.

Elaterinum (Elaterin.), U.S.P.; Elaterin.—A neutral principle obtained from *Elaterium*, a substance deposited by the juice of the fruit of *Ecballium Elaterium* (used in antiquity). White, hexagonal scales or prismatic crystals; odorless, and having a slightly acid, bitter taste. Insol. in water; slightly sol. in alc. (1:325). Dose, 3 to 6 mg., ½₂₀ to ½₁₀ gr., repeated in five hours if necessary, but not daily (U.S.P., 3 mg., ½₂₀ gr.). The dose of elaterium is 6 to 30 mg., ½ to ½ gr.

Elaterin consists of two crystalline substances, the levorotary α-elaterin, which is inert; and 60 to 80 per cent. of the active dextrorotary β-elaterin. Commercial elaterin varies in composition and activity (Power, 1912). Elaterin does not exist as such in the fruit, but is formed during the expression by a diastatic ferment, acting on a glucoside (Berg, 1909).

Davis, 1913, advises elaterium in hepatic cirrhosis to provoke watery stools (5 to 15 mg. at night; first day, two or three doses). This rarely causes nausea or pain, but may act during the night.

Trit. Elaterin.—10 per cent. Dose, 0.03 Gm., ½ gr.

CROTON OIL

This contains, besides ordinary fats, about 10 per cent. of "croton-resin," the active component (Dunstan and Boole, 1895). The old "crotonolic acid" was an impure mixture of this resin with inactive fatty acids. The resin produces the local and systemic effects of the oil (Kobert and Hirscheydt, 1890; Boehm, 1915). It is destroyed by boiling with alkalis.

Croton oil is the most violent of all cathartics, $\frac{1}{2}$ to 1 drop producing burning in the mouth and stomach, often vomiting, and after one-half to three hours, several extensive fluid evacuations, with much colic and tenesmus. It is used only in extreme cases of constipation (lead), and in unconscious patients (uremic and apoplectic coma). It should not be given to weak patients, nor if the gastro-intestinal canal is inflamed. Toxic doses produce collapse. Twenty drops have been fatal, but recovery is said to have followed $\frac{1}{2}$ ounce—presumably because of vomiting. The **treatment** would be evacuant, demulcent, opiates and symptomatic (directed against the enteritis and collapse).

Applied externally, croton oil produces irritation, proceeding to pustulation and even sloughing. When diluted with 2 to 10 parts of olive oil, it may be used as counter-irritant, but is dangerous.

Oleum Tiglii, U.S.P.; *Oleum Crotonis* (Ol. Croton.), B.P.; Croton Oil.—A fixed oil expressed from the seeds of Croton Tiglium. A pale yellow or brownish-yellow, somewhat viscid and slightly fluorescent liquid, having a slight, fatty odor. Slightly sol. in alc. *Dose* 0.06 c.c., 1 minim, U.S.P.; 0.03 to 0.06 c.c., $\frac{1}{2}$ to 1 minim, B.P.; on a lump of sugar, slice of bread or lemon. With unconscious patients, a small drop may be placed at the back of the tongue, and repeated every hour to three doses. Maximum dose, 0.06 c.c., 1 minim.

Lin. Croton., B.P.—12 per cent., in equal volumes of Ol. Cajup. and alcohol. Produces severe inflammation.

COLLOID AND EMOLLIENT LAXATIVES

These act mainly by retaining water in the intestine through imbibition, thus modifying the bulk and consistency of the feces, so that these are more easily expelled. They are useful in habitual constipation, especially if aided by the occasional administration of cascara. Their usefulness is due partly to their demulcent action. *Agar* is typical of this class. In *fruits* (prunes, grapes, tamarinds, etc.) this colloid action is supported by the organic acids and sugars. *Manna* acts through its difficulty absorbable sugar, the action being largely osmotic. *Petro-latum* is not absorbed and therefore softens and lubricates the feces. *Olive oil*, in so far as it escapes digestion and absorption, acts in the same manner.

Agar-agar.—This is prepared from various Japanese marine algæ. It consists mainly of the hemicellulose "gelose," which gelatinizes with water. It is tasteless and has been used for culinary jellies, but is not digested (8 to 27 per cent. is utilized in man; Saiki, 1906; Swartz, 1911; herbivore utilize about 50 per cent.; Lohrlich, 1908). It was introduced as a laxative by A. Schmidt, 1905. J. L. Morse, 1910, advises the chopped shreds, $\frac{1}{2}$ to 1 ounce for adults; 1 or 2 teaspoons for children; part with the breakfast cereal, part with sauce or cream at another meal. For children, it may be boiled with oatmeal, or made into a jelly (1:100 boiling water).

O. H. Brown and Sweet, 1917, recommend as daily dose two heaping tablespoonfuls in a quart of water, boiled till dissolved, seasoned and flavored to taste and preferably taken hot.

The effect is usually not noticeable for nearly a week. The efficiency is not very great, and it usually requires the addition of cascara or phenolphthalein (Bastedo, 1914).

PREPARATIONS

Agar, U.S.P.; Agar-agar.—The dried mucilaginous substance extracted from marine algæ growing along the eastern coast of Asia. Thin, translucent, membranous, agglutinated pieces, yellowish-white or brownish-white; odor slight; taste mucilaginous. *Dose*, 10 Gm., 2½ drachms, U.S.P.

Manna, U.S.P.—The dried saccharine exudation of an Ash-tree, *Fraxinus Ornus*. Contains mannite, about 90 per cent. *Dose*, 15 Gm., 4 drachms, U.S.P., to 60 Gm., 2 ounces, as infusion.

Tamarindus, B.P.; Tamarind.—The fruit of *Tamarindus indicus*. It owes its activity to organic acids, especially citric. It is used as a laxative, in *doses* of 4 to 30 Gm. (1 to 8 drachms).

For *Petrolatum*, see Index.

EVACUANT ENEMAS

Rectal injections or clysters increase the peristalsis of the large and small intestines in response to the mechanical stimulation. The effect is enhanced by the addition of irritants.

Enemata have an *advantage* over cathartics taken by mouth, in that they may be made absolutely non-irritant, and may therefore be used in conditions in which the other cathartics are positively contraindicated. If the purpose of the enema be merely to *soften hardened scybala*, they would be used warm, in copious quantities, preferably with soap; or as decoctions of mucilaginous substances.

To secure the maximum motor effect, the injection must be used cold, and in fairly large quantity: Adults a pint, quart, or more; children according to age (at a year, an ounce, and about ½ ounce more for each year). Water and bland oils are also often used by high injection.

The *irritants* which are most commonly used in clysters are: Soap; molasses, 1:8; salt, 1:16; turpentine, 1:20 (emulsified with egg-yolk); bile, 1:50.

Enemata also have other uses: For *local effects* on the rectal mucous membrane (astringents, etc.); for the *removal of parasites*; and as a method of *introducing medicine and nourishment*.

Irritant injections into the colon may either inhibit the emptying of the stomach, by pyloric spasm; or on the other hand, they may shorten the gastric sojourn by increased peristalsis (F. W. White, 1917, X-ray method with cats).

ANTHELMINTICS

Anthelmintics (*anti*, against; *helminthos*, worm) are remedies used against intestinal parasites.

Active peristalsis tends to remove intestinal parasites, as well as the other intestinal contents. Active cathartics are therefore *vermifuges*—*i.e.*, drugs which expel parasites. Catharsis alone, however, is usually only partly effective, since the worms fix themselves to the intestinal wall by suckers or hooks, or by serrated margins; or they may travel against the direction of peristalsis. They must therefore be weakened or narcotized or killed, if the cathartic is to be effective. These paralyzants or *vermicides* may also become toxic to the host, and must therefore be used only after a positive diagnosis has been made, and then in the smallest adequate doses, and under such conditions that they may have a maximal effect on the parasites, and a minimal effect on the patient.

Catharsis.—Safe doses of the vermicides usually depress but do not kill the parasites, and these would recover if left in the intestines. It is necessary, therefore to follow the vermicide by an active cathartic. This also prevents further absorption of the drug and so diminishes the toxicity. Magnesium sulphate (a tablespoon in a glass of water) is satisfactory as cathartic, and the magnesium may perhaps further depress the worm. There is no harm in giving calomel with the magnesium sulphate. Castor oil also produces a satisfactory catharsis, but it has been feared that it may increase the absorability of most of the anthelmintics, since these are more soluble in oil. This is doubtful, but as it has no advantage over epsom salt, the latter is generally preferred.

The intestines should also be cleared by a preliminary purgation with magnesium sulphate, administered on the previous evening, so that the vermicide may have better access to the worms.

Anthelmintic Routine.—The administration of anthelmintics is usually preceded by a fast, so that the parasites will not be protected by the diluent effect of the intestinal contents. It is very doubtful whether this weakens the parasites by starving them, as has been suggested. It is more likely to weaken the patient and to hasten absorption of the poison. The fast should therefore not be severe. It suffices usually to eat a light supper on the preceding evening. This is followed by the first dose of magnesium sulphate. The anthelmintic is taken fasting, early in the following morning, followed two hours later by the second dose of magnesium sulphate. Breakfast may be eaten an hour later. In case of failure, several days should elapse before repeating the treatment; this applies even if the failure is due to loss of the anthelmintic by vomiting.

Adjuvant Condiments.—Mustard, pepper or onions are recommended to be used freely in the preparatory supper. These are in fact fairly active vermicides, and whilst not sufficiently powerful alone, they aid materially the medicinal vermicides (Sollmann, 1918).

Vermicides.—Many poisons that would be toxic to parasites would be too dangerous to the patient. To be available in practice, a vermicide must either be poorly absorbable or it must be specifically toxic to the worms. Many anthelmintic principles are volatile or chemically *unstable*, and therefore become ineffective. The pharmaceutic extracts or isolated principles share this instability, although to a less degree.

Expulsion of Worms.—Most drugs that are toxic to earthworms produce primary irritation or agitation, resulting in withdrawal of the worm from the neighborhood of the poison. This is probably an important factor in the clinical effect of vermifuges.

Specific Vermicides.—The choice of these has been determined mainly by clinical experience. *Tape-worms* are treated mainly with aspidium (especially for *Bothriocephalus*), pelletierine (especially for *Taenia*), and kosotoxin; *round-worms* (*ascaris*) by santonin, chenopodium and spigelia; *thread-worms* (*oxyuris*) by rectal enema with soap-suds, quassia, ferric chloride, etc., and santonin; *hookworm* with chenopodium oil, thymol, and carbon tetrachloride. The specificity of the vermicides is only relative; all are more or less toxic to all the worms. The most difficult parasites are those (the *whip-worms*) that reside in the cecum, where the vermicides do not penetrate. It has been suggested that these be treated by intravenous injections, *f.i.*, of neoarsphenamine (Hall and Schillinger, 1924; but this also would not reach the cecal contents. Surgical removal may be the only effective treatment.

Evaluation of Effectiveness of Anthelmintics.—This may be attempted on dogs by comparing the number of worms removed with those remaining, as found by autopsy. (Hall and Schillinger, 1924). This needs to be checked by clinical trials, since the conditions of the alimentary tract are different.

Efficiency of Anthelmintics as Tested on Earthworms.—All clinical anthelmintics are markedly toxic to earthworms. These may therefore be used to determine whether a substance has any anthelmintic value, and to compare the relative activity of different samples of a drug. They could not be used, however, to compare the clinical value of different anthelmintics; since this often involves factors other than simple vermifugal efficiency, such as toxicity for the patient, irritation of the intestines, etc.

The following are some of the more important results observed on earthworms (Sollmann, 1918).

Highly effective are *Aspidium*, betanaphthol, carvacrol, chenopodium oil, chloroform, dibrom and dichlorobenzol, pelletierine and thymol. Santonin is also highly active in the presence of a suitable solvent (mixture of bile salts and sodium bicarbonate). Fresh pumpkin and squash seeds are quite efficient, the active principles being soluble in water, and injured by boiling.

Fairly efficient are granatum, kamal, kousso. *Spigelia* is weak.

Combination of Anthelmintics.—Spices and similar "sharp" substances, mustard, onions, pepper, also cantharidin, are quite toxic and seem to potentiate the effects of other anthelmintics. Mixtures of other anthelmintics give simple summation of their effects on the worms; but such mixtures are perhaps useful by decreasing the toxicity for the patient.

ASPIDIUM OR MALE FERN

Composition.—The anthelmintic action resides in several closely related substances, complex methane derivatives of phloroglucin and its homologues, with butyric radicles in ketone combination (Boehm, 1897). The most important is probably the amorphous *filicic acid*. Analogous compounds occur in several other anthelmintic drugs (kotlerin in kamala; ascaridol in chenopodium; tanacetin in tanacetum; kosotoxin in cusso).

The Active Constituents of Aspidium (Poulsso, 1891; Boehm, 1897) are: Amorphous filicic acid ($C_{35}H_{40}O_{13}$); aspidinin; albaspidinin; flavaspidic acid (weak); aspidin (probably from other species). The amorphous *filmaron* ($C_{47}H_{54}O_{13}$; Kraft; Jacquet; 1904) is perhaps an impure filicic acid (Schmiedeberg). *The inactive constituents* are: the crystalline filicic acid or filicin ($C_{35}H_{38}O_{11}$), and aspidinol. The crystalline filicic acid is the lactone of the active amorphous acid, the two being readily converted into each other. This probably explains the deterioration on keeping the root. All these substances are so closely related, and change so readily into each other that our knowledge is very confused; even the elementary formulæ are in dispute. *Aspidium* also contains volatile and fixed oil, tannin, etc. Filicic acid is decomposed in the body, yielding trimethylphloroglucin. *Filicin* is an inactive artificial reduction product of filicic acid or aspidin.

Actions.—Active filicic acid probably paralyzes the muscles of the parasites without affecting the nerves; at least it has this action in rain-worms, (W. Straub, 1902). This has been utilized for the standardization of filix preparations (Yagi, 1914). In frogs, it paralyzes the central nervous system, the heart and skeletal muscles; in mammals, it produces local gastro-intestinal irritation; followed by tetanic convulsions with simultaneous central and cardiac paralysis.

Administration.—*Aspidium* is used against tapeworms and hookworm. Its reputation dates from the ancients. The oleoresin is administered in capsules of $\frac{1}{2}$ to 2 c.c., or emulsions. If a cathartic is given, it no oil is taken and if the patient is vigorous, the ordinary doses cause little disturbance. If unsuccessful, several weeks should elapse before another administration.

Phenomena of Poisoning.—These may occur even with moderate doses (Sidler Huguenin, 1898); and larger doses are dangerous. Four grams of the oleoresin have produced severe poisoning, but 20 Gm. have been

given without toxic effects (Drenkhaw, 1911). The milder symptoms consist in colic, diarrhea, headache, dizziness, dyspnea, yellow vision, and sometimes temporary blindness. Severe cases showed delirium, violent muscle-cramps, syncope, tonic convulsions and coma; often glycosuria, albuminuria and casts, and icterus; death occurs by respiratory paralysis.

Recovery is slow, often with permanent blindness (Stuelp, 1904). This occurs also in animals. It is due to spasm of the retinal vessels, with subsequent optic atrophy (Harnack, 1912).

Hall and Schillinger, 1924, did not find the toxicity increased by the administration of castor oil.

The treatment would be evacuant, demulcent and symptomatic.

PREPARATIONS

Aspidium, U.S.P.; *Filix Mas*, B.P. (Male Fern).—The rhizome and stipes of *Dryopteris Filix Mas*; using only such portions as have retained their green color.

**Oleoresina Aspidii* (Oleores, Aspid.), U.S.P.; *Ext. Filicis Liq.*, B.P. (Oleoresin of Male Fern).—An evaporated ethereal extract (containing at least 20 per cent. of filicin, B.P.). Greenish oily liquid, often containing a crystalline sediment which should be incorporated before dispensing. Disagreeable taste and odor. The oleoresin preserves its activity indefinitely. The crystalline deposit is inert (Sollmann, 1918). *Dose*, 4 Gm., 1 drachm., U.S.P. (Caution; not repeated on same day); 45 to 90 minims, B.P.; in capsules or emulsion. Maximum dose, 15 Gm., 4 drachms.

Cusso, B.P.; *Koussou* (Brayera).—The pistillate flowers of *Brayera anthelmintica*. (The male flowers are powerfully emetic, and, therefore, useless as vermifuges.) Contains *kosotoxin*, related to filicic acid (Leichsenring, 1894; Lobeck, 1901). *Dose*, 8 to 16 Gm., 2 to 4 drachms, B.P., as infusion.

It is irritant, and apt to be promptly vomited; said to depress the heart; disagreeable in action; unreliable unless quite fresh.

Kamala (Rottlera).—The glands and hairs from the fruit-capsules of *Mallotus Phillipinensis*. Contains Rottlerin, related to filicic acid (Telle, 1907; Semper, 1910). *Dose*, 10 Gm., 2½ drachms.

PELLETIERINE

This is a mixture of alkaloids obtained from *Pomegranate bark*. It acts much more powerfully on *Tania* than on *Ascaris* (v. Schroeder, 1884; also effects on higher animals). Decoctions of the bark have been used as tapeworm remedy since the Romans; but the large amount of tannin (20 or 25 per cent.) often causes vomiting, so that the alkaloids are preferred. These are generally given in the form of the tannates to avoid gastric irritation, employing the usual preparation of the patient. The ordinary dose often causes mild toxic symptoms: vertigo, dimmed vision, great weakness and cramps in the legs, formication, convulsive trembling, etc. Toxic doses produce promptly mydriasis, partial blindness, violent headache, vertigo, vomiting and diarrhea, profound prostration, sometimes convulsions (Landis, 1889).

Active Constituents.—Tanret, 1878, found two active, volatile alkaloids, punicine and isopunicine. These are, further, two less active alkaloids, methylpunicine and pseudopunicine. More recently, K. Hess and Eichel, 1918, have worked on the separation of the alkaloids and determined their chemical structure.

PREPARATIONS

Pelletierina Tannas (Pellet. Tann.), U.S.P., B.P., Pelletierine Tannate.—A mixture of the tannates of alkaloids obtained from the bark of the root and stem of the pomegranate.

Commercial pelletierine tannate is of rather variable composition, containing from 17 to 23 per cent. of alkaloid (L. E. Warren, 1918). The vermifugal efficiency of different samples does not differ greatly.

The official tannate occurs as light yellow, amorphous powder, of astringent taste. Incompletely soluble in water (1:240), dissolving readily on very dilute hydrochloric acid. Soluble in alcohol (1:16). *Dose*, 0.25 Gm., 4 gr., U.S.P.; 0.12 to 0.5 Gm., 2 to 8 gr., B.P.; suspended in water.

A nostrum sold as "Tanret's pelletierine" is a dilute syrup, without apparent advantage.

Granatum, U.S.P.; Pomegranate.—The dried bark of the stem and root of *Punica Granatum*. *Dose*, 2 Gm., 30 gr., U.S.P.

Decoct. Granat.—20 per cent. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 2 ounces.

Fldext. Granat., U.S.P.—*Dose*, 2 c.c., 30 minims, U.S.P.

Areca.—The fruit of *Areca Catechu*. Contains a vermifugal volatile alkaloid (arecoline). *Areca* is used only in veterinary medicine. Arecoline is very effective against tape worms in dogs (Hall and Schillinger, 1924). Arecoline stimulates the parasympathetic receptive mechanism (see under *Pilocarpine*). It stimulates peristalsis (Paetz, 1910). *Arecoline hydrobromide* has been used locally, $\frac{1}{4}$ to 1 per cent., as miotic (smarting).

Pepo, U.S.P.; *Cucurbita Semina Præparata* (Cucurb. Sem. Præp., B.P.; Pumpkin Seed, Melon Pumpkin Seed.—The dried (fresh, B.P.) ripe seeds of *Cucurbita Pepo* (maxima). *Dose*, 30 Gm., 1 ounce, U.S.P., 100 Gm. bruised to a cream with water or milk, B.P.

Pumpkin or Melon Seeds, fresh or at least not over a year old, are eaten in $\frac{1}{2}$ ounce doses, on the day preceding the regular treatment. They are not sufficiently active themselves, but serve to support other measures. They were investigated chemically and pharmacologically by Power and Salway, 1910; but none of the constituents had any action on the host or parasites. Weinblum, 1912, found neither alkaloids nor glucosides, and also considers the action very unreliable. The earthworm test, however, shows that fresh seeds are actively vermifugal (Sollmann).

The fresh "milk" of the *cocoanut* is also said to be anthelmintic. Its efficiency is very doubtful; for intestinal parasites are very abundant in the Philippine Islands, where fresh cocoanuts are consumed very freely (De la Paz).

Spigelia, (Pink Root).—The dried rhizome and roots of *Spigelia marilandica*. It is said to stupefy round worms, but the earthworm test shows only a feeble activity (Sollmann, 1918). It contains a bitter acrid resin; a poisonous alkaloid; volatile oil, etc. Little is known of its action. Toxic effects, which are rare, resemble those of pelletierine.

Dose, 4 Gm., 60 gr.

Butea Semina, B.P.; *Butea* Seeds.—The seeds of *Butea frondosa*. Used in India as anthelmintic.

Pulv. Butea Sem., B.P.—*Dose*, 0.6 to 1.2 Gm., 10 to 20 gr., B.P.

CHENOPODIUM OIL

The oil distilled from America Worm-seed is a very effective anthelmintic, especially against round worm, hook-worm, and intestinal amebas. Against hook-worms, it is equally or more successful than thymol, and is less unpleasant. It does not require a preliminary fast, and does not usually make the patient sick (Coutant, 1916). It is relatively safe, although the full doses are sometimes toxic.

Efficiency.—Bruening, 1906, 1912, found that chenopodium oil has a high toxicity for ascaris, and a low toxicity for mammals. Subsequent experience has shown chenopodium oil to be effective against all forms of intestinal parasites, including hook-worms; parasites that infest the large intestines, such as oxyuris and whipworms; and also against intestinal amebas.

Efficiency against Hookworm.—Schueffner and Verwoort, 1913, found it clinically fully equal to thymol, and superior to beta-naphthol or eucalyptol. Bishop and Brosins, 1915, consider it more efficient than thymol, with the further advantage of easier administration. In the Orient, according to Heiser, 1915, the clinical results have been superior to other hook-worm remedies.

Darling *et al*, 1918, again found it more efficient than thymol, against anchylostomas. Necators are less resistant.

Efficiency against Ascaris.—M. C. Hall and Foster, 1917, found that it surpassed all other drugs. They insist that it should be given with castor oil.

Other Intestinal Worms.—Darling *et al*, 1918, discuss its efficiency against ascaris, clonorchis, tenia, oxyuris and trichuris. Hall and Schillinger, 1924, found it ineffective against tapeworm in dogs.

Mechanism of Action.—The effects on the worms are similar to santonin, viz., peripheral stimulation, followed with large doses by paralysis (Trendelenburg, 1915).

Administration.—Ordinary doses do not kill, but merely paralyze the worms, so that the drug must be given with a cathartic, usually castor oil. Oils do not increase, but rather diminish, the toxicity (Salant and Bengis, 1915). Magnesium sulphate also decreases the toxicity (Hall and Schillinger, 1924).

Dosage against Ascaris.—For children 5 to 10 drops of the oil are given on sugar two or three times a day for two days, and followed by a tablespoon of castor oil (Levy, 1914).

Dosage against Hookworm.—The routine of the Rockefeller Commission (1917) consists in a light evening meal, followed by a purgative dose of magnesium sulphate. In the morning, the patient receives some milk followed by 3 doses of chenopodium oil, each of 0.5 c.c. on a teaspoon of granulated sugar, an hour apart. Two hours after the last dose, magnesium sulphate is again given.

The course is repeated every three to five days, until the parasites have disappeared from the feces. The dosage for children is 1 drop per year, on sugar. The treatment may be contraindicated during the fever or acute gastro-intestinal inflammations.

Darling *et al*, 1918, found such treatment more effective and less toxic than double the dose in one treatment.

Bishop and Brosins, 1915, advise an even more simple technic, requiring no dietary preparation. The oil is used in capsules of 0.5 c.c. For adults, three doses, each of 1 c.c., are given at intervals of two hours. Castor oil, 2 ounces, is administered four hours after the last dose. For convenience in collecting the stools, the treatment is usually started in the evening.

Coutant, 1916, simply gives 10 drops, half an hour before a light breakfast, repeated for three mornings. The other meals are as usual.

Amebic Dysentery.—Chenopodium administered as for hookworm promptly relieves the clinical symptoms of subacute and chronic amebic dysenteries and causes the disappearance of the amebas from the stools. Chenopodium is often successful in patients and carriers that have resisted emetine, because of the encysted amebas. Relapse may occur, but not oftener than with ipecac (E. L. Walker and Emrich, 1917; Barnes and Coot, 1918).

Minor Side Effects of Therapeutic Doses.—Nearly a third of the patients react by some degree of dizziness, nausea, vomiting, tingling in hands and feet, temporary deafness, or general depression (D. A. Roth, 1918). Dizziness and nausea are the most frequent. Vomiting, sometimes with streaks of blood, occurs in about 16 per cent. of the cases, and increases with the dosage (Darling *et al*, 1918).

Deafness occurs in 20 per cent. It varies in intensity from a disagreeable after-effect, to complete bilateral loss of hearing, lasting usually for a week to several months, but in rare cases still present after 2 years (Roth, Oppikofer, 1919). Thymol does not produce deafness.

Severe Human Intoxications.—These are rare, and generally attributable to gross over-dosage. However, severe poisoning has been described after 2 doses of 10 minims, 4 hours apart (Coutant, 1916), and death has occurred after 2 treatments with 3 c.c. within a week. The symptoms are those of the minor cases, but terminate in coma, tachycardia and convulsions. Death occurs usually after 2 or 3 days of coma (Levy, 1914; Seifert, Nebenwink, 1915, page 140; Darling *et al*, 1918).

Treatment.—This would consist in purgatives and stimulants (Mottet, 1914).

Toxic Effects on Animals.—These have been studied especially by Salant and his co-workers, 1910-1916. The toxicity varies greatly, even with intravenous injection. It is increased by starvation, diminished by abundant diet. Cumulative effects have also been observed.

Intact animals first show depression of the higher centers, then convulsions. There is a cardiac fall of blood pressure and organ volume, with slowed heart and decreased vagus irritability. Somewhat larger doses also decrease the rate and amplitude of the respiration, independently of the circulation. Peristalsis is diminished, by intravenous injection, as well as in the excised intestine. The depression is antagonized by barium, but not by pilocarpine. Renal irritation is also evidenced. Caffeine antagonizes the respiratory depression; epinephrine and digitalis the cardiac depression (Salant and Livingston, 1916).

Oral and hypodermic administration may cause renal disturbance in rabbits fed on oats, but not in those fed on carrots (Salant and Bengis, 1917).

Absorption and Excretion.—The oil is absorbed from the ligated stomach and especially from the small intestine. The excretion occurs partly by the lungs (Salant and Livingston, 1915).

Active Fraction.—The activity of the oil has been reported to reside chiefly in the less volatile fraction, "*ascaridole*" (Ålsberg, 1913; Molloy, 1923), and in the more volatile fraction, which is less irritant and less emetic (M. C. Hall and Hamilton, 1918).

PREPARATIONS

* *Oleum Chenopodii* (Ol. Chenopod.), U.S.P.; Oil of Chenopodium (American Worm-seed).—A volatile oil distilled from *Chenopodium ambrosioides anthelminticum*. *Dose*, 1 c.c., 15 minims, U.S.P.

CARBON TETRACHLORIDE

This methane derivative, CCl_4 , is a very effective, relatively safe and inexpensive agent for the treatment of hook-worm infection. It is less effective against other worms. Since it is very slowly absorbed from the alimentary tract, and is itself somewhat cathartic, the anthelmintic dose lies very much below the ordinary toxic dose (probably about as 1:50), and even minor disturbances are generally absent if a saline cathartic is given. If the drug is absorbed, it acts similarly to chloroform, being somewhat narcotic, and leading to serious degenerative changes in the liver. With gastric administration this degree of absorption is reached only in the slow intestinal progress of herbivorous animals. Rabbits and sheep, for example, are very susceptible. In man, serious toxic symptoms have been observed from the inhalation of the vapor. This may occur in the use of the "tetra" for drying the hair after shampooing. It is also used extensively as a non-explosive fat-solvent. Industrial poisoning in rubber factories has been described by Hamilton, 1915.

Administration as Anthelmintic.—Carbon tetrachloride is an active irritant, and is therefore administered in gelatin capsules. Patients should be warned to swallow the capsules promptly, and not to break them in the mouth. The adult dose is 2 to 3 c.c. (30 to 45 minims); for children, 0.13 c.c. (2 minims) for each year of age up to 15 years. It should be taken fasting, in the morning. A purgative dose of magnesium sulphate is administered 2 or 3 hrs. after the anthelmintic. It is also advisable to administer a laxative dose of the salt on the preceding day. A test-dose of chenopodium oil (3 c.c., 45 min) may be given a week after the carbon tetrachloride to check the success. The administration of the tetrachloride should not be repeated within three weeks.

Anthelmintic Activity.—This was demonstrated on dogs by Hall, 1921, and confirmed on man by Nicholls and Hampton, 1922, and especially by S. M. Lambert, 1922. The first dose is completely effective usually in about 95 per cent. of the patients.

Clinical Side Actions.—These occur especially if the drug is given without the cathartic, or on a full stomach, so that the chances of absorption are increased. Fat is perhaps especially deleterious. The most frequent symptom is headache, which may persist for several days. Many patients become sleepy. Nausea and vomiting are rather exceptional. A few cases of serious symptoms and death have been reported, especially in patients addicted to alcohol, in whom the liver may have been impaired. With such patients it would seem advisable to make a preliminary test of the functional capacity of the liver.

Toxicity for Animals.—Rabbits succumb to 4 c.c. per kg., whilst dogs are apparently uninjured by 25 c.c. per kg., by mouth. The difference depends on absorption, for both animals are about equally susceptible to inhalation. Puppies are more susceptible than full grown dogs. Monkeys are uninjured by 1 to 5 c.c. by mouth, every two or three days for 12 to 16 doses. Fats and alcohol increase the toxicity. (Lamson, 1923; Hall and Schillinger; Lake, 1922).

Toxic Effects after Oral Administration.—These consist especially in severe damage to the liver, shown by the liver-function tests, by diminished coagulability of the blood, by bilirubinemia, and by the pathological changes at necropsy. There are also nervous symptoms and death occurs after several days (Lamson, 1923).

Toxic Effects of Inhalation.—These are more acute and chiefly narcotic (Lehmann, 1911; he also investigated other aliphatic chlorine derivatives). Excessive concentrations may be fatal by respiratory or cardiac failure (Lamson).

PREPARATIONS

Carbonei Tetrachloridum (Carb. Tetrachlor.), U. S. P.; Carbon Tetrachloride, Tetrachlormethane, CCl_4 .—A clear colorless fluid. Odor resembles chloroform. Not inflammable. Slowly decomposed by light in the presence of moisture. Very slightly soluble in water (1:2000). Miscible with alcohol, oils and fat solvents. Dose, 2.5 c.c., 40 minims, Caution!, U.S.P.

THYMOL

This is contained in a number of aromatic oils, for instance Thyme. Its chemical structure, $\text{C}_6\text{H}_3\cdot\text{CH}_3\cdot\text{OH}\cdot\text{C}_3\text{H}_7$, 1:3:4, is allied to that of the creosote constituents. Its actions are also similar to those of phenol. Its antiseptic efficiency is higher, restraining the growth of pus organisms in 1:3,000; it is not a very active germicide. The local effects and the toxicity are relatively slight, because of its slight solubility and slow absorption. The absorption from the alimentary canal is, however, practically complete (Seidell, 1915). The solution and absorbability are favored by alcohol or oil (Schultz, 1915); these must be avoided in the therapeutic use. Even after absorption its toxicity is but a fourth of that of phenol. About half of the thymol is completely destroyed in the body (Seidell, 1915). The remainder is excreted paired with sulphuric and glycuronic acid (Blum). The symptoms are similar to phenol (W. H. Schultz, 1911), except that there are no convulsions, the central nervous system being primarily depressed. It is rapidly absorbed from hypodermic injections of oily solutions (Schultz and Seidell, 1912).

Uses.—Thymol has a rather pleasant, clean taste; and a saturated watery solution makes a rather agreeable and fairly efficient antiseptic and deodorant mouth wash or gargle; lotion for discharging wounds, etc. Internally, it is occasionally employed as antipyretic and intestinal antiseptic. Its main use is as an anthelmintic in the treatment of hook-worm disease (Bozzolo, 1881).

Antiseptic Efficiency.—Thymol has a high phenol coefficient (25), but it is greatly impaired by the presence of organic matter. For instance, the addition of 3 per cent. of dried feces reduces the activity of thymol by two-thirds, that of phenol only by one-tenth.

Yeasts.—Thymol is very active against yeasts and moulds (H. B. Myers) and is being tried against skin-infections by these plants.

Administration in Uncinariasis.—It is given fasting, in the total dose of 2 Gm. for adults, and the usual modifications for age, divided into three portions, taken an hour apart, best as fine powder in 5-gr. capsules. The efficiency is increased by mixing the powdered thymol with equal parts of lactose or, better, sodium bicarbonate (Washburn, 1917).

The thymol is preceded and followed by a saline cathartic (not by castor oil). A rather detailed technic, established by Stiles (described in J. A. M. A., 65: 1546, 1913) should be used to insure success. The treatment is repeated at weekly intervals until successful.

Although highly effective against hook-worm disease, thymol is not ideal. It sometimes fails; produces some disagreeable after effects in nearly half the patients; in a few it causes severe poisoning; and its cost is high (Levy, 1914).

Clark quotes Caius and Mhaskar that a single dose of 2 Gm. is as effective as 3 Gm. given in divided doses; but that this dosage removes only 90 per cent. of the para-

sites, as checked by repetition of the treatment. The smallest wholly effective single dose is 3 Gm.; but even 4 Gm. are completely effective in only 70 per cent. of the patients. Incidentally, the 4 Gm. dose removes about 30 per cent. of the ascaris worms.

Carvacrol.—This isomer of thymol has about the same effect on worms, and the same *toxicity* for rabbits: with oral administration of 1 Gm. per Kg. death generally occurs after several days (Livingston, 1920).

Thymol in Trichinosis.—When the parasites are still in the intestines, thymol may be given by the uncinariæ technic. B. A. Booth, Goehring and Kahn, 1916, also report good results in one patient after the parasites had lodged in the muscles, by intramuscular injection of an oily solution (2 to 3 c.c. of 6 per cent., daily for 7 days; immerse and repeat). No toxic symptoms occurred.

Thymol Test of Hepatic Function.—Administration of 0.5 grams of thymol to man usually results in considerable increase of the ethereal sulphate of the urine. This response is sometimes absent in hepatic disease; but it is not distinctive (M. Kahn, 1918).

* *Thymol*, U.S.P., B.P.—Occurs in the volatile oil of *Thymus vulgaris* and in some other volatile oils. Large, colorless prisms; aromatic thyme-like odor; pungent, aromatic taste. Very slightly sol. in water (1:1,000); freely sol. in alc. (1:1) or olive oil (1:1.7); sol. in other fixed oils and in vol. oils. Liquefies when triturated with camphor, menthol or chloral. *Dose*, 0.125 Gm., 2 gr., U.S.P.; 0.03 to 0.12 Gm., $\frac{1}{2}$ to 2 gr., B.P., as antiseptic; 2 Gm., 30 gr. (caution!) per day divided into three doses, as anthelmintic, U.S.P.; 1 to 2 Gm., 15 to 30 gr., B.P.

The saturated watery solution furnishes an efficient mouth-wash (H. P. Goodrich, 1917).

SANTONIN

General Statement.—Santonica has been a favorite remedy against round worms since Dioscorides. It is also used against pinworms if these have ascended beyond the reach of enemas. Santonin is insoluble, non-irritant and almost tasteless, and is therefore easily administered to children. It may be mixed with some sugar, and combined with calomel or castor oil, which does not increase its absorption. To children of two to five years, 0.03 Gm., $\frac{1}{2}$ gr., may be given every hour for two or three doses, according to age, and then not repeated for at least three days. The adult dose would be three times as much. It should not be given on an empty stomach, since this would favor absorption.

Santonin is the lactone of santononic acid. It is dissolved in the intestine as sodium santoninate, and the greater part is eliminated unchanged in the feces. A small amount is absorbed, oxidized, and the derivatives (especially the crystalline *Santogenin*, Jaffé, 1890) are excreted by the urine. An unknown derivative imparts a bright yellow color to the urine when acid, changing to pink when alkaline.

Doses but little above the ordinary cause "yellow vision," persisting for some hours, without other bad effects. Overdoses produce serious poisoning. Santonin should therefore only be sold on prescriptions. The Troches, by their resemblance to candy, are especially liable to produce accidental poisoning.

Action on Worms.—It was formerly believed that santonin is not directly toxic to worms, but that they attempt to escape from it, and thus flee into the large intestine, from which they are evacuated by the purgative. However, the apparent harmlessness was due to the failure to imitate the solvent action of the intestine. Solutions of santonin in dilute bile and sodium bicarbonate mixtures are highly toxic to earthworms. The irritant effect on worms plays a part in securing their expulsion, but this effect does not differ from that of other anthelmintics.

Mechanism; Relation to Structure.—This has been studied by Trendelenburg, 1915, on rain-worms, leeches and ascaris. It consists in strong stimulation (increased tonus and contractions) of the muscle, persisting after removal of the ganglia. The effect is highly specific, since it is not produced in anything like the same degree by other substances (although some alkaloids have a weak action); nor does santonin stimulate

vertebrate muscle. It is connected with the lactone structure, as is also a depressant effect on the isolated frog heart. The convulsant effect on mammals, on the other hand, does not depend on the lactone, but on the naphthalene nucleus.

The Phenomena of Severe Intoxication.—These are vomiting, colic and diarrhea, painful micturition, hematuria, headache and vertigo, weakness, somnolence; finally *convulsions* (which may be unilateral), and fall of temperature (Binz, 1877; Harnack, 1901).

Treatment.—This would consist in evacuation, chloroform inhalation against the convulsions; and stimulants against collapse.

Fatal Dose.—In children, 0.06 Gm., 1 gr., has produced serious poisoning, and two such doses have been fatal; in other cases, 0.18 Gm., 3 gr., caused only light symptoms, and recovery has occurred after 0.72 Gm., 11 gr. By adults, 0.5 to 1 Gm. and more have been taken without damage (Lewin).

The Color of the Urine.—This may be confused with that of emodin (rhubarb, etc.). The emodin colors can be shaken out with ether, or precipitated by lime or barium water, while the santonin color can not.

Xanthopsia.—Doses as small as 0.1 Gm. may cause "yellow vision"—*i.e.*, white light has at first a violet, then a yellowish-green hue, and these colors tint the entire field of vision. The power of seeing in dim light is also lessened. It has been demonstrated that these effects are peripheral (Knies, 1894), and the theory is advanced, based on some experimental data, that santonin impairs the reproduction of the visual purple and violet, which are at first used very rapidly. There is no truth in the statement that it discolors the media of the eye (Filehne, 1900).

Colored vision also occurs, but more rarely with amyl nitrite, picric or chromic acid, and digitalis (de Schweinitz, 1899).

Uric Acid Elimination.—This is increased by santonin, as by other intestinal irritants (Abl, 1913).

Other Uses.—Santonin has been used in epilepsy and in diabetes, but with little success.

PREPARATIONS

**Santoninum* (Santonin.), U.S.P., B.P.; Santonin, $C_{16}H_{18}O_8$.—The inner anhydride or lactone of santonic acid obtained from *Santonica*. Colorless crystals (turning yellow on exposure to light); odorless and nearly tasteless when first placed in mouth, but afterward developing a bitter taste. Very slightly sol. in water, sol. in alc. (1:43). *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.06 to 0.2 Gm., 1 to 3 gr., B.P.; in powder, with a little sugar. Maximum dose, 0.2 Gm., 3 gr.

Santonica, "Levant Worm-seed" (really the unexpanded flowerheads of *Artemisia pauciflora*), also contains cineol, but this has no action on ascaris (Bruening, 1912).

Troch. Santonin., B.P.; Santonin Lozenges.—Each contains 0.06 Gm., 1 grain.

VERMICIDES FOR THREAD WORMS (OXYURIS)

These are usually treated most efficiently by the rectal injection of various irritants. The rectum is first washed with injections of iron, tannin, or bitters (quassia), to limit the secretion of mucus, and is then irrigated with solutions or emulsions of salt (3 ss to pt.), aloes (5 j to pt.), or turpentine (3 ij to pt.), etc. Mercury salts are sometimes used as injection or suppository but are dangerous.

CONVULSANT POISONS

Convulsions may be caused by direct stimulation of the muscles (veratrine); or of efferent motor nerves (physostigmine, aconitine; or by reflexes from strong afferent stimulation; or by stimulation of the motor centers in the cord, medulla or brain, either directly by the drug or as a result of asphyxia, etc. These produce different type of convulsions. *Spinal convulsions*, as typified by strychnine and caffeine, are generally

symmetrical and when fully developed, tetanic (*i.e.*, the contractions are maintained). *Medullary convulsions* (picrotoxin, camphor, asphyxia) are more irregular, asymmetrical and clonic (rapid intermissions). *Cerebral convulsions* (absinthe) are of the epileptic type, irregular, often involving only limited groups of muscles.

Convulsions are usually the result of extreme stimulation of the motor centers, and as such are mainly of toxicologic interest. Smaller doses of the convulsant drugs, however, may be used for therapeutic stimulation; their action often extending to other nervous centers, and exciting the respiratory and vasomotor centers.

STRYCHNINE AND NUX VOMICA

Strychnine, the main alkaloid of *Nux Vomica*, has considerable therapeutic and toxicologic importance. It increases the reflex excitability of the spinal cord and of the medullary centers. The action is chiefly on the dorsal gray matter of the cord.

Therapeutic doses produce a "bitter" and, therefore, tonic effect on the alimentary canal; improved tone and nutrition of muscle; and a limited amount of respiratory and vasomotor stimulation.

Toxic doses cause characteristic tetanus, violent changes in blood pressure, and spasmodic respiration. Death occurs from asphyxia and from the paralysis which succeeds the stimulations.

Actions closely resembling those of strychnine are produced by a number of other alkaloids, which have little practical importance. The actions of tetanus toxin also are very similar.

Description of the Motor Effects.—The principal symptoms of strychnine poisoning in all vertebrate animals are referable to modified and increased reflex excitability of the spinal cord, culminating in symmetrical convulsions and tetanus. The motor reflexes are modified so that smaller stimuli are effective; and the response even to slight stimulation is maximal, tetanic, and tends to spread to all the muscles. Ordinary reflexes are increased.

The tetanus, however, depends apparently not on this increase of the normal reflexes, but on the enormous exaggeration of the special reflex of the "start" from a sudden stimulus or fright (Cushny, 1919). This involves contraction of all muscles and therefore reversal of inhibitory reflexes.

The symptoms in man correspond to those in the lower vertebrates. With small doses, there is merely a greater response to stimulation, and the muscles feel somewhat more taut. As the dose is increased to 6 or 7 mg. in men, 5 or 6 mg. in women (Hartenberg, 1913), this tightening becomes more sensible, especially in the neck and jaws; the movements become rather abrupt; and slight twitchings may appear in the individual muscles, often in the little finger. In case of paralysis from a high lesion (apoplexy), the paralyzed muscles may be the first to react since they are removed from the cerebral inhibitory impulses.

Convulsant Effects.—With toxic doses, these symptoms are promptly succeeded by sudden convulsions, usually following some stimulation; or the premonitory symptoms may be absent. The attack may start with a loud cry, which is usually caused mechanically, by the convulsive movement of the air, rather than by pain. The convulsions involve all the voluntary muscles of the body, including the diaphragm. The move-

ments are at first rapidly intermittent, but become promptly tonic, resulting in a typical tetanus. Since all the muscles are contracted, the convulsions are symmetrical, and the body assumes the position corresponding to the stronger muscles, which in most situations are the extensors. Accordingly, the body is arched backward (opisthotonus), so that the patient may touch the ground only with the head and heels. The legs are adducted and extended, the feet curved inward. (A frog may be held horizontally by the feet.) The arms are either strongly flexed over the chest, or rigidly extended, with the fists balled. The jaws are fixed, and foam gathers at the mouth. The rigid diaphragm and the tense thoracic and abdominal muscles arrest respiration. The skin and mucosæ are, therefore, cyanotic and congested; the eyes protruded, evolved; and the pupils dilated. The pulse is small and tense, often imperceptible.

The patient remains perfectly conscious, and suffers severe pain from the violent contractions. The asphyxia may be fatal in the first attack. More commonly there is a:

Remission.—The tetanus lasts perhaps a minute, then the muscles relax, and the patient passes into a greatly depressed, almost paralytic condition, still perfectly conscious and very anxious and oppressed, with dry throat and thirst, sometimes sweating. This intermission lasts at most ten or fifteen minutes, when there is another attack, usually again following some slight stimulation. If this is not fatal by asphyxia, it is again followed by remission, and so on, the whole sequence being repeated. The remissions, however, become progressively shorter, the spasms become weaker and the paralysis more prominent.

Death occurs usually in the interval after the second to fifth attack, from exhaustion and general depression. It may be preceded by asphyxial coma.

Recovery may occur from sublethal doses, or under appropriate treatment, the convulsions and depression disappearing gradually. Animals, however, have been observed to relapse into fatal convulsions several hours after apparently complete recovery (Sollmann), so that patients should be watched:

Dependence of Convulsions on Reflex Stimulation.—In the lighter grades of strychnine poisoning, the convulsions occur only on reflex stimulation. In the severe grades, they are often apparently spontaneous, but even here they are really reflex, due to slight and accidental sensory stimulations. This is shown by the fact that *convulsions do not occur spontaneously if all sensory impressions are prevented from reaching the spinal cord*, as by dividing all the posterior roots in frogs (Hermann Meyer, 1846); together with the medulla (Hering, 1893; Verworn, 1900); or by placing the frog in a very weak cocaine solution (Poulsso, 1889).

Different Forms of Stimulation.—Practically all kinds of sudden sensory stimulation may provoke the convulsions. The skin is especially sensitive, even to the slight jars produced by heavy walking. Sudden light and sound are also dangerous. Gradual stimulation is much less effective (as with all reflexes), so that a patient may support considerable but deliberate manipulation, as for instance artificial respiration; when a slight, but abrupt or unexpected touch would cause an attack.

Stimulation of the exposed intestines does not cause convulsions, since these are produced in sensory fibers.

Chemical stimulation (the application of dilute acids) not only fails to produce tetanus, but even the normal reflex is greatly diminished (Schlick, 1890). The absence

of tetanus is easily explained because the slow penetration of the acid leads to a gradual instead of abrupt stimulation. The various explanations of the diminished reaction are mainly hypothetical (Baglioni, 1900 and 1900; Sano, 1908).

Simple and Crossed Reflexes.—The effects of strychnine are relatively greater (*i.e.*, the threshold is lowered more) for the crossed or leg-arm reflexes than for simple uncrossed reflexes, apparently because the excitability in simple paths is normally already so high that it can not be materially increased by strychnine. Therefore, the strychnine increase of excitability is better marked in the more difficult complex paths, where several synapses are interposed; or when the normal threshold has been raised by ether or asphyxia (E. L. Porter, 1914, 1915). The excitability is increased for single induction shocks, as well as for interrupted stimuli (van Leeuwen, 1913).

The Modification of the Short Reaction of Ordinary Reflexes into the Prolonged Contraction of Strychnine Tetanus.—It might be supposed that the strychnine tetanus is due to the summation of repeated stimuli: that each muscular contraction, by the movements of the tendons and joints, sets up a fresh reflex, these rapidly succeeding stimuli fusing into a tetanic contraction which persists until the nerve centers are exhausted (Baglioni, 1900). However, there is good evidence that this is not necessary, but that the tetanus is in fact a true multiple response to a single stimulus: For it occurs also if all reflexes but the original single stimulus are excluded; *f.i.*, tetanus occurs in a leg with a single stimulus of its divided sensory nerves, the remainder of the animal being curarized (Veszi, 1913; Buchanan, 1912; Henkel, 1913). The spinal stimuli, in strychnine tetanus, reach the muscles at the rate of 50 per second (Fahrenkamp, 1914).

Sherrington, 1912, concludes that the strychnine action consists in greater sensitiveness of the central receptor cells; not in greater spread of the impulses, nor in greater intensity of the afferent impulses.

Normal and "Start" Reflexes.—Cushny, 1919, pointed out that strychnine has two apparently distinct actions on reflexes. A strychninized frog (0.05 mg.) responds to weak and slowly acting stimuli by reflexes of a normal coördinated character, but with lower threshold; whereas stronger and sudden stimuli produce the typical universal tetanus. This differs from normal reflexes not only quantitatively, but in that it causes the contraction of even antagonistic muscles. Cushny considers that this is a distinct reflex, which finds its physiological expression in the "start," for instance on a sudden fright; but which is enormously exaggerated by strychnine, so that it tends to displace the ordinary reflexes.

Reversal of Reciprocal Innervation.—The modification of the reflexes by strychnine is not merely quantitative, but also qualitative. Sherrington (1905 to 1909) showed that in a normal animal, the contraction of a muscle is accompanied by the automatic relaxation of its antagonistic muscles. The reciprocal reflex is destroyed by such substances as strychnine and chloroform. With strychnine, all reflex stimulations result in simultaneous contraction of all the muscles, including the antagonist; while with chloroform, they result in simultaneous relaxation. The vasomotor system presents analogous phenomena (Bayliss). The work of de Barenne (quoted under "Localization") shows other qualitative changes in the functions of the sensory cells.

Location of the Tetanizing Action.—The distinction between the possible sites of convulsant action furnishes interesting illustrations of the general methods of experimental pharmacology. Most of these experiments can be carried out more conveniently on frogs; but they can also be demonstrated on mammals.

The Action is Localized in the Spinal Cord.—This can be easily shown by exclusion: (a) The *peripheral motor apparatus* is excluded by section of the nerve trunk, which arrests the convulsions in the corresponding muscles (Johannes Mueller, 1844). Conversely, no convulsions will occur if strychnine is injected directly into a muscle—say the leg; provided that the leg is first ligated so that the poison can not reach the general circulation. (b) If this experiment is modified so that the nerve is not included in the ligature, the absence of convulsions will also prove that strychnine does not affect the *peripheral sensory apparatus* (Magendie, 1819).

(c) *The brain and medulla oblongata* are not essential to the convulsions, for these occur in frogs in which these centers have been destroyed.

d) *The posterior root ganglia* are also not concerned; for typical tetanus

can be obtained, by direct stimulation of the cord, when all the posterior roots have been cut in frogs (Hermann, 1846; Verworn, 1901); and in dogs even when the afferent fibers from these ganglia have completely degenerated after section (Sherrington, 1898). Nor does the localized application of strychnine to the exposed posterior root ganglia produce any effects (de Barenne, 1910).

(e) *Action on the Spinal Cord*.—It is evident, therefore, that the strychnine action is located somewhere within the spinal cord. The next question, whether it acts on the sensory or on the motor tracts, or on both, has not been conclusively answered, although it has been the subject of much ingenious investigation. At present, it appears that both the motor and sensory portions of the cord must be poisoned, to obtain the typical strychnine convulsions.

Methods of Anatomical Isolation.—The basic experiments in this direction were made by Hermann Meyer in 1846: after cutting away the entire posterior columns of the spinal cord, he found that strychnine does not produce tetanus, even if the remaining cord is touched. If the ablation is confined to a part of the cord, the corresponding muscles do not participate in the convulsions. This seems to indicate that the action is located in the posterior and not in the anterior columns. However, as pointed out by Verworn, 1900, the proof is not conclusive, for the operation produces too much shock, and besides, destroys all the physiological relations of the motor cells. Similar objections apply to all anatomical methods, so that these can not furnish conclusive evidence. It was therefore necessary to have recourse to physiological means.

Localized Application of Strychnine to the Spinal Cord.—Houghton and Muirhead, 1895, basing themselves on the earlier and imperfect work of A. J. Spence, 1866, attempted to utilize the fact that impulses go from the sensory cells of the cervical segments of the cord to the motor cells of the caudal segments, and *vice versa*. By destroying the circulation and applying strychnine locally to the exposed cord it is therefore possible to make impulses pass either through a poisoned sensory cell to an unpoisoned motor cell; or through an unpoisoned sensory to a poisoned motor cell. If strychnine is restricted to the cervical half of the cord and the foreleg is stimulated in this frog, the hindleg participates in the convulsions. When the hindleg is stimulated, there is no convulsion.

Analogous observations have been made on mammals (Ryan and McGuigan, 1911); on frogs with the sensory paths paralyzed by phenol (Baglioni, 1900); and on the excised nervous system of toads (Baglioni, 1909).

These results were interpreted as proof that strychnine acts essentially on the sensory mechanism of the cord, and that the motor cells were at best unessential: for convulsions appeared whenever the impulse passed through a poisoned sensory cell, even though the motor cell be unpoisoned; whereas no convulsions appeared when the sensory cells were not poisoned, even though the motor cell was poisoned.

However, these results are obtained only when the cervical cord is poisoned. If the strychnine is applied to the lumbar cord, the convulsions do not spread at all to the cervical segments, but remain confined strictly to the poisoned area (McGuigan and Becht, 1914). Furthermore, if the *entire* animal is poisoned by small doses of strychnine, the same phenomena are observed as in the Houghton-Muirhead experiment: namely, minimal stimuli applied to the forelegs produce general convulsions, whereas the same stimuli applied to the hindlegs produce only local contractions. The Houghton-Muirhead phenomenon may therefore be explained by the more easy spreading of impulses in the caudal than in the cephalic direction. (The entire subject is reviewed by McGuigan, Keeton, and Sloan, 1916.)

Barenne, 1911 to 1913, adduced some new facts. By strictly localized application of strychnine to the exposed spinal cord of frogs and dogs he finds:

1. When the application is restricted to the ventral surface of the cord, no perceptible symptoms are produced.
2. When it is restricted exclusively to the dorsal surface, there is no tetanus; but instead, a characteristic syndrome, comprising sensory disturbances (paresthesias), increased reflexes, and incoördinate asymmetrical twitches. These "dorsal symptoms" are sharply localized on the skin according to the level and site of application to the cord; the skin areas being identical with the "dermatomata" defined by anatomic-physiologic isolation methods. They occur even after the division and degeneration of the posterior root fibers.

3. Typical tetanus occurs only if *both* the sensory and motor tracts are poisoned. *F. i.*, if the strychnine is applied dorsally to the arm region, and ventrally to the leg region, then stimulation of the leg causes only normal reflexes (unpoisoned sensory to poisoned motor); stimulation of the arm causes tetanus of the legs (poisoned sensory to poisoned motor) in which the arms do not participate (poisoned sensory to unpoisoned motor). This experiment (which was confirmed by Beritoff, 1913) would indicate that both the sensory and motor cells must be poisoned, to obtain the typical tetanus.

Motor Cortex.—The cerebral motor centers react to the direct application of strychnine (and also to picrotoxin) by increased excitability to electric stimulation, and even by rhythmic spontaneous movements, identical with those which would be induced by electric stimulation. The action is not abolished by deep anesthesia (Bickeles and Zbyszewski, 1913). It is localized in the gray matter, for it disappears on ablation and no effect is produced by direct application to the white matter (S. S. Maxwell, 1906 and 1907; Baglioni and Magnini, 1909).

Strychnine acts in this respect like creatine and picrotoxin; in contrast to calcium precipitants and barium. These stimulate only the white matter directly, although they may lower the threshold of the gray matter to electric stimulation.

De Barenne claims that local application of strychnine to the cerebral cortex produces sensory excitation of the corresponding zones, but no motor symptoms.

The "silent area" of the brain does not respond to the local application of strychnine (Amantea, 1913).

Psychic Centers.—These are evidently not affected by strychnine, since consciousness is not disturbed until the onset of asphyxial coma.

Practical Significance of the Location of Strychnine Action.—The location of the tetanizing action of strychnine in the spinal cord explains, for instance, why strychnine convulsions are abolished by curare, since curare blocks impulses from the cord to the muscles. Also, that strychnine has a stronger action on a paralyzed limb in those cases of paralysis in which the lesion is above the cord, for cutting off of the spinal cord from the brain always increases its reflex excitability.

The fact that strychnine in small doses increases the *tone of muscles* is also due to its heightening the reflex excitability of the spinal cord. Not only the convulsive centers, but other spinal centers are put in a condition more favorable to reflexes. It is in this way that strychnine is useful in *impotence* or in *paralysis of the bladder or other sphincters*, when these are due to lowered activity of their respective spinal centers.

Indirect Results of the Motor Actions.—The increased activity of the muscles brings about several secondary results, such as pain, asphyxia, increased metabolism, disturbance of temperature, tendency to rise of blood pressure and quickening of pulse; early postmortem rigor. The asphyxia in turn produces its characteristic phenomena.

Pain.—Strychnine convulsions are extremely painful, just as any other form of muscle cramp.

Metabolism.—The increased muscular tone or convulsions result in increased consumption of oxygen and output of carbon dioxide, and increased use of glycogen. The increase of gaseous metabolism is observable even with therapeutic doses (Edsall and Means, 1914). The asphyxia may also cause hyperglycemia and glycosuria.

Effect of Convulsants on Temperature.—All convulsant poisons (santonin, picrotoxin, strychnine) produce characteristic changes in heat regulation. Small doses cause increased heat loss and a slightly smaller heat production. Larger doses increase metabolism, through muscular action, and hence increase heat production, which is accompanied by a further increase of heat loss. Paralytic doses diminish the heat production very greatly. The *temperature* is accordingly variable: Small doses tend to lower it; moderate convulsive doses would increase it; paralytic doses lower it greatly. The heat loss is particularly conspicuous in small and young animals while larger animals tend to show a rise of temperature, with moderate doses.

Lactic Acid.—Strychnine and other convulsions cause the appearance of lactic acid in the blood, provided that the glycogen store is adequate (Lusk, 1916).

Nux Vomica.—The preparations of Nux Vomica, and its second alkaloid, Brucine, act essentially like strychnine.

Brucine.—The action of brucine is much weaker than that of strychnine, the ratio varying with different animals. The paralytic and curare effects are relatively stronger (resembling methyl-strychnine), so that brucine is less useful therapeutically (*cf.* Dixon and Harvey, 1908).

Brom-Strychnines.—The two mono-brom-strychnines act similarly to strychnine, but are only $\frac{1}{8}$ or $\frac{1}{6}$ as effective. Dibrom-strychnine is also convulsant, but in frogs it produces mainly the curare effect (C. R. Marshall, 1912).

Other Spinal Convulsants.—Spinal tetanus, in every respect similar to that of strychnine, is produced by caffeine, thebaine (an opium alkaloid), gelsemine, calabarine and hydrastine, etc. It is also a late phenomenon in morphinized frogs. *Tetanus toxin* likewise induces spinal tetanus, the minor differences being due mainly to peculiarities of absorption (Froehlich and Meyer, 1915).

The Convulsant Action of Sulphonated Dyes; Inhibitory Action of Cerebrum.—Acid Fuchsin (Barbour and Abel, 1910), and other water-soluble, neurophilic sulphonated dyes (Macht, 1912), produce strychnine-like convulsions in frogs. In normal frogs, the tetanus occurs only after a long latent period (up to twenty hours), and requires relatively large doses. If the anterior third of the cerebrum is removed (either before or after the injection), the convulsions occur much more promptly (within thirteen minutes), and very much smaller doses ($\frac{1}{10}$ to $\frac{1}{20}$) suffice. This was originally attributed to the removal of inhibitory central impulses; but Thomas, 1920, and Syz, 1923, find that identical results are produced by injury to any part of the nervous axis, and incline to attribute the greater effect mainly to more rapid penetration of the injured tissue.

Cardiotomized Frogs.—Joseph and Meltzer, 1911, found that the late convulsant action of acid fuchsin, and of morphine, could be greatly hastened, and that a very much smaller dose would suffice, in frogs in which the heart had been tied, the circulation of the blood being thus arrested. According to Abel, 1912, this interesting observation is explained by the peculiar distribution of the poison. The ligation of the heart prevents the dissipation of the poison in the body, and the anterior lymph hearts drive the solution directly into the communicating vessels of the central nervous system. This is therefore exposed to a much more concentrated solution. At the same time the interruption of the normal circulation, and the partial asphyxia, increase the sensitiveness of the nervous system to convulsants; for the outbreak of these is hastened even if the heart is excised *after* the drug has been injected. Meltzer, however, did not accept this explanation.

Carbon Dioxide.—This also greatly hastens the convulsions, when its tension in the air exceeds 20 per cent. (Joseph, 1915). The gas also lowers the threshold for strychnine convulsions (Pilcher and Sollmann, 1915).

Therapeutic Use of Strychnine in Paralyses.—Strychnine and nuxvomica are used to preserve muscular nutrition in paralysis from functional neurites and high lesions; to raise the tone of the rectal and vesical sphincters in incontinence of urine or feces; to improve the effects of cathartics, especially in atonic constipation. They are also used (but probably useless) in sexual impotence. Most of these uses have been discussed in the text.

Paralytic Disorders.—It should be remembered that strychnine only increases the excitability of existing structures. It must therefore be useless in organic lesions of the cord. In spastic paralysis, and in inflammatory conditions, it would be contraindicated. Moderate doses (1 to 2 mg., three times a day) may be useful in functional depression of the cord (lead poisoning, or sometimes in diphtheritic paralysis); but its main indications are for maintaining the muscular tone, and thereby preventing muscular atrophy while awaiting the repair of cerebral lesions (apoplexy); but large doses of strychnine may bring apoplectic attacks in predisposed patients. The trophic effect should be supported by massage and electricity. Strychnine is also said to lessen the pain of some older paralyses.

Incontinence of Urine.—Strychnine would be useful only if the incontinence is due to atony of the sphincter; if due to overaction of the detrusor urinae, the indication would be for atropine.

Medullary Actions of Strychnine.—These are analogous to its effects on the spinal cord, consisting in a more or less violent and convulsive exaggeration of the reflex excitability, particularly of the respiratory and vasomotor centers, followed by paralysis with toxic doses. These effects are modified by the coexistence of asphyxia.

These medullary stimulations are very marked and violent with convulsive doses. With therapeutic doses, they are so slight that they can not be demonstrated with certainty, either clinically or experimentally. The therapeutic use of strychnine as a respiratory or circulatory stimulant therefore rests on a very insecure basis. It was doubtless due mainly to the uncritical transfer of the results of convulsive doses to therapeutic doses.

Therapeutic Doses on the Circulation.—These produce either no effect whatever, or a very slight (10 to 20 mm.) rise of blood pressure, fairly well sustained. The rise is rather more marked in the diastolic pressure. Direct observation of the vasomotor center may also, but exceptionally, show a slight and doubtful stimulation; but in asphyxia, the same doses (0.05 mg. per kg.) cause intense vasomotor stimulation (Pilcher and Sollmann, 1915). These effects (aside from asphyxia) are so inconstant and small that they could be accidental. The cardiac contractions are not changed. Clinical observations on the blood pressure and heart rate, in health and in various diseased conditions (cardiac diseases, fevers, etc.), give similarly negative or inconclusive results, even when rather large doses ($\frac{1}{10}$ gr. every hour) are used (Cabot, 1904; Parkinson and Rowlands, 1913 and 1914; Newburgh, 1915; Lucas, 1914). Positive results of Cook and Briggs, 1903, and Marvin, 1913, must therefore be viewed with caution.

The pulse-flow (the change of blood flow during the pulse cycle) is also unaffected in man by 3 to 6 mg. (Hewlett, 1917).

Convulsive Doses.—While small doses of strychnine have but little effect on the circulation, convulsive doses cause very conspicuous changes; especially a large rise of blood pressure, due to central vasomotor stimulation, produced mainly by the direct action of strychnine on the medullary and spinal vasomotor center; but aided by the convulsions and asphyxia. This is followed by vasomotor depression.

These effects are synchronous with the convulsions: the typical course is shown in Fig. 4. With the onset of the *irregular spasms* at (b) the mean pressure rises (central vasomotor stimulation), the heart being slowed and strengthened (central vagus stimulation). During the *tetanus* (c), the pressure is very high (intense stimulation of vasomotor center), the heart beats are faster and smaller (reflex vagus depression, mainly through muscular exertion). As the *tetanus disappears* (d) the pressure falls below normal (central vasomotor paralysis), and the heart beats become very slow (intense vagus stimulation, mainly asphyxial). The phenomena b to d are repeated during each spasm.

As death approaches, and the respiration stops permanently, the pressure remains low, and the heart beats rapidly but weakly (total paralysis of vasomotor and vagus centers), and finally stops.

This description applies almost equally well to the effects of convulsions produced by any other cause; and particularly to asphyxia (see Fig. 5). These are both present in strychnine poisoning, and must be contributory factors. However, they are not the main cause of the rise of blood pressure; for this occurs when convulsions are excluded by complete curarization; and when asphyxia is prevented by artificial respiration. Only the portion (d) of the tracing is entirely asphyxial.

Vasomotor Center.—Pilcher and Sollmann, 1915, found that the vasomotor center is greatly stimulated by convulsive doses, independently of the convulsions or asphyxia. Very large doses (above 1 mg. per kg.) depress and paralyze the center.

The *vein pressure*, which is also unchanged by therapeutic doses, rises during tetanus, indicating cardiac insufficiency (Capps and Matthews, 1913). In man also, the vein-pressure is unaltered by therapeutic doses (G. Rosenow, 1919).

Vascular Areas.—During the strychnine rise of pressure, all the splanchnic vessels contract, while those of the skin (Wertheimer and Belezenne, 1897) and cerebrum (Roy

FIG. 4.—Convulsive doses of strychnine on blood pressure.

and Sherrington, 1890) dilate. The vessels of the pia mater and retina are constricted (Hirschfelder, 1915).

Vasomotor Convulsions.—In curarized animals, the rise in blood pressure occurs spasmodically (S. Mayer, 1872), and can be brought on by reflex stimulation, just like the convulsions in ordinary animals. The dose required to produce the convulsant and the vasomotor action are also identical. This supports the view that the action of strychnine on the medullary centers is essentially identical with its action on the

FIG. 5.—Asphyxia on blood pressure (Dog). The trachea was tied at X. The respiratory movements are at first exaggerated, but become shallow, and stop at XX. The heart stops at (g); but it often gives a few isolated beats (h) after having stopped for several minutes.

spinal centers. The convulsive centers are, however, affected by smaller doses than the spinal vasomotor centers (Langley, 1919).

Spinal Vasomotor Centers.—Attempts to demonstrate these have usually been vitiated by shock. Langley, 1919, 1924, showed that with spinal curarized cats—provided the blood pressure is good—convulsive doses of strychnine produce a large rise of blood pressure, almost as great as if the spinal cord were intact; this occurs also after the adrenals have been excised. The spinal vasomotor centers therefore play a large part in the vaso-convulsive action of strychnine, at least in cats. The margin between

the ineffective and effective dose (about 0.5 mg.) is narrow. Excessive doses decrease the excitability, and tend also to lower the pressure by peripheral mechanisms.

Vasomotor Reversal.—According to Bayliss, 1908, contraction of the vessels through the vasomotor center is always brought about by stimulation of the vasoconstrictor nerves and simultaneous automatic inhibition of the vasodilators—the reciprocal innervation of Sherrington. Bayliss claimed that this is modified by strychnine and chloroform in exactly the same sense as with skeletal muscle; and there is the same antagonism between the two drugs. The vasoconstrictors are so much more powerful than the dilators, that under strychnine, every reflex stimulation will cause a rise of blood pressure; under chloroform, a fall through inhibition. Langley, 1912, however, failed to confirm the “reversal” of depressor fibers by strychnine; small doses simply increase the response of the pressor fibers and large doses (10 to 20 mg. per rabbit) produce transient paralysis of the depressor response, but never “reversal.”

Paralysis of Autonomic Ganglia.—Large doses of strychnine and brucine, like curare, paralyze all autonomic ganglia. This can be antagonized by stimulant doses of nicotine.

The fall of blood pressure resulting from the paralysis of the peripheral nerve cells can not be permanently restored by any means (Langley, 1918).

Heart.—Among clinicians, the opinion prevails very widely that strychnine is a “cardiac stimulant.” This clinical term does not necessarily imply that the drug stimulates the heart directly, but merely that it improves the pulse. The expression is used so loosely that the student is advised to discard it altogether.

As a matter of fact, strychnine has no effect whatever on the heart in therapeutic doses with *living animals*. Convulsant doses cause some stimulation of the ventricles (Wiggers, 1916). Cameron claims increase of cardiac tone in animals with 0.03 mg. per kilogram; but this lacks confirmation.

When perfused directly through the *excised* heart, the effects are first stimulant, then depressant (Hedbom, Igersheimer, 1905); but the necessary concentration could not be maintained *in vivo*.

Perfusion of Cardio-inhibitory Center.—This produces stimulation (cardiac slowing, in turtles; A. D. Bush, 1919).

Epinephrine Output.—Large but subconvulsive doses of strychnine ($\frac{1}{10}$ to $\frac{1}{3}$ mg. per kg., hypodermic; corresponding to $\frac{1}{40}$ to $\frac{1}{3}$ grain for a man) considerably increase the output of epinephrine by stimulation of the thoracic cord, independently of convulsions or asphyxia. The increase may be to 10 times the previous concentration, but does not exceed the maximal normal concentration. It persists for a considerable period (1½ hours). The epinephrine content of the adrenal glands is not lowered, so that there must be increased manufacture of the base. Smaller doses of strychnine may temporarily lower the output (G. N. Stewart and Rogoff, 1919, 1920).

It is conceivable that this increased epinephrine output might benefit the circulation, but this is very improbable in view of the negative clinical results.

Cardiac Poisons and Irregularities.—M. I. Smith, 1917, found the effects on excised hearts of frogs and rabbits purely depressant; but this tended somewhat to correct the overstimulation irregularities resulting from toxic doses of aconitine, ouabaine, or coronary occlusion. Living animals, however, were not saved by strychnine from toxic doses of the stimulants.

Irregularities due to impaired conduction (cocaine) or to myocardial depression (apomorphine, ergotoxine) were not benefited by strychnine, but rather aggravated.

Respiration.—In animals, therapeutic doses of strychnine increase respiration mainly by acceleration (Cushny, 1913). This is due to increased excitability of the center, and indirectly to the increased movements. The increase of respiration is not always conspicuous, on account of the variable excitability of the respiratory center. Clinically, it is practically absent (Newburgh, 1914; Edsall and Means, 1914; Higgins and Means, 1915, 4.5 mg. hypodermically). It is presumably more conspicuous when the excitability is partly depressed, as in anesthesia or morphine poisoning (Biberfeld, 1904; Hanzlik, 1923); but is practically not very efficient even then (R. Meissner, 1923).

Similarly, strychnine causes a distinct and fairly lasting improvement of respiration when this has been depressed by cerebral compression (Loevenhart *et al.*, 1918).

With toxic doses, the respiration is spasmodic, arrested during the tetanus; accelerated immediately after; and depressed during the intermissions.

The respiratory tetanus is reflex, like the muscular tetanus; for it does not occur if the posterior roots have been divided (Pike *et al.*, 1919).

Therapeutic Use of Medullary Stimulation.—The supposed circulatory and respiratory actions of strychnine led to its use in collapse (fainting, trauma and hemorrhage; fevers; depressant poisons, alcohol, anesthetics, coal-tar derivatives, snake venom, etc.) and in exhaustion of the respiratory center (pneumonia, phthisis). It is probably inefficient. In any case, it should be remembered that it would be only a temporary remedy to tide the patient over a crisis; it could not in itself produce any permanent improvement in the central nervous system. It would merely raise the reflex excitability; and it is doubtful whether the permanent maintenance of this artificially raised irritability is ever of benefit.

Traumatic Shock.—Profound surgical shock involves complete peripheral paralysis of the vessels, probably the capillaries, associated secondarily with depression of the heart. The poor circulation causes the prompt degeneration of the nervous centers, in which they can not respond to strychnine or any other stimulant (Sollmann and Pilcher, 1914). Even epinephrine, transfusion or other mechanical means, while they may temporarily restore the blood pressure and may thus help to prevent "shock," can not restore the nervous centers (Crile). *Excessive hemorrhage* presents the same conditions.

Minor Degrees of Collapse and Especially in Hemorrhage, in Fevers, and in Intoxications.—In these, the increased excitability of the vasomotor center might somewhat counteract the lowered blood pressure, and enhance the effect of other stimulant measures (saline infusion, etc.). Moderate doses of strychnine (2 mg.) are used, preferably hypodermically. However, the clinical studies of Newburgh, 1914, and Lucas, 1914, were entirely negative. Its effects are certainly much less pronounced than those of the reflex vasomotor stimulants (ammonia, alcohol, ether, camphor). These reflex stimulants are most useful especially for fainting and temporary myocardial insufficiency.

In *Heart Disease* proper strychnine would be theoretically contraindicated, unless it be to ease the dyspnea; even this effect could be secured better by caffeine. Newburgh, 1914, found no effect from $\frac{1}{30}$ to $\frac{1}{10}$ grain in broken compensation.

Depressant Effects of Toxic Doses of Strychnine.—The medullary and spinal functions all show a curious mixture of stimulant and depressant response to strychnine; the stimulation predominating during the convulsions, the depression during the intermissions. The paralytic effects gradually increase as death approaches, the respiratory center, vasomotor center, vagus center, and the cardiac muscle failing in about this order. Exhaustion and asphyxia, as well as the direct depressant action of strychnine, are important factors in this paralysis.

Contributory Factors in Strychnine Paralysis.—That exhaustion is an important contributory factor is shown by the fact that life may be greatly prolonged by preventing the convulsions through chloral or curare. The prolongation of life by artificial respiration shows the contributory action of asphyxia. However, animals die from large doses of strychnine, when exhaustion and asphyxia are both excluded, in the manner indicated. Indeed, the direct depression seems generally to be the main factor (Heubner and Loewe, 1913).

There is reason to believe that in the frog the paralysis of the central nervous system is caused largely by the failure of the circulation through cardiac paralysis; but this is not the sole cause, for the heart is often still beating when the reflexes have disappeared. In the case of mammals death usually occurs before the heart has stopped.

Importance of Treating the Paralysis.—It is important to bear in mind that the convulsions are not in themselves the dangerous element in strychnine poisoning. Death is rather due to paralysis. Remedial meas-

ures must therefore be directed not only against the convulsions, but also against the subsequent paralysis.

Tetanus alone is not so dangerous a condition. Thus, tetanus quite as violent as that of strychnine has been produced, e.g., by camphor, without being fatal, and the very severe convulsions of traumatic tetanus may last for weeks, whereas large doses of strychnine may kill after a single twitch or even without any signs of convulsions (death may then, however, be due to cardiac paralysis).

Special Senses.—Strychnine (2 to 3 mg.) increases the sharpness and field of vision for all colors (Dreser, 1894), and also the olfactory sense. The sense of touch is little, if at all, affected. These actions are central. In the eye it acts probably also on the retinal ganglion cells, the effects being obtainable unilaterally by injection into the temples or under the conjunctiva. It has been employed to arrest the progress of optic atrophy amaurosis (Nagel¹), sometimes with temporary improvement; $\frac{1}{2}$ to 1 c.c. of a $\frac{1}{2}$ per cent. solution (2.5 to 5 mg.) being injected into the temple.

Bitter and Tonic Actions.—Strychnine is extremely bitter (perceptible in dilution of 1:400,000 to 1:100,000, according to the sensitiveness of the observer). It shares the stomachic effect of other bitters, and is therefore used to improve appetite and digestion in nervous dyspepsias, chronic gastric and intestinal catarrhs, hyperemesis, seasickness, etc., and thus favor nutrition. The increased tone of the muscle creates a feeling of vigor which contributes to the "tonic" effect. To enhance the local action, the tincture of nux vomica (1 c.c. diluted, before meals) is often preferred to the alkaloid (1 to 2 mg.). It is often combined with other tonics (Elixir Ferri, Quininæ et Strychninæ Phosphatum). If the bitter effect alone is desired, the dose of the tincture may be reduced to 1 or 3 drops, which is too small to produce any central effects.

In seasickness it has been employed as a prophylactic in conjunction with atropine (Skinner, N. Y. Med. Jour., December, 1893; Girard, 1906).

Drug Habit.—The bitter and tonic effects of strychnine make it a useful adjuvant in the treatment of chronic alcoholism and other drug habits.

Diabetes Insipidus.—Strychnine is said to be occasionally effective in reducing the polyuria. There is no pharmacologic explanation for this action, if it exists.

Peristalsis.—Strychnine is often used as an addition to other cathartics ("Aloin, Belladonna and Strychnine") with the idea of improving their action, especially in atonic constipation. It stimulates the intestines on direct application (Langley and Magnus, 1907), but it has not been shown whether this action would occur in its therapeutic use. Hypodermically, it probably has no direct effect in ordinary doses, while toxic doses weaken or arrest peristalsis (Pollak, 1910). Any results may perhaps be explained by increased tone of the spinal centers which influence intestinal movements and defecation. For this purpose, the extract of Nux Vomica is generally used (15 mg. in pills).

Emetic Center.—Direct application of strychnine or brucine to the floor of the fourth ventricle induces vomiting by increasing the sensitiveness to afferent impulses (Hatcher and Weiss, 1923).

Other Peripheral Actions.—Strychnine, when used systemically, has practically no peripheral action on muscle, nerve, or glands except the bitter effect.

The local application of strong solutions paralyzes most nervous and muscular tissues; for instance, the heart muscle, superior cervical ganglion, striped muscle endings. The last effect (*curare action*, Lapique, 1913) also occurs weakly in living frogs. Small doses seem to sensitize the neuro-muscular junction, lowering the threshold to indirect stimulation, and delaying fatigue (Hammett, 1916). The curare effects are stronger in brucine; and methyl-strychnine may be counted in the curare group. After death, strychninized frogs cease to respond to sciatic stimulation much earlier than normally (Cithens and Meltzer, 1912).

Phagocytosis.—This is hindered by strychnine *in vitro* (Arkin, 1913); but the doses are very different from the clinical.

Invertebrates.—Strychnine acts as a weak protoplasmic poison on ameboid cells, yeast, etc. Higher invertebrate animals are also relatively insusceptible. Many insects are quite immune, others are only slightly injured (Juchenack and Griebel, 1910).

¹ Cf. Derby, 1902, Boston Med. & Surg. Jour., 20, 508.

It reverses the positive phototropic reaction of certain aquatic larvæ. It expands the chromatophores in others.

Strychnine reverses the reciprocal inhibitory innervation of the muscular system of earthworms, planarians and starfish, but not of medusæ or sea-anemones (A. R. Moore, 1913, 1916). Its antagonism with nicotine on starfish is described by Moore, 1920. Romanes, 1884, also reported characteristic effects of strychnine on jellyfish and sea-urchin.

Absorption.—Strychnine is promptly absorbed, mainly from the intestine. In rabbits, none is absorbed from the stomach proper; it is not known whether this is also true for man.

Gastric Absorption.—Rather variable results have been obtained by different investigators when strychnine was placed in ligated stomachs. Generally, alcoholic solutions are absorbed readily, aqueous solutions scarcely at all. These results seem to depend partly on the ligation; for from unligated stomachs (Pawlow's pouch) aqueous solutions are well absorbed, better than alcoholic (Ryan, 1912).

Excretion.—A part of the strychnine is excreted unchanged (in man, 20 per cent. or less; S. Weiss and Hatcher, 1922) mainly by the urine, practically none in the bile and feces. The excretion by urine starts within five minutes after absorption (Ipsen, 1892); and is practically completed within forty-eight to seventy-two hours (Bukunin and Majone, 1906; Hatcher and Eggleston, 1917), although traces may be found even after five days (Plugge, 1885; Hale, 1909; Kuenzer, 1914). In the remarkable case of a patient who had swallowed 15 grains and survived, Hewlett, 1913, recovered $4\frac{1}{2}$ grains from the first stomach washings, and a total of $1\frac{3}{8}$ grains from the urine, mainly between the first and tenth hour. Traces were present on the fourth, none on the fifth day.

The urinary excretion of strychnine can be increased to only a limited extent, by very active diuresis (sodium sulphate injection); but even when this is maximal, it does not save life after doses only 20 per cent. larger than the M.F.D. (Hatcher and Eggleston, 1916; S. Weiss and Hatcher, 1922).

Destruction.—At least a fourth, and often much more, of the administered strychnine can not be recovered from the excreta (Kobert); nor from the tissues of mammals, if these survive the administration three hours.

The disintoxication occurs mainly in the liver, chiefly by destruction, but somewhat by storage in a loose combination (Hatcher and Eggleston, 1917; S. Weiss and Hatcher, 1922). Both processes can be demonstrated by the perfusion of the excised liver. Hashed liver, however, destroys only small amounts.

The rapidity of the disintoxication is illustrated by the high tolerance of the repeated administration of sublethal doses. When the administration is spread over 12 days, 25 times the ordinary fatal dose does not produce any permanent damage (Hatcher and Eggleston, 1917; they also discuss the older contradictory literature).

Loudini, 1918, claims that strychnine is disintoxicated by cholesterol and therefore by the cholesterol content of antitetanus serum. Confirmation is desirable.

Distribution in Body.—In fatal cases, the strychnine is found mainly in the blood, liver and kidneys, in frogs especially in the spinal cord, but there is no evidence that strychnine is bound by spinal cord emulsions (Dixon and Ransom, 1912).

W. Koch and Mostrom, 1911, found that phosphatides increase the solubility of basic strychnine; but this is probably a simple solution phenomenon, and has nothing to do with its selective action on the nervous system. Lombardi, 1913, also claims that the toxicity of strychnine is somewhat diminished when it is first digested with brain substance; but not if the brain of a strychnine-poisoned dog is used.

Sojourn in the Blood-stream.—When strychnine is injected into a vein, 30 per cent. leaves the blood-stream within 2 minutes; 50 per cent. within 5 minutes; all but traces in 40 minutes (S. Weiss and Hatcher, 1922).

When added directly to blood, half or more passes into the blood corpuscles (*idem*).

Influence of Absorption and Channel of Administration on Effect.—

Since the capacity for the excretion and destruction of strychnine is relatively great, the effect of the same dose will vary considerably with the rapidity of its absorption. Hypodermic injections are therefore two to eight times more active than oral administration; intravenous injections are two to three times more active than hypodermic. The effects of rectal administration approach more closely to hypodermic than to

oral administration. The toxicity of strychnine is slightly reduced by the administration of large quantities to fluid (Kleiner and Meltzer, 1912). Colloids have a marked retarding effect (Hatcher, 1904).

Even very large doses may produce no symptoms, if the experiment is arranged so as to make their absorption very gradual; for instance, by injecting it into the ligatured limb of a guinea pig. A considerable quantity will be gradually absorbed through the ligatured tissue; and if the ligature is released, after several hours, the effects will be correspondingly small.

Influence of Age.—Children are said to be comparatively insusceptible to strychnine. In old people with atheromatous arteries, large doses might lead to apoplexy.

Increased Susceptibility on Continued Administration.—The continuous use of strychnine does not lead to tolerance; on the contrary, the repetition of its action “educates” the nervous system to respond more readily, so that the effects are apparently slightly increased.

After the repeated administration of equal tetanic doses to frogs, the spasms occur earlier and last longer (Mostrom and McGuigan, 1912). In mammals, the experiments of W. Hale, 1909, gave rather inconclusive results, some indicating increased susceptibility, others slight tolerance.

Susceptibility of Different Animals.—This varies greatly. With subcutaneous administration, man, cats, and dogs require about the same dose, 0.75 mg. per kilogram, to produce a fatal effect; rabbits are slightly more susceptible. Guinea pigs and frogs require about six times, and snakes eighteen times, this dose. With the frog, the spasms appear with one-sixth the fatal dose; with the guinea pig they only set in when at least 95 per cent. of the fatal dose has been given. The differences for oral administration are even greater. Some birds are almost insusceptible to oral poisoning, the fatal dose for chickens by mouth being 30 to 40 mg. per kilogram.

Resistance of Fowls to Strychnine.—This is due entirely to the long sojourn and slow absorption from the stomach. If the strychnine is injected hypodermically, or when it is placed in the empty stomach, the toxicity is similar to that in other animals (Heinekamp, 1924).

Temperature on Convulsions in Frogs.—Smaller doses suffice to produce tetanus when the temperature is either below or above the ordinary (55° to 75° F.). In the cold, the tetanus appears later, but lasts longer (Githens, 1913). The rapidity of onset, with large doses, rises with the temperature according to van't Hoff's law (Schlomovitz and Chase, 1916). This, however, may depend on absorption.

Toxicology of Strychnine.—The symptoms and course of strychnine poisoning have been sufficiently described under the convulsant effects.

Toxic Dose.—In man, 5 to 10 mg. may exceptionally produce convulsive effects, more pronounced with 20 to 30 mg. These doses may even be fatal. The ordinarily fatal dose, by mouth, would probably be about 100 mg. With efficient treatment, patients may be saved after 250 mg.; and even doses of a gram and over are said to have been treated successfully (Hewlett). The fatal dose of *Nux Vomica* lies about 0.75 to 3 Gm.

Time of Appearance of Symptoms and of Death.—These depend upon the mode of administration, the condition of the stomach, and other factors influencing absorption. With oral administration, the symptoms generally appear in fifteen to thirty minutes; the convulsions sometimes only after an hour or later. Death occurs usually in one to three hours, but the time may be as short as ten minutes, or as late as nine to twenty hours, or even later.

Differential Diagnosis of Strychnine Poisoning.—Strychnine tetanus may be confused with traumatic tetanus, spinal meningitis, epilepsy, or hysteria. *Traumatic tetanus* is characterized by previous malaise and slow development. The convulsions begin in the jaw. The muscles

remain rigid in the intermission. The course is comparatively slow. Strychnine tetanus may also begin in the jaw, but this is not so conspicuous. In rare cases of strychnine poisoning the muscles also preserve their rigidity during the interval, so that the diagnosis is sometimes difficult. When in doubt, strychnine treatment should be used, as it is beneficial in all similar conditions. The course of the case will clear up the diagnosis.

In *spinal meningitis* the diagnosis may be made by the fever and history. *Epilepsy* differs by the loss of consciousness; the reflexes are normal. In certain cases of *hysteria* the diagnosis may be impossible. Such cases should also be treated as for strychnine.

Postmortem Phenomena.—Death by strychnine is characterized by early and often persistent rigor. This, however, is common to all forms of convulsions, and is presumably due to the increased production of acid. The anatomical appearances are those of asphyxia and violent convulsions: venous congestion, often hyperemia of the central nervous system, and small hemorrhages; in a few cases hyperemia of the alimentary tract.

Identification of Strychnine.—Strychnine may be identified in the suspected material, vomitus, or tissues (after isolation and purification) by its taste, convulsant effects on frogs, and chemical tests (violet and cherry color with bichromate-sulphuric acid).

Strychnine largely disappears during *putrefaction*; although it may sometimes be found even a year after burial (Sandrich, 1884). The failure to find it is not conclusive (Hatcher and Eggleston, 1917).

Treatment of Strychnine Poisoning.—This comprises the prompt administration of chemic antidotes (permanganate, iodine, tannin); evacuation by emetics or stomach-tube (under chloroform); suppression of the convulsions by chloroform and chloral or ether; and artificial respiration. Absolute quiet of the patient is imperative.

Chemic Antidotes.—Potassium Permanganate is probably the most effective, if it is given sufficiently early, since it destroys the strychnine. One gram ($\frac{1}{4}$ teaspoonful) should be dissolved in a quart of warm water, carefully decanted, and administered in tumbler doses at short intervals. Iodine (15 drops of tincture in $\frac{1}{2}$ glass of water) or tannin (teaspoon in $\frac{1}{2}$ glass of hot water) merely delay absorption, but this is distinctly useful. Tea or coffee should be avoided, since the caffeine is synergistic. Charcoal, or better caramel or Fuller's earth, are useful by adsorbing the strychnine and delaying its absorption (Sabbatani, 1914; Fantus, 1915); but their efficiency is limited.

Evacuation.—Emesis by zinc or copper sulphate or mustard may be tried, or apomorphine (although the depression is theoretically objectionable). Gastric lavage should be done if the patient is thoroughly under chloroform—otherwise it may start a fatal convulsion. Diuresis and catharsis are probably of little use. Very energetic diuresis (as by 2 per cent. sodium sulphate intravenously; or drinking large quantities of hot water) removes some strychnine (Hatcher, 1916; Kleiner and Meltzer, 1917); but it is unable to save the animal if the minimum fatal dose is exceeded by 20 per cent. (Eggleston and Hatcher, 1917).

Physiologic Antidotes.—Chloroform, chloral, paraldehyde, ether, etc., suppress the strychnine convulsions. By preventing their painful and exhaustive effects, they conserve the energy of the patient so that he may more successfully resist the strychnine depression. They also lessen the danger of tetanic asphyxia, and are therefore the most useful antidotes.

Chloral is given in doses of 2 Gm. ($\frac{1}{2}$ drachm), with the addition of another gram (15 grains) after half an hour or longer, as necessary. There is some danger, its paralytic effects may coincide with those of the strychnine, and thus increase the risk. For this reason *chloroform* or *ether* is preferred, since their action can be better controlled. Ether has the advantage that it is not liable to the dangers of late chloroform poisoning. Githens and Meltzer, 1911, advise the intratracheal insufflation of air and ether, combined with intravenous injection of Ringers' solution. Bicheles and Złyszewski, 1913,

found differences in the antispasmodic action of the various narcotics; amylene hydrate being especially effective, barbital very little, and chloral between.

Morphine is theoretically objectionable, since its action on the spinal cord is synergistic to strychnine. It has been employed, however, and its analgesic and euphoristic action would be useful; but it does not take the place of ether or chloral and these should be preferred. Other depressants which have been used, but are of doubtful efficiency, are bromide, nicotine, and pilocarpine.

Epinephrine counteracts the cardiac depression, on local application (Januschke, 1910); but systemically, it increases the convulsive effects, so that there is no therapeutic antagonism.

Artificial Respiration.—This prevents or suppresses the convulsions, and may save life if it is carefully maintained until the patient is out of danger. The effect is probably due mainly to the removal of the synergistic effects of asphyxia.

There are, however, some conflicting theories and data: Osterwald, 1900, claimed that strychnine spasms are diminished by excess of oxygen in the air, and *vice versa*. This might suggest that the result is due to destruction of the strychnine by oxygen; but there is no other evidence for this view. Meltzer and Gies, 1903, found that the mere rhythmic movements of the chest were also important, for these prolonged life even when the animals were in an atmosphere of pure hydrogen. They suggest that this is due to a reflex inhibitory effect on the convulsive centers. It is also conceivable that it might be due to removal of carbon dioxide. Paradoxically, however, Ryan and Guthrie, 1908, find that the inhalation of carbon dioxide also arrests strychnine convulsions, in frogs and mammals. Difference of dosage may explain the contradiction.

It is claimed as a result of animal experiments that the application of *external heat* also decreases the strychnine mortality.

PREPARATIONS

Nux Vomica, (Nux. Vom.), U.S.P., B.P. (Strychni semen, P.I.).—The dried, ripe seeds of *Strychnos Nux Vomica*, East Indies; yielding not less than 2.5 per cent. of total alkaloids, U.S.P.; not less than 1.25 per cent. of strychnine, B.P. *Dose*, 0.1 Gm., $1\frac{1}{2}$ gr., U.S.P.; 0.06 to 0.25 Gm., 1 to 4 gr., B.P. Maximum dose, 0.25 Gm., 4 gr.

The constituents are strychnine, brucine, tannin, fat, etc.

The drug was unknown to the ancients, and was probably introduced by the Arabs. The first good description occurs in 1540. Strychnine was discovered in 1818.

The bark contains the same principles in less amount, but relatively more brucine. It was formerly found in commerce under the name of "false angostura." Several arrow poisons are also derived from the genus *Strychnos*, especially the *Upas Tieuté* from Java. Some of the *strychnos* species do not contain any active principle.

Nux vomica contains a small quantity of a third alkaloid, igasurine, which has not been closely studied, but which seems similar to strychnine.

Ext. Nuc. Vom. Liq., B.P.—1.5 per cent. of strychnine. *Dose*, 0.06 to 0.18 c.c., 1 to 3 minims, B.P.

Extractum Nucis Vomicae (Ext. Nuc. Vom.), U.S.P.; *Ext. Nuc. Vom. Sicc.*, B.P.—A powdered extract. The U.S.P. extract is about $1\frac{1}{2}$ times as strong as that of the B.P.; 1 Gm. representing about 6 Gm. of drug, 16 per cent. of total alkaloids, U.S.P.; 5 per cent. of strychnine, B.P. *Dose*, 15 mg., $\frac{1}{4}$ gr., U.S.P.; 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P., as pills. Maximum dose, 60 mg., 1 gr.

* *Tinctura Nucis Vomicae* (Tr. Nuc. Vom.), U.S.P., B.P.; Tincture of *Nux Vomica*.—10 per cent. of drug, 0.25 per cent. of alkaloids, 0.125 per cent. strychnine, in about 75 per cent. alcohol. Miscible with water and alc. Incompatibilities as for Strych. Nit. *Dose*, 1 c.c., 15 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P. Maximum dose, 2.5 c.c., 40 minims.

Strychnina, B.P.; $C_{21}H_{22}N_2O_2$.—An alkaloid obtained from *nux vomica* and other plants of the *Loganiaceae*. Colorless, transparent crystals or white, crystalline powder. Very slightly sol. in water (1:6420); slightly sol. in alc. (1:136). *Dose*, 1 to 4 mg., $\frac{1}{64}$ to $\frac{1}{15}$ gr., B.P.

* *Strychninae Nitras* (Strych. Nit.), U.S.P.; $C_{21}H_{22}N_2O_2 \cdot HNO_3$.—Sol. in water (1:45); slightly sol. in alc. (1:150). All strychnine salts occur as colorless crystals or white powder; intensely bitter, even in dilute solutions. They are *incompatible* with alkalies, iodides and bromides (slow precipitation), tannin, arsenates and arsenites. *Dose* (of all

strychnine salts), 2 mg., $\frac{1}{30}$ gr., U.S.P.; 1 to 4 mg., $\frac{1}{64}$ to $\frac{1}{16}$ gr., B.P. Maximum dose 0.01 Gm., $\frac{1}{6}$ gr.

(The limits of incompatibility with alkalies, iodides and bromides were investigated by Finnemore and Williamson, 1914).

Strych. Sulph., U.S.P.; $C_{21}H_{22}N_2O_2 \cdot H_2SO_4 \cdot 5H_2O$.—Sol. in water (1:35) and in alc. (1:81). Dose, etc., see "Strych. Nit."

Strych. Hydrochl., B.P.; $C_{21}H_{22}N_2O_2 \cdot HCl + 2H_2O$.—Sol. in water (1:60). Dose, etc. see "Strych. Nit."

Elix. Ferri. Quin. et Strychn. Phosph., N.F.—The dose (4 c.c., 1 drachm) contains (about): Strychnine, $1\frac{1}{3}$ mg., $\frac{1}{40}$ gr., Quinine, 45 mg., $\frac{3}{4}$ gr.; Ferric Phosphate, 90 mg., $1\frac{1}{2}$ gr.

Inject. Strych. Hyp., B.P.—0.75 per cent. Dose, 0.3 to 0.6 c.c., 5 to 10 minims, B.P.

Liq. Strych. Hydrochl., B.P.—1 per cent. Dose, 0.12 to 0.5 c.c., 2 to 8 minims, B.P.

Syr. Ferr. Phosph. c. Quin. et Strych., B.P. (Easton's Syrup).—Ferrous Phosphate, 1.7 per cent.; Quin. Sulph., 1.5 per cent.; Strych., 0.57 per cent. Dose, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

PICROTOXIN GROUP

General Statement.—The pharmacologic group of which picrotoxin is the main representative produces a conspicuous stimulation of the medullary centers, with characteristic convulsions, slowed pulse, etc. There is also some stimulation of the spinal cord. These effects are followed by paralysis. The actions are not utilized therapeutically, but are of some toxicologic as well as scientific interest, since the members of the group have often caused poisoning.

The Principal Members of the Group.—These comprise *picrotoxin* from *Cocculus indicus* (the seed of *Anamirta paniculata* ("Fish-berries;" used for poisoning fish, the flesh of which becomes toxic; also for adulterating beer; and in "knockout drops." The external use against pediculi has given rise to toxic effects); *Cicutoxin* from the rhizome *Cicula virosa* "Water Hemlock," an umbelliferous plant eaten by mistake for parsley, etc. (the American species, *Cicuta maculata* and *bulbifera*, are also toxic). *Cicutoxin* is a complex pyrone derivative, occurring as an unstable resinous substance (C. A. Jacobson, 1915). Some of the *decomposition products of digitalis* (digitaliresin, toxiresin) are also counted in this group.

Less important members are: *Coriamyrtin* (from *Coriaria myrtifolia*); and *Tutin* (from *Coriaria* species of New Zealand) (C. R. Marshall, 1910). W. W. Ford, 1910, found that tutin combines with nervous structures, thereby losing its toxicity; but no tolerance is acquired.

Chemical Nature.—Most of the substances are non-alkaloidal, non-nitrogenous "neutral principles," more soluble in alcohol than in water. Some are glucosides. *Picrotoxin* itself consists of a mixture (or perhaps a feeble combination; Sielisch, 1912) of nearly equal parts of picrotoxinin and picrotin (Cervello, 1911; structural formula, Angelico, 1912). These are closely allied chemically and have identical actions, but picrotoxinin acts far stronger. *Coriamyrtin* seems to vary. That first isolated by Riban was very soluble, while Merck's is almost insoluble, but probably more active (Marshall, 1912).

Picrotoxin Convulsions.—The characteristic effects on the frog, and the localization of the convulsions in the medulla, are described in the "Laboratory Guide." In mammals, also, the convulsions are not modified by destruction of the hemispheres (Gruenwald, 1909; Morita, 1915) or section below the optic thalami (Pollock and Holmes, 1915). Direct application to the cerebral motor cortex produces some stimulation. The white matter does not respond to direct application (Maxwell, 1906 and 1907). Spinal Tetanus may often be observed in frogs after the medulla is destroyed, the spinal stimulation having previously been masked by the more intense stimulation of the higher centers (Luchsinger, 1878). The convulsions are not so much dependent upon reflex stimulation, so that they are probably in part due to a direct stimulation. According to Baglioni, 1909, the action is located in the sensory cells. The muscle-creatine is not increased (O. Riesser, 1916).

Symptoms of Picrotoxin Poisoning in Mammals. The effects of convulsive but non-fatal doses were described by J. Crichton Brown, 1875, as: Salivation and vomiting

(central; Eggleston and Hatcher, 1915); then quiet and apathetic; then restless and apprehensive; then trembling of legs; lies on side, with efforts to stand; progressively stronger twitching of face and neck muscles; head drawn back. Then, suddenly, generalized clonic convulsions; clonic champing of jaws; closing of eyelids; marked frothing at mouth; involuntary urination; pupils dilated during the convulsions. The clonic spasms change imperceptibly to running movements, become slower, and finally cease. The animal remains quietly on its side, and then, after some efforts, regains the erect position. After a time, varying with the dose, the convulsions may recur.

With digitaliresin, toxiresin, and oleandresin, the convulsions are preceded by immobility.

Respiration.—This is stimulated before the convulsions; becomes irregular during the initial twitching and arrested during the clonic spasms (Pollock and Holmes, 1915). These authors point out the similarity of the respiratory, convulsive and circulatory changes with those of epileptic attacks (Pollak and Treadway, 1913). The threshold of the respiratory center to CO_2 is lowered by Coriamyrtin (Wieland, 1915).

Spasms of the laryngeal muscles lead, with the frog, to distention of the body with air and to a characteristic cry similar to that sometimes heard with strychnine.

Circulation.—In the early stages, the blood pressure may rise from stimulation of the vasomotor center. About three to eight seconds before the convulsions, the blood pressure falls, remaining low until asphyxia sets in (Pollock and Holmes, 1915).

Vagus Center.—The heart is greatly slowed, and may even cease for a time. After division of the vagi, the heart returns almost to normal. There is, however, some depression of the cardiac muscle involved in this slowing. Later there may be a quickening, partly due to stimulation of the accelerator center and partly to paralysis of the vagus center and to fatigue of its endings.

The vomiting, salivary, and sweating centers are also excited. The sweat may, however, be suppressed by vasomotor constriction. Direct application of picrotoxin to the floor of the fourth ventricle produces vomiting (Hatcher and Weiss, 1923).

Autonomic Centers.—Gruenwald, 1909, pointed out that picrotoxin produces the symptoms of parasympathetic stimulation: Contraction of pupils, salivation, vomiting, slowed pulse, contraction of urinary bladder, erection, etc. These effects are central, for they do not occur after section of the nerves. They are not hindered by decerebration.

Vago-gastric Centers.—In turtles, the injection of picrotoxin produces powerful tetanic contraction of the stomach. This does not occur if the vagi have been divided (F. T. Rogers, 1918).

Uterine Spasms.—These have been observed, and depend probably on stimulation of the spinal cord, since they cease upon destruction of this organ.

Paralysis.—With larger doses, all the stimulant effects give way to paralysis.

Hemolytic Action.—Picrotoxin, cicutoxin, and phytolacca decandra are said to act similarly to saponin.

Excretion.—This occurs by the urine; picrotin is partly unchanged; the picrotoxinin is decomposed (Chistoni, 1912).

Toxic Dose.—According to Lewin, 0.03 to 0.24 Gm. of cocculus is toxic, 2.4 Gm. fatal. Of picrotoxin, 20 mg. are toxic. The fatal dose is not known.

The Symptoms of Poisoning in Man.—These consist in burning sensation, nausea, salivation, cold sweat, pallor, colic, vomiting, diarrhea; pulse slowed or quickened; palpitation; shallow respiration. These are rapidly followed by confusion, stupor and unconsciousness. After one-half to three hours, trembling, clonic and tonic convulsions. These generally pass into paralysis and death by asphyxia, after several hours.

The postmortem findings are those of asphyxia. The poison disappears rapidly during putrefaction (within one or two weeks); so that the toxicologic analysis must be made promptly. The characteristic effect of the isolated poison on the frog constitutes the best test. The intensely bitter taste (discernible in dilutions of 1:80,000) may arouse suspicion.

Treatment.—The chemic alkaloidal precipitants would not be efficient. The best treatment would be emetics (if vomiting has not occurred), permanganate, chloral, chloroform, and external heat. The combined administration of chloral, morphine, and minimal doses of atropine has been recommended as the result of animal experiments.

Therapeutic Uses.—The medullary stimulation produced by the group might be expected to have many therapeutic uses; in fact, however, they have not been found available, perhaps because the effective doses are too near to the toxic. Picrotoxin (0.5 to 2 mg.) has been used in the night sweats of phthisis, and in epilepsy, but with very doubtful results.

Solubility.—Picrotoxin is soluble in about 8 parts of alcohol, or 240 parts of water.

Cocculus Indicus.—The ointment (2 per cent.) and Tincture (full strength) are sometimes used against pediculi. This use is dangerous. They should never be applied to abraded skin.

CAFFEINE, THEOBROMINE, AND OTHER METHYL-XANTHINES

Members.—This group comprises the various methyl derivatives of xanthine (dioxypurine). These occur in several plants; as products of metabolism in animals; and may also be obtained synthetically. The most important are *caffeine* (trimethylxanthine), the principal alkaloid of coffee, tea, kola, guarana, maté, etc.; *theobromine* (3,7 dimethylxanthine) from cacao; and *theophylline* (1,3 dimethylxanthine), which is usually prepared synthetically. Xanthine itself, and all its other methyl derivatives, produce the principal actions of the group.

Nature of Caffeine.—Caffeine is capable of forming salts, and is, therefore, an alkaloid, but it is so feeble a base that it does not turn litmus, and the salts are dissociated by water. Its solubility is also peculiar. It was isolated from coffee in 1820 by Runge, Pelletier and Caventou, and Robiquet. Its identity with the alkaloid of tea (sometimes called *Theine*) was surmised by Berzelius, and confirmed by Jobst and Mulder in 1838. Commercial caffeine is now produced almost exclusively from tea.

Occurrence.—Caffeine occurs in plants of at least six families, which are scattered over many portions of the globe. It is rather remarkable that these plants have nearly all been discovered and consumed by the natives as stimulants. The plants often contain volatile products or tannin, which slightly modify their effects. Theobromine is often associated with the caffeine; in cacao, the theobromine predominates.

The chemical structure and derivation of the purine derivatives have been elucidated by Emil Fischer. The most important are as follows:

Principal Actions.—1. Increase of the reflex irritability of the central nervous system from above downward; leading to stimulation of the psychic areas (insomnia, etc.); of the medullary centers (respiratory, vaso-motor and vagus); and with large doses to heightened reflexes and tetanic convulsions. With toxic doses, the stimulation is accompanied by paralysis.

2. Increased ease of muscular contraction, progressing to loss of elasticity and to rigor; this affects all forms of muscle to a varying degree. The heart rate is thereby quickened.

3. Vasodilation by a direct action on the vessels, with moderate doses; this combines with the cardiac stimulation to quicken the circulation.

4. Diuresis results through the interaction of several factors.

Caffeine is used as a psychic, muscular and respiratory stimulant; and as a cardiac tonic and diuretic. Theobromine and theophylline are probably more effective when the peripheral actions are desired.

Psychic Functions.—In man, moderate doses of caffeine (to 0.3 Gm.) produce a quicker and clearer flow of thought; disappearance of drowsiness and fatigue; more sustained intellectual effort; more efficient appreciation of sensory impressions, and more perfect association of ideas (Kraepelin, 1872; Dietl and Vintschgau, 1878; Ach, 1900; Hollingsworth, 1912). The central actions of theobromine are relatively much weaker than those of caffeine (Filehne, 1886). Theophylline is intermediate (Dreser, Pouchet, Thomas).

With larger doses, these effects pass into wakefulness, excitement, and the other unpleasant reactions described under the toxicology.

The lower mammals react by restlessness and excitement. The cat is said often to become frantic. Frogs do not exhibit any symptoms referable to the brain.

Motor and Mental Efficiency.—Hollingsworth, 1912, conducted a series of tests on normal human subjects, which led to the following conclusions: *Motor speed* (tapping) is increased by small and large doses (0.06 and 0.39 Gm. of pure caffeine, respectively). With the more complicated typewriting, speed is also increased by the small dose, but retarded by the large. Errors in typewriting are fewer with all doses. *Association tests* (naming colors or opposites; calculations) are speeded by all doses. *Choice* (cancellations, etc.), seems retarded by small, and stimulated by large doses. *Unsteadiness* (tremors) of the muscles is a frequent result. None of the stimulant effects are followed by depression.

The effects start in 1 to 3 hours after oral administration, and last from 2 to over 7 hours; the mental effects being more persistent than the purely motor.

Caffeine as Analeptic.—W. W. Duke, 1923, recommends the *intravenous* injection of 2 grains of caffeine sodium benzoate, to arouse moribund patients from the collapse of pneumonia, etc.; consciousness is restored, even when other analeptics fail; but the effect is rarely more than temporary.

Use as Antidote in Narcotic Poisoning.—Caffeine is used as an antidote against acute poisoning by morphine (Bennett, 1874); alcohol (Binz, 1878); paraldehyde (Schroeder, 1887); chloral (Airila, 1913; Sollmann). The psychical actions are directly antagonistic, the mental and muscular coordination being immediately improved, although the effect is not lasting. The respiration (Voegtlin & Wiggers, 1918) and circulation may also be somewhat stimulated, but the effects easily become additive, so that with fatal alcohol poisoning, caffeine is actually deleterious. With morphine, the conditions are probably more favorable.

As a stimulant antidote, the caffeine is usually administered as very strong, hot, black coffee, to secure the synergistic stimulant action of the heat and oils. Strongly boiled tea, through its tannin, would be a chemical antidote in poisoning by corrosive metals. Coffee has not this precipitant effect.

Mutual Antagonism of Alcohol and Caffeine.—This has been studied especially by Pilcher, 1912. He found that with the *smaller doses*, each drug tends to act qualitatively as if present alone. In alcohol sleep, small doses of caffeine cause awakening, restore the reflexes, and diminish the fall of temperature. With *larger doses*, there is a qualitative change in the direction of greater depression. Light alcohol coma is intensified by moderate or large doses of caffeine; the reflexes are further depressed. With *toxic doses*, the fatality is greatly increased if both drugs are present, mainly by their deleterious action on the heart.

Medullary Centers.—These are moderately stimulated by caffeine, similarly to strychnine. There are, however, some important differences:

With caffeine the stimulation is on the whole weaker for toxic doses, but rather stronger and much more prolonged with therapeutic doses; and there is little or no subsequent depression, even with toxic doses. The most conspicuous effect is on the respiration. The stimulation of the vasomotor and vagus centers is interfered with by other factors, as described under "Circulation."

Respiration.—In man, the respiration is only moderately increased (Edsall and Means, 1914), or scarcely affected by oral therapeutic doses (Newburgh, 1914; Taylor, 1914); unless cardiac dyspnea is improved by the circulatory effect. With hypodermic injection of 0.15 to 0.25 Gm., there is definite evidence of respiratory stimulation.

The CO₂ tension is markedly lowered. The rate and depth of the respiration, and the minute-volume are increased. There is also increased gas metabolism, and sometimes bronchial dilation (Higgins and Means, 1915).

The respiratory response to CO₂ was not significantly altered by small or large doses, in normal human subjects (Grabfield and Means, 1917).

Anesthetized animals respond by increased rate (Binz, 1878; and generally also increased depth of the respiration (Heinz, 1890; Impens, 1890). The latter is probably due to partial awakening from the anesthesia; for with decerebrated animals, the increase is confined to the rate, the depth being unchanged or more shallow (Cushny, 1913). Inhibitory reflexes are less effective.

The respiration of unanesthetized rabbits may be depressed by the hypodermic injection of moderate doses, 10 mg. per Kg. (Hanzlik, 1923).

Subdural Injection.—Breslau-Schutz, 1921, claims very useful therapeutic response from injection in the region of the medulla.

Use in Asthma.—Coffee sometimes gives relief in asthmatic attacks. The action is probably partly psychic, partly bronchial; for in guinea pigs, it relaxes the bronchial spasm produced by peptone or muscarine (Pal, 1912). Bronchial dilation is also sometimes observed in man (Higgins and Means, 1915). F. Meyer, 1915, concludes that caffeine acts mainly by stimulating the respiratory center to greater effort. He considers it less efficient than atropine, epinephrine or nicotine.

Respiratory Paralysis by Cerebral Compression.—In this condition, caffeine was a less effective stimulant than strychnine or especially cyanide (Loevenhart *et al.*, 1918).

Spinal Cord.—Ordinary doses of caffeine heighten the reflexes (Wood, 1912; Lecuwen, 1913). Toxic doses produce convulsions of spinal origin (Bing, 1901), which agree in all essential respects with those of strychnine, except that the tetanus is neither as violent nor as prolonged. The exhaustion in the intervals is also less pronounced. The tetanus may produce death by fixation of the respiratory muscles. The convulsant dose is relatively large, and it is therefore doubtful whether it has ever been observed in man. Ordinary toxic doses produce only tremor. In frogs, the tetanus is not increased or hastened by removal of the cerebrum (difference from morphine; Githens, 1914).

The *paralytic action* of large doses can be shown in frogs by protecting the muscles from rigor; *i.e.*, by ligating a leg exclusive of the nerve. Caffeine will then destroy its reflexes.

Skeletal Muscle.—Ordinary doses of caffeine increase the functional activity of skeletal muscle so that it contracts more readily and more completely and powerfully, and is less easily fatigued (Wood, 1912). This improvement can be demonstrated by the ergograph, as well as in the excised or curarized frogs' muscle. It is, therefore, at least in large part, peripheral.

Larger doses produce spontaneous contracture, culminating in rigor, even in the living animal. Before this final stage is reached, the response to artificial stimulation becomes progressively smaller. The caffeine contracture appears to involve the same mechanism as the normal contraction of muscle.

The Stimulant Phase.—A smaller stimulus suffices to produce contraction (Paschkis and Fal, 1886). The latent period is shortened. The height and rapidity of the con-

traction are greater, and a larger weight can be lifted (Kobert, 1881). Fatigue is lessened, and a greater amount of work can be performed (Dreser, 1890), so long as the load and stimulation are optimal; but with excessive load or stimulation, caffeine diminishes the total work (Golowsky, 1915). The other methyl-xanthines affect muscle qualitatively like caffeine (Golowsky).

The Depressant Phase.—As the dose or concentration is increased, these effects are reversed. The contraction becomes less powerful, and the curve resembles that of a fatigued muscle; *i.e.*, it is lower and more drawn out. This lengthening shows first in the relaxation (Buchheim and Eisenmenger; Golowsky), eventually also in the contraction. The elasticity is lessened. The muscle is exhausted more rapidly by tetanus.

Similar muscular effects are produced by xanthine (Paschkis) and creatine (Dreser).

Resemblance to Fatigue.—The successive increase and diminution of the muscular functions by caffeine resembles the successive phenomena of work and fatigue; and suggests that a part of these may be due to the accumulation of the xanthine products which are formed in metabolism; but fatigue is the resultant of a number of factors, especially of the accumulation of lactic acid (Lee, 1906). Weichardt, 1904, had claimed the existence of a special fatigue toxin ("Kenotoxin") in the juice of fatigued muscle; but Lee and Aronovitch, 1924, showed that the juice of unfatigued muscle produces the same effects, and that these are due partly to the lactic acid.

Caffeine Rigor.—This was observed by Voit, 1866, and then investigated by Johannsen, and by Schmiedeberg, 1872. Its occurrence in the living body can be demonstrated by hypodermic injection in certain species of frog (the European *Rana temporaria*, and the ordinary American laboratory frog, *R. pipiens*); while another European frog (*R. esculenta*) is less susceptible to the rigor, and therefore succumbs to spinal convulsions. In both cases, the frog becomes rigidly extended; but the rigor (as distinguished from tetanus) persists after division of the sciatic nerve (Johannsen) and occurs after curare. The heart may continue to beat strongly for some time. Mammals also show some stiffness after large doses of caffeine, but actually rigor results only if the alkaloid is injected directly into an artery. The coagulant action is possessed by other xanthines, being strongest with xanthine itself, and progressively weaker with theobromine, theophylline and caffeine (Filehne, 1886; Dreser).

The muscle in caffeine rigor is inexcitable and appears white, bloodless, stiff and considerably swollen and shortened, and is acid to litmus (Ransom, 1911).

Microscopic Changes.—If the caffeine is applied to a teased muscle under the microscope, the contents of the fiber are seen to move; the cross-striations disappear, and the longitudinal striae become more prominent. The sarcolemma becomes detached. The fibers shorten by half (Johannsen).

These changes have been studied by Secher, 1914, through perfusion with dilute solutions of xanthine and the various methyl-xanthines, which all produce similar effects. The histologic changes increase with the concentration, to disorganization (caffeine, 1:2,000). Short of disorganization, the changes are reversible. The disorganized fibers also eventually regenerate, provided their nuclei are intact. Hardening and true rigor is confined to the destroyed fibers. Similar changes are produced by chloroform and other poisons, and in other vertebrates, although mammals require higher concentrations.

Perfusion of the muscle with saline or blood, if undertaken soon after the onset of the rigor, restores the plasticity but not the excitability (v. Fürth).

Nature of Caffeine Contracture.—The spontaneous progressive contraction of muscle by caffeine is associated with the production of lactic acid (Ransom, 1911); a large consumption of oxygen (Meyerhof, 1921), and the production of heat; the total with heat production corresponding closely with that of exhaustion by artificial stimulation (Hartree and Hill, 1924). From this it would appear that the caffeine contracture involves the same mechanism as ordinary muscular contraction; *i.e.*, the non-oxidative conversion of glycogen into lactic acid; and the reconversion of lactic acid into glycogen with the loss of a fifth through oxidation. In normal contraction, the two processes occur abruptly and in succession; in caffeine contracture they take place continuously and side by side.

Theory of Caffeine Action.—E. Frey, 1923, conceived the effects of caffeine, veratrine, and a number of other stimulants to consist in a delay of the disposal of the acid; which would make the contractions higher and more persistent.

Coagulation of Muscle Extracts.—Rigor may also be produced in living animals by the injection of a number of other substances in sufficient concentration; for instance, by chloroform. All of these, as well as caffeine, favor the coagulation of muscle extracts (v. Fürth, 1896). However, there need not be any relation between rigor and this coagulation; for certain substances coagulate muscle extracts even more actively, but are incapable of producing rigor during life.

Muscular Effects in Man.—Morse showed by the *ergograph* that moderate doses of caffeine (0.1 to 0.6 Gm.) increase the muscular work. In the first hour this may be raised four or five times; the effect then lessened, but extended over two to seven hours. Practically all subsequent experimenters have confirmed the increase, although it was not always as great (Hellesen, 1904). Sometimes the increase was mainly in the height of contraction (Kraepelin); with others, in the number (Rossi). This indicates that the action is both on the muscle substance (height) and on the motor centers (fatigue). Rivers and Weber, 1907, found it quite variable, and sometimes followed by a decrease. Schumburg showed that the effect is less when the experiment is made fasting on an exhausted muscle. Hyde, Root and Curl, 1917, in fasting subjects, found considerable increase of muscle power and endurance after 0.09 to 0.15 Gm.; but marked depression after 0.23 Gm. (by mouth, as beverage). The increase of efficiency is due partly to a lesser feeling of fatigue (Rivers and Weber), but it is at least in part peripheral since the efficiency is also increased when the muscle itself is stimulated electrically.

Creatine.—Caffeine increases the creatine content of the muscles, even after curare (Riesser, 1916. He attributes the effect to increase of the sympathetic muscular tone).

Use of Caffeine against Fatigue.—The psychic and muscular actions of caffeine are popularly used against fatigue. This will be discussed under the "Caffeine Beverages."

Use in Headache.—Fairly large doses of caffeine (0.5 Gm. = $7\frac{1}{2}$ grains) are rather effective against certain forms of headache, such as migraine, neuralgia, fatigue, etc. It may be combined with acetanilide. It does not prevent the depressant effects of the latter; but rather increases its toxicity (Hale, 1909; Salant, 1912); it also increases the toxicity of alcohol and barium chloride by its circulatory action. Caffeine is useful in some cases of *nervous dyspepsia*.

Smooth Muscle.—The effect of caffeine on smooth muscle consists in a longer and more persistent contraction curve. Larger doses prolong the period of relaxation. The tone seems to be affected differently in various muscles. The arteries are relaxed by relatively small doses; whereas the caffeine has a tonic effect on the pelvic portion of the ureter (Lucas, 1907). It has very little effect on the uterus (Röhrig):

Intestines.—Caffeine has little or no effect on normal peristalsis (Nasse, 1866); but direct contact with *excised intestine* modifies the functions. Salant and Schwartz, 1916, state that the contractions are stimulated by dilute solutions (Caffeine, 1:10,000; theobromine, 1:25,000; theophylline, 1:50,000). Higher concentrations (1:2,000) produce marked depression of the rhythm and tonus.

Sympathetic System.—Fredericq and Me'lon, 1922, found that caffeine, theobromine and theophylline destroy the response of the heart to accelerator stimulation. They attribute this to paralysis of the accelerator endings; but as the heart muscle had already been very considerably quickened by the caffeine, it would naturally be practically incapable of further acceleration. They also point out the *mutual antagonism between caffeine and epinephrine* in the arteries and intestines; *i.e.*, after epinephrine, caffeine dilates arteries and contracts the intestinal muscle.

Subdural Injection.—Breslauer-Schutz claims very useful therapeutic response from injection in the region of the medulla.

Other Peripheral Actions.—Caffeine has no action on peripheral nervous structures when it is used systemically (Aubert, 1872); nor does it cause any local irritation.

It has a paralyzing action only when it is applied in a very strong paste directly to the nerve (Pratt). It does not act on any *ganglia*, nor on any *glands* other than the kidney; nor on red corpuscles, nor on fibrin formation. Small doses increase the movements of leucocytes in shed blood, whilst higher concentrations kill them. Arkin, 1913, found *phagocytosis* unaffected, *in vitro*.

Lower Organisms.—The actions of caffeine on these are not characteristic (Brunton, 1882: oxidation of guaiac; Haskins, 1903: gas formation by yeast; Bokorny, 1894, and Korentschewsky, 1903: amebae; Romanes, 1807: medusae; Sollmann, 1906: adult and embryonic fish; Pickering, 1893: embryonic chick's heart; Ransom, 1911: germination of seeds).

Metabolism.—The results of different investigators have been contradictory, but it appears that caffeine causes a rather small and variable increase in urea and CO_2 . Both effects are probably indirect; the urea being explained by the diuresis, the CO_2 by the increased movements. This also explains the slight rise of temperature.

Basal Metabolism.—Means, Aub and Du Bois, 1917, find constantly in man increase (7 to 23 per cent.), of *basal metabolism* from doses of 0.5 to 0.65 Gm.; the maximum occurring in 1 to 3 hours. The respiratory quotient was not changed. The elimination of water from the lungs and skin was increased. The *total nitrogen* of the urine was also increased by 6 to 37 per cent. The *pulse-rate* showed no significant changes.

Smaller doses do not influence basal metabolism (Boothby and Rowntree, 1923).

The earlier investigators claimed diminished urea excretions (J. Lehmann, 1853; Böcker, 1854, and others), with varying results as to CO_2 . The earlier work has not been confirmed, and may possibly be explained by imperfect methods. (However, Farr and Welker, 1912, describe decreased *N* elimination after theophylline in health and renal disease; whilst Endilyi claims an increase of *N* after theophylline or theobromine. The contradictions probably depend on differences of diuresis.) C. J. Lehmann, Voit, Roux and others have demonstrated increased urea excretion after caffeine; Reichert, increased heat production; Heerlein, 1892; Edsall and Means, 1914; and Higgins and Means, 1915, found increased CO_2 and O_2 metabolism, with therapeutic doses. Salant and Phelps, 1910, and Salant and Rieger, 1914, found slight changes in the excretion of creatine and creatinine.

Blood-nitrogen.—Laufberger, 1923, reports increased creatine, creatinine, and calcium; no increase of uric acid or residual nitrogen. The creatine change occurs too rapidly to be muscular or renal action. It may perhaps be connected with the stimulation of the glycosuric center.

Temperature.—The rise was demonstrated by Binz and Peretti, 1878. It is very slight in normal animals (1° to 1.5°C). It is perhaps rather more effective in preventing the fall of temperature which occurs in light narcosis, but is ineffective in deep narcosis (Pilcher, 1912). The rise is much greater in thyroidectomized dogs (Karelkin, 1914).

Glycosuria.—During the caffeine or theobromine diuresis, there is commonly a slight hyperglycemia and glycosuria, especially in rabbits fed on carbohydrate food. However, it occurs also in fasting animals (E. Hirsch, 1915). It may be induced by oral administration, also in cats, but not in dogs (Salant and Knight, 1909). The phenomenon, which occurs also with other diuretics, has not received a satisfactory explanation (Miculicich, 1912). It is not renal, for sugar appears in the urine only when there is a considerable rise of blood sugar (Hirsch). The hyperglycemia indicates increased glycogenolysis, which resembles that produced by *piqûre* (Nishi, 1909). Like this, it is generally (but not always; Jarisch, 1914) prevented by section of the splanchnics, excision of the suprarenals (A. Mayer, 1906) and by nicotine (Hirayama, 1911). It must therefore be usually central, perhaps through increased reflex irritability; but under certain conditions it is also peripheral (Jarisch).

Digestion.—The effects will be discussed under the beverages.

Circulation.—Caffeine acts on the heart and blood vessels, peripherally and centrally. The effects are therefore complex and vary with the dose and other conditions. The predominant action of therapeutic and moderate physiologic doses consists in vasodilation, combined with sufficient cardiac stimulation to maintain the blood pressure, or even to raise it somewhat. Both actions should combine to favor the blood flow, and would therefore be useful in circulatory diseases; the diuretic action being a further desirable feature. On the other hand, the effects of caffeine are not so powerful nor so lasting as those of digitalis; and its side actions often interfere with its use. The other methyl-xanthines act very similarly to caffeine, and the same description probably applies to all.

Theobromine is more powerful than caffeine, and theophylline is still more active

Stages of Action.—The effects in animals may be divided into the immediate effects of intravenous injection, the more persistent effects of moderate (stimulant) doses; of larger depressant doses; and fatalities (Sollmann and Pilcher, 1911; Wood, 1912; Salant, 1913; Pilcher, 1912).

Intravenous Injection of Caffeine.—This produces a fairly severe fall of blood pressure, with prompt recovery. The *acute fall of pressure* is presumably due to depression of the myocardium by the concentrated drug. It does not occur with other methods of administration, and therefore has little practical importance. It is not characteristic for caffeine, but occurs with many other drugs. The organ volume (oncometer) falls with the pressure (indicating that the action is cardiac). Direct observation of the heart shows dilation with diminished excursions. The heart rate is quickened and the vasomotor and respiratory center are stimulated by the low pressure.

Stimulant Doses.—Small and moderate doses (to 20 mg. per kilogram) generally produce a slight (10 to 26 mm.) rise of blood pressure, usually with more or less increase of the heart rate. The tone of the heart is increased and the amplitude of its excursions may be greater. This, and the faster rate, raise the output of the heart. The vein pressure is not changed (Capps and Matthews, 1913). The blood flow is increased (Landgren and Tigersted, 1892; Loewi, 1905). The volume of the splanchnic organs (Phillips and Bradford, 1887; Albanese, 1881; Gottlieb and Magnus, 1901; Loewi, 1905) and of the cerebrum (Roy and Sherrington, 1887) increases. This oncometric change is more marked and more persistent than that of the blood pressure, and therefore indicates a marked vasodilation. It has been claimed that the dilation is more powerful in the kidney than in other organs (Phillips and Bradford; Loewi); but in fact it seems to be about equal, at least in the splanchnic area (Sollmann and Pilcher). The vasodilation is peripheral, since the perfusion method shows that the vasomotor center is actually stimulated. Ordinarily, the peripheral dilation is more powerful than the central constriction; but under some conditions the constriction may predominate, so that the oncometer falls with the rising pressure. This, however, is very exceptional. The older conception of a powerful and constant constriction was based on slender and indirect evidence (mainly on the experiments of Wagner, 1885, and Schroeder, 1886). Vinci, 1895, found that caffeine gave a much larger rise of blood pressure (presumably cardiac) in animals which had been weakened by anemia or starvation.

Depressant Doses.—Doses of caffeine above 40 mg. per kilogram progressively lower the blood pressure, until a level of 60 to 85 mm. is reached, with doses of about 140 mg. per kilogram. This level is then maintained until death approaches. If the original pressure was low, it may not be further lowered. The tone of the heart is decreased, so that it gradually dilates, and the amplitude of the excursions and the output are diminished. The oncometer falls with the blood pressure, so that cardiac depression is the dominant element. It is accompanied, however, by a progressive and finally complete vasomotor paralysis, when epinephrine, splanchnic, and other forms of vasomotor stimulation become less and less effective. (Epinephrine still causes a relatively small rise through cardiac stimulation.) The vasomotor center can be shown (by the perfusion method) to be stimulated even after very large doses; but this stimulation can not become effective against the peripheral paralysis.

Fatal Doses.—Death occurs by acute cardiac failure. Caffeine serves to lower the resistance of the heart, so that the fatal dose may vary greatly in different animals.

Factors Involved in the Circulatory Actions of Caffeine.—These may be summarized as follows: Cardiac stimulation or depression, according to the dose and rapidity of injection.

Increased heart rate, not due to vagus depression. If the vagus is intact, there may be slowing through central stimulation, but with large doses the heart escapes from the vagus tone.

Vasodilation, through peripheral depression of the vasoconstrictor mechanism.

Central vasoconstrictor stimulation generally ineffectual; also convulsive stimulation.

Cardiac irregularities, with large doses.

Direct Action on Blood Vessels.—These tend to dilate when excised organs are perfused with caffeine (Beco and Plumier; Cow, 1911). The effect is not very great with caffeine alone, since the vessels are already dilated after death; but very little caffeine

suffices to counteract the constrictor effect of epinephrine (Sollmann and Pilcher). The caffeine must therefore act on or beyond the structure stimulated by epinephrine; *i.e.*, on the receptive or muscle substance.

Special Vessels.—The *coronary flow* is very considerably increased, in perfused hearts (Heathcote, 1920; bibliography), as well as intact animals; and this is aided, in the latter, by passive stretching of the vessels if the blood pressure rises (F. Meyer, 1912). Toxic doses generally dilate (Sakai and Saneyoshi, 1915; Macht, 1915). The *Lung Vessels* are first constricted, soon ceding to dilation (Berezin, 1914). Macht, 1914, observed dilation of excised pulmonary artery. Theobromine was practically negative. Baehr and Pick, 1913, found no effect with caffeine on long perfusion. The *Liver veins* are dilated (Berezin, 1914). The vessels of the *pia mater* and *retina* are dilated during life (Hirschfelder, 1915). The dilation of the eye-vessels may raise the intra-ocular tension even with falling systemic blood pressure (Wessely, 1915).

However, Raphael and Stanton found no changes in the human *brain volume* (plethysmograph) after intravenous injection of 0.25 Gm. of (absolute) caffeine.

The Heart Rate.—When the vagi are intact, small doses of caffeine may cause some slowing through stimulation of the vagus center (Swirski, 1904) and increased vagus excitability (Fredericq, 1913). This slowing does not occur in all animals. With larger doses, or always if the vagi are paralyzed, the rate is markedly quickened. With the vagi divided, 2 mg. per kilogram increases the rate by 25 per cent.; 20 mg. per kilogram by 33 per cent.; 30 to 100 mg. by 50 per cent. Beyond this there is no further increase, but the heart shows *arrhythmia* and *irregularity*.

The increased rate is not due to vagus paralysis, and accelerator stimulation occurs only after large doses. It is therefore attributed to increased contractility of the muscle substance itself, especially in the region that sets the pace. The quickening is evidently not due to *vagus* depression, since it occurs after section of the vagi or atropine (Johannsen, 1869, and others). The vagus tone is indeed lost after large doses (Aubert, 1872, and others), and the response to vagus stimulation is uncertain; but direct central vagus stimulation may still cause marked slowing.

Nor is the quickening due to stimulation of the *accelerator mechanism*. The effect occurs after excision of the stellate ganglia and in the excised mammalian heart. Swirski, 1904, found that when the caffeine quickening had reached its maximum, a further increase would be obtained by stimulating the accelerator. (Large doses destroy the response to accelerator stimulation, Fredericq, 1913). Cushny showed that the details of the cardiac curve are different in caffeine and accelerator stimulation. Dixon, 1903, found that caffeine quickens the heart after apocodeine, which paralyzes the accelerator endings. Pickering, 1893, observed it in the embryonic chick's heart before the nervous structures had become developed.

Frog's Heart.—Small doses increase the rate (Voit, 1860), excursions (Wagner, 1885), pulse volume, and especially the absolute force or maximal resistance (Dreser, 1887). The diastole is shortened more than the systole.

Large doses cause slowing and weakening (Maki), with diastolic tendency (Faval). The heart beats for some time after the skeletal muscles are in rigor (Wagner). The final arrest may be either in systole (Johannsen, 1869) or diastole (Faval).

With hypodermic injection, the stimulant dose is 5 mg.; the depressant 25 mg. (Wagner). Dropped on the exposed heart, 1:10,000 is stimulant, and 1:100 depressant (Sollmann).

The terrapin's heart responds similarly to the frog's (Beyer, 1885).

Perfusion of the medulla in turtles with 0.04 per cent. of caffeine has practically no effect on the heart rate, in contrast with strychnine (A. D. Bush, 1919).

Excised Mammalian Heart.—When studied by modifications of the Langendorff method, caffeine and the other xanthines produce increased rate, amplitude, and force of the cardiac contraction, and generally quickened coronary flow (Hedbom, 1899; O. Loeb, 1904; Beco and Plumier, 1906; Lifschitz, 1907; Plavec, 1909). The increased amplitude is first in the systole, then also in the diastole; but the cardiac tone is not increased (Plavec). The stimulation is greatest with theophylline, then theobromine, then caffeine. The coronary vasodilation is also greatest with theophylline.

For the perfusion of rabbit's hearts, the effective concentration of caffeine is 1:10,000; of theobromine 1:30,000; of theophylline, 1:20,000.

These experiments seem to refer only to stimulant concentrations, and they may be considerably modified by changing the conditions (Lifschitz, 1907; Plavec, 1909; Bock, 1900).

Electrocardiograms from the excised mammalian heart show that whilst the three principal methyl xanthines agree in quickening the rate, they differ in their effects on conduction. This is depressed by theobromine, increased by caffeine and theophylline (Sakai, 1919).

Mammalian Heart in Situ.—The effects of the various doses were studied by Pilcher, 1912, with the results described under the general discussion of the circulatory effects.

Experimental Heart-block.—In complete block, caffeine increases the strength of the ventricular contraction. Larger doses produce ventricular extrasystoles and tachycardia. The strength of the auricles is temporarily quickened (Egmond, 1913).

Circulatory Effects in Man.—These correspond with what would be expected from animal experiments. With doses to 1.5 Gm., the acute effects are inconstant and generally slight. The heart rate may be slowed or quickened or unchanged (literature, Sollmann and Pilcher; Wood, 1912). Palpitation is common, but apparently largely subjective. The blood pressure may rise (Wood, 1913); or fall (Mirano, 1906); or remain unchanged (Lucas, 1914; Newburgh, 1914). The volume of the human arm is diminished (Hewlett, 1913). The blood flow tends to improve by increased systolic output.

Human Blood Flow.—Hypodermic doses of 0.3 to 0.5 Gm. in resting men, produce a definite increase of the total blood flow (Krogh-Lindhard method). The improvement occurs by increased systolic output. It does not occur during work. Means and Newburgh, 1915, attribute the rest effect to increased venous return to the heart, by some action outside of the heart. During work, the venous return is adequate even without caffeine, and is not materially increased by the drug.

Blood Pressure.—In advanced *myocarditis*, full and continued doses of caffeine (about 1 Gm. per day) cause a progressive and permanent lowering of blood pressure, reaching a total of 10 to 50 mm. This is parallel to the diuresis, and to the relief of the edema and other symptoms (L. Taylor, 1914). Theobromine does not lower the pressure, although it is otherwise equally or more efficient.

Therapeutic Effects on Circulation.—The methyl-xanthines are used as cardiac stimulants in syncope, and especially in cardiac dropsies. They lack the permanent, tonic action of digitalis, but are useful as adjuvants or when a quick effect is desired. In Taylor's *myocarditis* series, the results were excellent in one-half, moderate in one-fourth, and unsuccessful in one-fifth. Theobromine is effective on the first day, if at all, so that its usefulness can be determined more quickly than with caffeine. Furthermore, the side actions of caffeine interfere with its employment, especially in excitable patients. Theobromine therefore deserves preference.

The dilation of the coronary vessels may be concerned in the use of theobromine in angina pectoris, for which it has been employed by Ask-anazy and by Brener (Heathcote).

In hypotension and infectious diseases, caffeine fails to improve the circulation (Newburgh, 1914; Lucas, 1914).

Clinical Side Actions.—Effective doses of caffeine, especially in cardiac cases, produce palpitation, insomnia, nausea, vomiting, headache, vertigo, restlessness, anxiety and sometimes delirium. Theobromine is relatively free from these objections, but they may arise (Seifert, *Nebenwirkungen*, 1915, p. 128). They are also produced by theophylline (Widmer, 1914; Seifert, l.c., p. 131). The side actions occur much more violently, and with much smaller doses (0.3 Gm. of caffeine per day, or even less) in patients with *interstitial nephritis* (L. Taylor).

Effects on the Urine.—The most important therapeutic effect of caffeine consists in a considerable diuresis. The increase concerns mainly the water of the urine. The absolute quantity of all urinary solids is also

increased, but less than the water, so that their percentage is lowered. The efficiency varies with conditions, especially with the amount of water in the body (Widmer, 1914); the diuresis is most abundant in dropsical conditions, and fails entirely with dry food. It is much greater in man and in wet-fed rabbits than in dogs. Cats practically do not respond. It fails also in glomerular nephritis, but is effective in tubular nephritis unless the vessels are involved. The albumin in nephritis may be increased. Theobromine and especially theophylline are more effective. This difference is explained in part by the relatively larger doses which can be taken without prohibitive side actions.

The Mechanism of Caffeine Diuresis.—*The Circulatory Factor.*—The blood flow and the filtration pressure in the renal vessels is improved by the caffeine group, through increased output of the heart and dilation of the renal arterioles; and this would be an adequate explanation of increased urine flow. It is presumably a very important factor in the diuretic action of the group.

Renal Circulation.—The scientific investigation of the diuretic action of the methyl xanthines started essentially with von Schroeder in 1886 and 1887. He found that the increased urine flow is not conditioned on increase of the general blood pressure; and therefore concluded that it could not be due to increased "filtration," in the sense of the Ludwig theory; which he conceived to demand increased blood-pressure. He therefore assumed that caffeine must directly stimulate the "vital" secretory function of the renal epithelium, according to the Heidenhain theory. The fundamental error of von Schroeder consisted in the assumption that the general blood pressure is an index of the filtration pressure in the glomeruli, without considering the probability of vasomotor adjustments within the kidney, or of an altered balance between general vascular tone and cardiac output. These conditions would be reflected in the kidney volume, much more closely than in the general blood pressure; and in fact, Phillips and Bradford, 1887, and others since then, observed that the caffeine diuresis is paralleled fairly closely by increase of the kidney volume, although the agreement is not absolute. Increased kidney volume must necessarily mean increased filtration pressure, unless it is due to contraction of the veins; the latter was excluded by the observation of Loewi, 1905, that caffeine increases the renal blood flow. Sollmann and Pilcher, 1911, showed that caffeine produces a very considerable dilation of the renal vessels if these have been previously constricted, by epinephrine, whilst at the same time the output of the heart is increased. Richards and Schmidt have also shown marked dilation and increase in the functioning glomeruli by direct microscopic observation in the frog.

There was thus considerable evidence that caffeine produces changes in the circulation that would tend to increase filtration. This would not exclude the coöperation of other factors in the caffeine diuresis. The existence of such was suggested by the failure of absolute correspondence between the vascular changes and urine flow. Some degree of divergence might be expected in an organ of such complicated vascular topography; but Cushny and Lambic 1921, showed that the duration of the caffeine diuresis is so much greater than that of the vaso-dilation, that other factors must be assumed; and they suggested a change in the permeability of the glomerular filtering membrane.

Interference by Vasoconstriction and Vagus.—Whilst the stimulation of the vasomotor center has not ordinarily the importance attributed to it by von Schroeder, it may sometimes be sufficiently powerful to overcome the peripheral dilator effect. At all events, the diuresis is aided by the hydrocarbon narcotics. Curare is also said to aid the diuresis (Cervello and LoMonaco).

Corin, 1886, claimed that the vagi exert an inhibitory influence, which Anten, 1901, attributed to a direct inhibitory influence of these nerves on the secreting cells. Atropine would therefore increase the diuresis. These claims need confirmation.

Denervated Kidney.—Excised and re-implanted kidney, after resumption of its normal function, responds in the normal manner (oncometer and diuresis) to theobromine and caffeine; also to urea and hypertonic saline (Quinby, 1917).

Perfusion of Excised Mammalian Kidney.—Varying results have been described, (cf. Sollmann and Hatcher, 1907); but when positive the effects were generally in the direction of increased vein flow and ureter flow, pointing to vasodilation. Richards and Plant 1915, also obtained increased ureter flow when the perfusion flow was kept constant. This has been interpreted as showing a non-circulatory factor in the diuresis;

but it is doubtful whether changes in the renal circulation are really excluded in this manner.

Changes in the Size of Excised Kidney Cells and Absorption of Saline Solutions.—Sections of kidney treated with caffeine absorb less fluid from hypotonic salt solutions than do control sections (Filehne and Biberfeld, 1902); but the change is small and inconstant (Sollmann and Hatcher, 1907). Histologically, the epithelium of the convoluted tubules tends to swell slightly in caffeine solution (W. W. Williams, 1907).

Ureter Peristalsis.—Lucas, 1907, found that caffeine has a tonic effect on the pelvic portion of the ureter. This would have but little influence on the urine flow, since this is not influenced even by a considerable negative ureter pressure (Sollmann).

Filtrable Fluid.—The quasi-mechanical response to the improved circulation is modified in degree by the amount of filtrable liquid in the body. Consequently the diuresis is most marked in edema, and is arrested when the organism becomes relatively "dry," for instance by continuation of the diuretic with restricted water income; or more acutely by the withdrawal of blood. The availability of filtrable liquid depends on the imbibition and adsorption affinity of the colloids of the blood and tissues. This factor varies not only with the ratio of water, salts, etc. to colloid, but is also affected by the chemical and physical changes in the colloids themselves. These in turn can be modified by numerous agencies; for instance very conspicuously by changes in the hydrogen-ion concentration. There is evidence which suggests that the caffeine group effects an analogous change, particularly in the blood, diminishing the imbibition attraction of the colloids, and therefore "liberating" water and salts for filtration. This is shown by the observation that caffeine causes the blood to lose fluid not only in diuresis, but even when the kidneys have been previously removed (Paul Spiro, 1918); this occurs also if caffeine is added to serum perfused through frog's muscle; and caffeine increases the ultrafiltration of colloids (Ellinger and co-workers, 1921). The "liberation" of this fluid from the blood-plasma would facilitate secretion and especially filtration of liquid, and therefore increase the lymph and urine flow, as observed by Karl Spiro, 1902.

Water-affinity of the Serum.—The observation of Paul Spiro that caffeine causes the blood to lose fluid, even when the kidneys have been removed, suggested a decrease of the water-affinity of the serum colloids. In the attempt to confirm this directly Ellinger and his co-workers, 1921, found that serum perfused through frog-legs produced edema very readily if caffeine (1:7,000) was added. However, the conditions are complicated by the fact that caffeine causes an increase in the acidity, and therefore in the water-affinity, of the muscle itself. More convincing therefore is the change in the speed of the ultra-filtration of serum, which appeared definitely increased by caffeine, even in dilutions of 1:56,000. The aggregation of the serum colloids by the same concentration, was also observed with the ultra-microscope.

However, in some unpublished and incomplete experiments of the author, dry gelatin laid into serum appeared to swell less rather than more, when caffeine (1:10,000) was added. It also decreased the speed with which the serum rose in a strip of filter-paper. These observations suggest rather an increased water-affinity of the serum. The subject evidently requires more investigation.

The imbibition-affinity of the whole frog (*i.e.* the quantity of water taken up on immersion, the reciprocal of the quantity lost in dry air, by winter-frogs) was not increased by caffeine, although mercurials and urea increased the water-retention (Mollitor and Pick, 1922).

Changes in the Water and Salt Content of the Blood.—These have been reported as diminished and as increased. The divergence is explained partly by the water and salt content of the body; but especially by the stage of the diuresis. Generally, the proportion of water and chloride in the blood is diminished during the diuretic stage; and rises to the normal during the compensating oliguria (Paul Spiro, 1918; clinically, Veil, 1922; Bauer and Aschner, 1922).

The Chloride Level of the Blood and Urine.—In rabbits, the caffeine group appears to break down the mechanism of chloride retention; indeed, some observations point to

this as the cause of the diuresis in these animals. This does not apply, at least to the same degree, to dogs and to man.

In rabbits, the caffeine group may increase the output of chlorides, without increasing the quantity of the urine (Katsuyama, 1898); whilst in man, the chloride concentration is generally diminished (Sellei, 1912; Wuescher, 1925), and only rarely increased (for instance in diabetes; E. Meyer, 1905; drop of plasma-chloride in nephritis, E. H. Mason, 1918). With rabbits, the caffeine group maintains or restores a high chloride excretion when this has been lowered by deficient salt income, or by sulphate or water diuresis (Gruenwald, 1909; Barcroft and Straub, 1910; Pototzky, 1902; Loewi, 1902); but in dog, and in man, the chloride retention is not broken down (Sollmann, 1903; Haskins, 1904; Sollmann and Hofmann, 1905; Sacccone, 1911). *Bromide excretion* is also accelerated in rabbits (Frey, 1910).

Source of the Chloride and Water Excretion in Rabbits.—Sasaki, 1925, found that continued administration of theobromine increased the water excretion only when the rabbits are fed on wet food; but that the chloride excretion is increased also on dry food, *i.e.* independently of the diuresis. Analysis of the tissues shows that the water excreted in excess of the income is derived mainly from the skin; the chloride from the skin and muscles. Eventually the chloride level of the blood is also lowered.

Diuretic Response in Rabbits Conditioned on Rise of Chloride Level of Blood.—G. M. Curtis, 1925, reports that "euphylline" diuresis is preceded by a rise in the blood chloride; and that no diuresis occurs if the blood chloride is lowered, for instance by the intraperitoneal injection of an isotonic sugar solution. He therefore conceives the action of the caffeine group as exerted on the tissue, resulting in a transfer of their chloride to the plasma, and this in turn resulting in the diuresis.

Other Constituents of the Urine.—Increased urine flow generally lowers the concentration of urinary solids, but increases the absolute quantity, at least for a time. This holds true also of caffeine (von Schroeder, 1886). The relative increase of the different solids is not the same (salts and urea, Le Noir and Camus, 1903; Anten; Na and K, Bock, 1911; sulphate and phosphate, man, Wuescher, 1925).

Hippuric Acid Synthesis.—Caffeine, in common with other diuretics, increases the amount of benzoate that can be synthesized into hippuric acid (Astolfani, 1905).

Theories of Direct Cellular Action.—The diuretic action of the caffeine group has also been attributed to direct effects on the renal cells; either to stimulation of secretion, (von Schroeder) or to paralysis of reabsorption (Sobieranski), or to alterations in the glomerular filtering membrane (Cushny and Lambic). These assumptions, which are practically unsupported by positive evidence, were based essentially on the inadequacy of the earlier attempts at the more mechanical explanations. The advances that have been made, whilst they do not disprove the possibility of direct action on the renal cells, may dispense with these assumptions until they are supported by stronger evidence. On the other hand, the mechanical factors cannot be effective if the renal cells are too greatly altered.

Theory of Interference with Tubular Reabsorption.—Sobieranski, 1903, attributed caffeine diuresis to diminished reabsorption of the glomerular filtrate. His arguments were based on observations on the excretion of stains, the interpretation of which is necessarily unconvincing. Similar objections hold against the conclusions of Hirokawa, 1908, based on the osmotic pressure of the renal cortex; and against those of Gruenwald, 1907, on the chloride of the cortex.

Oxygen Consumption.—The advocates of the secretory theory of caffeine action have generally contented themselves with seeking weak places in the evidence of the filtration theory, without adducing much evidence on their own behalf. However, Barcroft and Straub (1910) found that caffeine produced increased oxygen consumption in the kidneys; an evidence of local energy consumption that would not be needed by a physical filtration process. Other observers have failed to obtain this effect (Miwa and Tannura); and it is very probable that Barcroft's result was due to concentration of the urine, and not to diuresis.

Perfusion of Frogs' Kidneys.—Cullis claims that if the perfusion is arranged so that the caffeine acts only on the glomeruli, the effects are unsatisfactory; if it is confined to the tubules, it increases the perfusion

flow and starts the urine. This result would indicate that the action of caffeine is on the tubules; but it is opposed to the findings in mammalian nephritis; and the conditions are too complex to make deduction quite safe.

The Influence of Condition on the Diuretic Response.—Two mechanical factors appear definitely concerned in caffeine-diuresis: improved circulation in the kidneys, and increase of filterable fluid in the blood. The relative importance of these varies with conditions; but neither can be very effective if the other is unfavorable; and both are more or less ineffective if the kidney filter is obstructed by nephritis.

Excess of Fluid.—Superabundance of fluid is very evident in edemas and ascites; and these conditions therefore give the largest response to the caffeine diuretics (Hofmann, 1890), provided that the conditions that caused the edemas are no longer operative. A part of the diuretic effect in cardiac edemas, however, is due to the cardiac improvement. In normal subjects, a fairly liberal water supply is necessary for continued diuresis (Sobieranski, 1895; Loewi, 1905); however, the very free diuresis produced by a very liberal supply of fluid is not further enhanced by caffeine (Sollmann and Hofmann, 1905; diabetes mellitus, Meyer, 1905).

Reduction of Fluid.—This, on the other hand, interferes very notably with caffeine-diuresis, and is the chief reason why the large initial diuresis cannot be maintained (clinically, Le Noir and Camus, 1903; animals, Phillips and Bradford, 1887; Loewi, 1905; M. H. Rees, 1924) for in the proportion that the initial diuresis removes the excess of fluid, the caffeine finds it more difficult to obtain further fluid.

Hemorrhage (Michaud, 1904), muscular work (perspiration) (Asher and Bruck; Wuescher, 1925) and restricted consumption of liquids similarly diminish or prevent diuresis.

The Diuretic Response in the Normal Human Subject.—This is comparatively small. Raphael, 1904, found the daily urine increased (under otherwise constant conditions) by 0.5 Gm. theobromine sodium salicylate, 2 per cent.; 1.5 Gm., 14 per cent.; 3 Gm., 53 per cent. This was much less than the increase secured by the consumption of an extra liter of water or beer (100 per cent.); whilst a liter of milk increased the urine by 153 per cent.

Wuescher, 1925, states that the diuretic effect of a pint of tea was not increased by the addition of a gram of theobromine-sodium salicylate.

Habituation.—H. B. Myers, 1918, gave rabbits a daily hypodermic injection of 100 mg., of caffeine for several months, without apparent damage. However, these animals required for diuretic response the intravenous injection of about twice as much caffeine, or $1\frac{1}{2}$ times as much theobromine, as is required by normal animals. A certain degree of tolerance had therefore apparently been induced.

Interference by Renal Irritation.—All forms of nephritis are likely to interfere more or less with the diuretic response. Experimentally, the interference is greatest in glomerular and least in purely tubular nephritis.

Caffeine in Experimental Nephritis.—Hellin and Spiro, 1897, found caffeine ineffective in glomerular and general nephritis, but quite effective in pure tubular nephritis. This has been confirmed by Schlayer and Hedinger, 1907; and by Pearce, Hill and Eisenbrey, 1910; and these further showed that the failure of diuresis is accompanied by failure of the oncometric reaction. *This is important evidence that the diuretic action is exerted on the glomerular circulation and not on the tubular epithelium.*

In *uræmic nephritis*, diuretics, including caffeine, are effective during the early polyuric stage; but they become ineffective when the anuric stage is reached, although the circulatory response may be well preserved (MacNider, 1912; Boycott and Ryffel, 1913). This depends on the intactness of the renal epithelium (MacNider, 1914). In the subacutely fatal form, caffeine and the other methyl-xanthines did not prolong life (Christian, 1914). The phthalein excretion was rather improved, but the nitro-

gen retention in the blood was not materially affected (Christian, 1913; Christian and O'Hare, 1913; Fitz, 1914).

For *chromate nephritis*, on the other hand, theobromine and theocine were distinctly harmful, since they diminished the phthalein output and the animals died more promptly (O'Hare, 1915), although the nitrogen excretion was unchanged, and the elimination of urine and chloride was increased (Fitz, 1914). Finally, the kidneys ceased to react (fatigue?). This is especially marked if the caffeine has been preceded by several injections of saline (Mosenthal and Schlager, 1913).

Renal Irritation by the Caffeine Group.—Ordinary doses of caffeine do not appear to produce demonstrable injury, even in nephritic subjects. Large doses, however, may increase the albuminuria. With theophylline the continued use even of moderate doses is considered inadvisable.

Albuminuria.—Sollmann and McComb, 1899, found that caffeine did not increase a physiologic albuminuria, and Emerson, 1903, saw no increase of albumin in acute or chronic nephritis under theobromine. Pouchet and Chevalier, 1903, claim that large doses of theophylline injure the glomerular and tubular epithelium.

Animals respond to large doses of caffeine (40 mg. per kilogram), especially when long continued, by definite nephritic changes: albuminuria of 1.4 per 1,000; leucocytes, epithelium and casts in the urine. The kidneys show dilated vessels, cloudy swelling, to vacuolar degeneration and necrosis of the epithelium, and slight interstitial swelling. These histologic changes may be present even when the urine appears normal. Dogs are more subject than rabbits, but the lesions are usually only transitory, disappearing a few days after discontinuance. No lesions are perceptible with doses of 5 to 10 mg. per kilogram, corresponding to 5 to 10 grains in man (Vinci, 1914).

Relative Efficiency of the Xanthine Derivatives.—Caffeine has been largely supplanted, as a diuretic, by theobromine (diuretin), and by theophylline (theocine), which are credited with a much more powerful action. With theobromine, this is not surprising, since the customary dose is four times as large as with caffeine; with theophylline, the superiority is genuine. Both are superior to caffeine in producing less of the nervous side actions. Theobromine also acts much more promptly, *i.e.*, within a day, whilst caffeine requires four days to reach its full efficiency. Exceptionally, caffeine succeeds where theobromine fails (Christian, 1915).

The drugs of the caffeine group are often administered as double salts, with sodium acetate, benzoate, salicylate, etc. This increases their solubility, but does not otherwise alter their actions.

No reliable quantitative experiments on the relative diuretic action of the various xanthine derivatives have been made—the much-quoted experiments of Ach being based on too few animals. The attempt to correlate the diuretic and muscular action (Schmiedeberg) is therefore premature. Mendel and Kahn, 1913, found that most of the newer methylated xanthines are not diuretic.

1:7:9 trimethyl 2:8 dioxypurine (Johns) was examined by Salant and Connet, 1918. It is a weak cardiac stimulant, little if at all diuretic for rabbits, and much less toxic than caffeine.

Differences in the Members of the Group.—Caffeine has the most powerful central nervous action, with relatively weak peripheral effects. The strongest diuretic action is produced by *theophylline* (theocine), which also causes the most marked cardiac stimulation and coronary dilation. Its central effects and its action on muscle approach those of caffeine. *Theobromine* (diuretin) acts most powerfully on muscle; its effect on the heart and urine are intermediate. It causes very little central stimulation.

The pharmacology of theobromine was first investigated by Mitcherlich, 1859, and further by Filehne, 1886. It was used experimentally as a diuretic by von Schroeder, 1887, to avoid the supposed vasoconstriction of caffeine. He found it effective without

chloral; and the action on oral administration extended over twenty hours—presumably because its insolubility caused slow absorption. This led to its clinical introduction by Gram.

The toxicity of theobromine to isolated muscle is 112 times that of caffeine (Veley and Walker, 1910).

Therapeutic Use of Diuretic Action.—The methyl-xanthines are employed mainly for the removal of cardiac *effusions*. The diuresis is proportional to the effusion, sets in promptly, and ceases when the drug is withdrawn. It is therefore especially useful for two or three days at the beginning of the most slowly acting but more permanent digitalis treatment. Caffeine is the least active of the series. It may be given in the doses of 0.3 Gm. (5 grains) of citrated caffeine, in watery solutions, three times a day, but Taylor found at least 0.5 Gm., four times daily, necessary for a full effect.

Theobromine (1 Gm. or 15 grains of theobromine-sodium-salicylate, or diuretin, in water, four times a day) has the advantage of producing a better diuretic response with the least side actions. Taylor found that a daily dose of 30 grains produced very little effect; 40 grains a moderate diuresis; but 80 grains (5 Gm.) were required to secure the maximum efficiency. This quantity, when divided into four doses, was well tolerated. It has also been used intravenously, 20 c.c. of 5 per cent., Neuhoﬀ, 1913; but it is doubtful whether this is justified. Theophylline (theophylline-sodium-acetate, or theocine) is the most powerful, but has been charged with sometimes causing renal irritation. Its dose is 0.3 Gm. = 5 grains, three times per day, administered in hot tea.

In *renal or hepatic effusions*, the efficiency is less certain. In acute or chronic parenchymatous nephritis, there is often no response whatever, while chronic interstitial nephritis usually responds (J. Miller, 1912); but unless the dosage is very small and carefully watched, the toxic side actions may set in, and the renal condition grow worse. Theophylline and theobromine may cause renal irritation; it would therefore be better to avoid the methyl-xanthines when the kidneys are acutely irritated. In anuria, the methyl-xanthines are generally ineffective. Christian et al., 1915, and 1916, state that diuretics are generally ineffective in chronic nephritis, unless there is edema. They would therefore be of little use against nephritic toxemia.

Clinical Efficiency of Theophylline.—Christian, 1916, reports on the response of patients with acute and chronic nephritis and cardiorenal disease, to doses of 0.1 Gm. three times daily:

In the *absence of edema*, these had little or no value. The urine volume and the nitrogen elimination were but little increased; the phthalein output was often diminished.

In cardiorenal disease with *marked edema*, positive benefits were observed, especially when used in conjunction with digitalis. There was an active diuresis, increased chloride elimination; and diminution of the edema. This was often followed by diminished urea excretion, which was interpreted as a secondary depression of renal function, making it advisable not to continue the drug too long. This interpretation however, is doubtful.

Milk-secretion.—This is not affected by caffeine (Ott and Scott, 1912).

Absorption, Fate and Excretion.—Caffeine is readily and completely absorbed: none appears in the feces even after large doses. Only a small fraction is excreted unchanged in the urine. This excretion starts and is mainly completed promptly, but traces may continue for two or three days (Salant and Rieger, 1912). A somewhat larger fraction loses a part of its methyl group, and appears in the urine as di- and mono-methyl-xanthines. It is not known whether this is effected by oxidation or hydrol-

ysis. The remainder—up to 80 per cent.—is completely oxidized to urea. Practically none of the caffeine is converted into uric acid (which is largely the fate of hypoxanthine and of xanthine).

Theobromine undergoes changes similar to caffeine, but a larger fraction (32 per cent.) escapes decomposition. The greater part leaves as heteroxanthine.

Quantitative Excretion.—The quantity of caffeine which is excreted unchanged varies with the dose and with different animals, being only 1 per cent. in carnivora, less than 8 per cent. in man, and 6 to 20 per cent. in rabbits (Rost, 1895; Salant and Rieger, 1912). The relative quantity of the various mono- and dimethyl-xanthines also varies in different animals, representing 10 to 40 per cent. of the caffeine (Albanese, 1895; Bondzynski and Gottlieb, 1895; Krueger and Schmidt). The literature has been summarized by Bloch, 1906. The demethylation is retarded by alcohol (Salant and Phelps, 1912). Emory and Salant, 1909, report experiments on the decomposition of caffeine in the liver. A trace appears in the stomach, intestines and in the bile (Salant and Rieger). The gastro-intestinal excretion is higher when the kidneys are excised (Salant and Rieger, 1913). The loss of methyl groups occurs in pretty much all organs (J. Schmidt, 1910).

Uric Acid.—In man with a purine-free diet, the continued administration of caffeine, 1 Gm. per day, produced a slight but definite and progressive increase of urate excretion (S. R. Benedict, 1916).

Toxicology.—The fatal dose of caffeine is so large (presumably about 10 Gm.),¹ that no fatal case of poisoning is on record; but doses above 1 Gm. may produce alarming symptoms, and even *therapeutic doses* may cause unpleasant side actions.

With *larger doses*, the pulse is full and hard, quickened or slowed, with palpitation and precordial distress (sometimes anginal attacks). The head is heavy, throbbing, confused; often intense headache and great anxiety. Restlessness and excitement, insomnia (sometimes mild delirium, aphasia, fever). Vertigo, nausea, general discomfort, fatigue, weakness (sometimes burning in the throat, gastric distress, heat flashes, perspiration, insensible pharynx, swollen tongue, ringing in the ears, flashes in eyes). Tremors of jaws, hands and feet, and muscular stiffness. Quickened, embarrassed respiration. Increased micturition (sometimes ardor urinæ and erection).

In *very severe cases*, there is vomiting (sometimes violent diarrhea and tenesmus); violent choreic tremors. Collapse, with small, irregular arrhythmic pulse, cold extremities, dilated pupils. Consciousness is usually intact, but there may be delirium.

Doses of 1 Gm. and higher have been taken to evade military service, especially by producing tachycardia (sometimes to 160 per minute). The drug is easily detected in the urine (Hollande and Thevenon, 1916).

Toxic Effects on Animals.—The symptoms in animals correspond fairly to those observed in man: restlessness and increased reflexes; increased respiration, vomiting and diarrhea; muscular weakness. Then: clonic or tetanic convulsions, during which respiration may stop, with or without resumption; exhaustion and increasing paralysis; death in one to four hours. The fatal dose lies about 0.15 Gm. per kilogram. Dogs and cats are somewhat more susceptible than rabbits and guinea pigs. The dose by mouth is but little larger than the intravenous dose, except in rabbits (Salant and Rieger, 1910, 1912). Young mice are more resistant than old. The effects in *birds* are similar (Brill); in *frogs* they are modified by the onset of rigor. The toxicity for frogs is diminished by temperature above 98°F. At 45°F. the muscular effects predominate; while the convulsions become more prominent as the temperature is increased (Salant, 1913).

Recovery is usually complete within a day, even when the symptoms were violent. Some restlessness and weakness may remain for a time. It is claimed (Kunkel) that large therapeutic doses have been followed by nephritic urine, but on the other hand, daily doses of 1.25 Gm. have often been given without detriment (Becher, 1884). *Idiosyncrasy* toward caffeine is marked, as every one knows. Children and nervous and weak-

¹ The doses refer to pure caffeine; the corresponding doses of citrated caffeine would be twice as large.

ened individuals appear to be relatively more susceptible. Overdoses should be avoided, especially in *myocarditis*.

Treatment.—This consists in evacuation and narcotics—bromide, alcohol, chloral, or morphine. It is important to reassure the patient.

Theobromine and theophylline, in excessive doses or in susceptible individuals, may produce toxic effects similar to caffeine: headache, nausea, vomiting, epileptic spasms, albuminuria, gastric hemorrhage, etc. (Kobert, Schmiedeberg, Seifert). These manifestations are, however, rare. In epileptic patients, large doses of theophylline are said to have provoked attacks (Schlesinger, 1905). Chevalier, 1914, claims that some commercial theobromines contain toxic impurities; this requires confirmation.

Two deaths from cardiac failure are attributed by Cadburg, 1918, to theophylline (about 1 Gm. in divided doses). However, the patients were under digitalis treatment for heart disease. The causation is therefore rather doubtful.

PREPARATIONS

**Caffeina*, U.S.P., B.P.; Caffeine (Theine); $C_8H(CH_3)_3O_2N_4.H_2O$.—A feebly basic alkaloid, usually prepared from tea. White, silky, needle-crystals; odorless; bitter taste. Sol. in water (1:46) and in alc. (1:66). Its solubility in water is greatly increased by heat, citric acid, benzoates or salicylates, bromides, antipyrine and a number of other substances. *Incompatible* with tannin. *Dose*, 0.15 Gm., 2½ gr., U.S.P.; 0.06 to 0.3 Gm., 1 to 5 gr., B.P.; in capsules. Maximum dose, 0.5 Gm., 8 gr.

**Caffeina Citrata* (Caff. Cit.), U.S.P.; (*Caffeina Citras.*), B.P.; Citrated Caffeine; Caffeine Citrate.—A mixture of caffeine and citric acid, containing about 50 per cent. of caffeine. White powder; odorless; slightly bitter, acid taste. Citrated caffeine gives a clear syrupy solution with a little water, but precipitates on dilution. The precipitate redissolves on the further addition of water, the solubility being about 1:32. *Incompatible* with carbonates. *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.12, to 0.6 Gm., 2 to 10 gr., B.P., in water. The free acid renders this unsuitable for hypodermic use. Maximum dose, 1 Gm., 15 gr.

Caffeina Citras Effervescens (Caffein. Cit. Eff.), B.P.; Effervescent Caffeine Citrate.—A granulated mixture of Sodium Bicarbonate and Tartaric and Citric Acid, with about 2 per cent. of caffeine. *Dose*, 4 to 8 Gm., 1 to 2 drachms, B.P.

**Caffeina Sodio-Benzozas* (Caff. Sod.-Benz.), U.S.P.—A mixture of about 50 per cent. caffeine with sodium benzoate. A white powder; odorless; bitter taste. Freely sol. in water (1:1.1), sol. in alc. (1:30). *Dose*, 0.3 Gm., 5 gr., by mouth; hypodermic, 0.2 Gm., 3 gr., U.S.P.; the most suitable compound for hypodermic use. Maximum dose, 1 Gm., 15 gr.

Theobromina, Theobromine.—A dimethylxanthine prepared from Cacao seeds (*Theobroma Cacao*) or synthetically. Very slightly sol. in water.

**Theobromina Sodio-Salicylas* (Theobrom. Sodio-Sal.), U.S.P.; *Theobrom. et Sod. Salicyl.*, B.P.; Theobromine-sodium-salicylate (Diuretin).—Sodium Theobromine ($C_7H_7N_4O_2Na$) and Sodium Salicylate, in approximately molecular proportions. Not less than 46.5 per cent. of theobromine. White, odorless powder; sweetish saline and somewhat alkaline taste. Freely sol. in water (1:1); slightly sol. in alc. It gradually absorbs carbon dioxide from the air with the liberation of theobromine, becoming partially insoluble in water. It must therefore be protected against exposure to air, and is *incompatible* with acids; also with chloral. It should not be given with meals, to avoid precipitation by the gastric acid. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.6 to 1.2 Gm., 10 to 20 gr., B.P.; well diluted. Solutions do not keep.

Other Theobromine Salts.—The following are listed in N.N.R., but have no special advantage: Sodio-acetate (*Agurin*); Sodio-formate (*Theophorine*).

Allyltheobromine (allyl in place of one CH_3) is more soluble than the ordinary theobromine and more diuretic; therefore more available for hypodermic or intravenous injection (Pouchet, 1920).

**Theophyllina* (Theophyll.), U.S.P.; Theophylline (Dimethylxanthine, Theocine); $C_8H_{10}(CH_3)_2O_2N_4.H_2O$.—White crystalline powder; odorless; bitter taste. Sol. in water (1:120) and alc. (1:80). *Dose*, 0.25 Gm., 4 gr., U.S.P., three times a day, in warm tea. After two or three days, it should be replaced by theobromine.

Theophylline Sodio-acetas, N.N.R. (Soluble Theocine).—Contains 66 per cent. of the alkaloid. It dissolves in 23 parts of water.

Boerhaavia Diffusa, an East Indian weed (*Punarnava*) contains a diuretic alkaloid. It produces some rise of blood pressure; but this is not the main mechanism of the diuresis. Clinically, the fluidextract is an effective diuretic in ascites and edema, especially in early liver, peritoneal or renal disease, and more effective than other diuretics in early hepatic cirrhosis and chronic ascites; but it has relatively little effect in cardiac disease (Chopra et al, 1923).

Albamyricetin.—A glucoside from the blossoms of a tropical tree; is strongly diuretic, depresses excised intestine and blood vessels, and inhibits the heart (Abe and Takahira)

CAFFEINE BEVERAGES

Caffeine is an important article of popular consumption, in the form of coffee, tea, and other beverages. The annual per capita consumption in the United States is about 10 pounds of coffee and 1 pound of tea (Graham, 1912). A cup of coffee or strong tea contains about 0.1 Gm. ($1\frac{1}{2}$ grains) of caffeine. Its effects are somewhat modified by the associated products (the volatile products causing more psychic stimulation, the tea-tannin and coffee oil deranging digestion); but essentially the actions are those of the alkaloids. They consist in increased mental and physical efficiency, psychical stimulation, comfort, and relief from muscular and mental fatigue and from their attendant unpleasant sensations. These effects may be useful in certain conditions, as in those exposed to severe hardship, hunger, fatigue, etc., but ordinarily they are mere luxuries—pleasant, but superfluous. They may do no harm if the consumption is kept within bounds; but nervous individuals, who are the most apt to be injured by caffeine, are most likely to exceed these bounds. The bad effects are usually not very serious, and disappear promptly if the habit is discontinued. They consist in nervousness, tremor, palpitation, insomnia, headache, and digestive disturbances.

The habitual consumption of caffeine confers a very limited tolerance. Its withdrawal does not produce any marked abstinence symptoms.

Coffee and chocolate are *useful flavors* and extemporaneous vehicles, especially for castor oil and cod liver oil.

Coffee (*Coffea*) consists of the dried seed of *Coffea Arabica*, Rubiaceæ. The constituents of the "green bean" are caffeine, fat, coffalic and chlorogenic acid, saccharose, etc. The chlorogenic acid gives a green color with iron, similar to tannin, and in its impure form it was formerly called "*Caffeotannic acid*." Gorter, 1910, has found it in about 100 plants. On oxidation it yields caffeic acid. It differs from tannins in that it does not precipitate proteins, and is therefore not astringent. The percentage of caffeine varies in different specimens from $\frac{2}{3}$ to $2\frac{1}{2}$ per cent., usually about 1.2 per cent. (Koenig). It exists mainly as caffeine-potassium chlorogenate (Gorter, 1908).

In the process of *roasting* (i.e., heating the seed to 200° to 250°C.) a small amount of caffeine is volatilized; but since about 10 per cent. of water is driven off, the percentage of caffeine is actually a trifle higher (1.25 per cent.). The main change in roasting consists in the production of aromatic, brown and oily products. This oil (*Caffeol* or *Caffeon*), according to Erdmann, 1902, and Grafe, 1912, consists of 50 per cent. of furofural alcohol, and small quantities of valerianic acid, phenol, pyridine, and a nitrogenous aromatic substance. It is probably derived mainly from the hemicellulose.

The beverage, *coffee*, is a decoction made with 6 to 10 per cent. of the drug. Practically the entire caffeine (perhaps $\frac{2}{10}$) is thus extracted; so that a cup of strong coffee, prepared from 15 to 17 Gm., contains about 0.1 to 0.12 Gm. of the alkaloid.

The use of coffee arose in Arabia and Egypt about the middle of the fifteenth century. Coffee and tea were introduced into Europe about the last quarter of the seventeenth century, about the same time as the potato, cinchona, tobacco and chocolate.

Action of Coffee Oil.—The volatile aromatic constituents produce local irritation and reflex stimulation, in the same manner as the condiments. The hot water contributes to this effect; and possibly the greater reactivity induced by the caffeine heightens the reflex response (Schmiede-

berg). The local irritation stimulates peristalsis, and with excessive use, tends to nervous dyspepsia. It is doubtful whether the quantities taken in the beverage cause any direct central stimulation.

Wilhelm, Rorer, and Reichert could not obtain any effects with coffee distillates. I. Lehmann, Archangelsky, Hare and Marshall, and Erdmann found, with *small doses*: pleasant stimulation; increased respiration; increased heart rate, but fall of blood pressure; muscular restlessness; insomnia; perspiration; congestion. *Large doses*: increased peristalsis and defecation; depression of respiration and heart; fall of blood pressure and temperature; paralytic phenomena.

V. Grafe, 1915, believes that the products of roasting contribute to the action.

The intravenous injection of coffee is more toxic than the corresponding caffeine. This is presumably due to the potassium (Aubert). By mouth, however, the potassium (0.44 Gm. KCl in 20 Gm. coffee) is not sufficient to produce any effect.

Decaffeinated coffee does not produce the cardiac or diuretic effects of coffee or caffeine (Busquet and Tiffeneau, 1912). The caffeine content of commercial decaffeinated coffees and other coffee substitutes is given by Street, 1916.

Tea (*Thea*) consists of the dried leaves of *Thea sinensis*, Theaceæ. *Constituents*: Caffeine (1.4 to 3.5 per cent., usually 2 to 3 per cent.); tannin (1 to 30 per cent.); traces of theobromine, theophylline, xanthine, adenine, and volatile oil. The black and green teas differ only in the treatment to which the leaves are subjected—a fermentation with the black variety, which mainly alters the color and flavor; the green tea is rather more rich in volatile oil. The beverage is a 1 to 4 per cent. infusion. A cup of strong tea prepared from 5 Gm. of leaves, contains about 0.1 Gm. of caffeine (Aubert). A quick infusion extracts practically all the caffeine, but only a part of the *tannin* (which is especially abundant in the finer sorts). The customary brief infusion is therefore commendable, since the tannin may be deleterious to digestion, by precipitating proteins and albumoses, by lessening absorption, and by irritating the gastric mucosa.

The *tea-distillate* is credited by Archangelsky with actions similar to those of caffeine. Lehmann and Tendlau found it inactive.

Cola (*Kola*, the seed in *Cola acuminata*, Sterculiaceæ).—This is used extensively by the natives of Africa, the fresh and often germinated seed being chewed. The dried seed, which has been introduced as a popular “tonic,” contains caffeine ($1\frac{1}{2}$ to $3\frac{1}{2}$ per cent., usually $2\frac{1}{3}$ per cent.); theobromine ($\frac{1}{40}$ per cent.), tannin (*Kola red*); fat, sugar, etc.

In the fresh nut, the caffeine is combined with a glucosidal tannin (“*Kolatin*,” Goris, 1907). This compound, which was formerly termed “*Kalanin*,” is partly decomposed in drying, by an oxidase, into free caffeine, glucose, and *Kola red* (Chevrotier and Vigne, 1907).

Guarana.—A dried paste, prepared by the Indians of South America, consists chiefly of the dried and pounded seed of *Paulinia cupana*, Sapindaceæ. It contains 4 to 5 per cent. of caffeine, tannin, etc. *Dose*, 2 Gm., 30 gr. **Maté** (Paraguay tea) consists of the leaves of *Ilex paraguayensis*. It contains 0.13 to 1.85 per cent. caffeine (2 per cent., Bertrand and Devuyt, 1910), 10 to 16 per cent. of tannin, etc. It is used in South America for preparing a beverage.

Cacao is consumed extensively as a beverage and in the form of chocolate. (The latter is a mixture of melted cacao and sugar, often with the addition of flavors, starch, etc.). It contains theobromine, instead of caffeine, and therefore acts less on the nervous system. It is also rich in fat, which is nutrient. A part (about half) of this fat (*Oleum Theobromatis* or *Cacao Butter*) has been removed from the commercial powdered cacao.

The name Cacao should not be confused with Cocoa (the palm yielding the cocoa nut), nor with Coca, the source of cocaine.

Cacao consists of the fermented, dried and often roasted seeds of *Theobroma Cacao*, Sterculiaceæ. *Constituents*: Theobromine ($1\frac{1}{2}$ to $4\frac{1}{2}$ per cent., usually $1\frac{1}{2}$ per cent.); a trace of caffeine; 50 per cent. of fat; starch, tannin, etc. The theobromine is liberated from a glucoside during the fermentation.

The fat is generally considered rather indigestible, but Neumann, 1906, showed that it is digested as well as other fats.

Chicory.—The roasted root of this plant is used as an adulterant and substitute for coffee. It probably contains similar empyreumatic substances, but no caffeine. Schmiedeberg, 1912, considers it a harmless stimulant, stomachic and antiseptic; while Horwith, 1908, believes it liable to disturb digestion. Still less is known about roasted malt and other cereals which are used as coffee substitutes.

Phenomena of Chronic Caffeine Poisoning.—These have been described most commonly in excessive tea drinkers. A good analysis of the effects is given by Bullard, 1886. The first symptoms are usually *dyspeptic*—epigastric uneasiness after meals, and a general lowering of the mental and physical tone. This is succeeded by *restlessness and nervous excitability*, tremors, and disturbed sleep, soon followed by anorexia and by headache, vertigo, confusion. Constipation is very common, but not more so than in individuals who are not addicted to tea. *Palpitation*, generally associated with irregularity, becomes distressing, and is often accompanied by dyspnea. In the severer cases, these symptoms become aggravated and continuous. Neuralgias, sensory and hysterical disturbances are common, but it is not easy to say whether these are the cause or effects of the caffeine habit. Children who drank coffee were found by Taylor, 1912, to average below the normal weight, height and strength.

The quantity of tea required to develop these symptoms varies greatly with the individual. The daily average consumption of Bullard's patients was five cups, which corresponds to about 0.6 Gm. or 8 grains of caffeine. The susceptibility is much greater in youth, anemia, weakness, insufficient food, exhaustion, and in "nervous" individuals.

Differences between Tea, Coffee, and Cacao.—The effects of excessive coffee consumption differ only in minor details from tea; whilst tea tends to constipation, coffee is laxative. Both interfere with digestion, but in different ways: the coffee through the irritant effects of its volatile oil; the tea through the coagulant action of the tannin. It may therefore be observed that different individuals are more injured by one or the other. The caffeine itself probably contributes to the digestive derangement, through its vasodilator action. This may account for the common tendency to hemorrhoids. Cacao may disturb the digestion through its richness in fat, but the other symptoms are not common; partly because there is less inclination to its excessive use.

The acute effects on digestion deserve special mention. Cushny states that coffee and tea retard the action of the *ferments* considerably (in test-tube experiment), whilst caffeine slightly accelerates the action. The secretion of *gastric juice* has been investigated by Pincussohn, 1906, using dogs with the Pawlow gastric pouch. Coffee gave a considerable but brief increase of quantity and acidity. "Malt coffee" (the type of the coffee substitutes prepared by roasting cereals) has a similar, but weaker action. Tea and ordinary cacao decrease the secretion; but cacao in which the fat has been reduced to 15 per cent. causes some increase.

With normal men, a liter of coffee or tea, hot or cold, taken with meals, has no definite effect on the acidity or the evacuation time of the stomach. Cocoa, $\frac{1}{2}$ to 1 liter, decreased the acidity and delayed evacuation (R. J. Miller *et al*, 1920); presumably through its fat.

Chronic Caffeine Poisoning in Animals.—Salant and Rieger, 1910, found that the continued administration of doses which did not cause acute effects, eventually produced emaciation, often ending in death. The stomach and, to a less degree, the intestine showed inflammatory changes.

On the other hand, they found that habituation increased the tolerance to acute poisoning, the fatal dose being 15 to 80 per cent. larger than ordinary. Gourewitch, 1907, also claims a "histogenetic" habituation.

Mice kept continuously under caffeine were found to exhibit less than the normal activity, but showed a normal gain in weight (Nice, 1912).

OPIUM, MORPHINE AND RELATED ALKALOIDS

Members.—Opium contains two chemically distinct groups of alkaloids. The group of morphine, or the phenanthrene derivatives, is practi-

cally the most important. It comprises morphine and the esters formed by replacing the H of one or both hydroxyls of morphine. Some of these occur naturally in opium (methymorphine or codeine, dimethyl-morphine or thebaine). Others are produced synthetically (ethyl-morphine or dionine, diacetyl morphine or heroine, etc.).

The second group, or isoquinoline derivatives, is represented by papaverine and narcotine. Similar alkaloids preponderate in other plants of the poppy family. Their actions depend apparently on the presence of the benzyl radical; and are shared by simpler synthetic benzyl derivatives.

Since morphine is the most important of the opium alkaloids, it will be considered first.

Central Nervous System.—The most important actions of morphine are on the central nervous system. It depresses the brain, especially its higher functions. The medullary centers are first stimulated, then depressed. The reflexes and the spinal functions are mainly stimulated. The effects are broadly identical in all vertebrate animals, although the dosage varies greatly, and the symptoms show considerable differences in the relative prominence of certain phenomena and in the time required to produce the successive actions.

Narcotic Action.—The descending depressant action of morphine is well illustrated by the frog, in which the development of the symptoms corresponds closely to those produced by progressive removal of the brain. This is also the general course in mammals; but with these the symptoms are more confused. The difference is explained by the more rapid action of the drug, and by the more intimate correlation of the nervous centers.

Effects of Morphine on Frogs.—After doses of 20 to 50 mg. the symptoms start with diminution, and then absence, of voluntary movements, but the animal reacts normally when stimulated. (This corresponds to ablation of the hemispheres.) The frog sits quietly in the normal position; he will climb up an inclined plane and give the croaking reflex when stroked. When placed in a tumbler filled with water and inverted in a large vessel of water, it will leave the glass to seek the air. As the narcosis deepens, it will remain under the glass. Placed on the table, its leaps become more and more clumsy, and it does not avoid obstacles in jumping (corresponding to excision of the corpora quadrigemina). Then the animal fails to leap even when stimulated (paralysis of cerebellum); but when turned on its back, it will resume its normal sitting position. This reaction also becomes more and more delayed, and can be obtained only by reinforcing the stimulation through pinching, etc., until finally it fails altogether (paralysis of medulla oblongata). The reflexes are weakened, but present. The respiration is decreased.

Morphine Tetanus in Frogs.—After the frog has remained in this depressed condition for some time (a few minutes to several hours; the shorter, the larger the dose), the respiration becomes spasmodic, resembling superficially the Cheyne-Stokes type; then the spinal reflexes return; and the frog passes gradually into a tetanus of the strychnine type, located in the spinal cord. The delayed appearance of this tetanus is due to the slow absorption of the effective dose, for it appears at once on intravenous injection (Stockman, 1891). The convulsions occur more promptly if the heart is tied off (Githens and Meltzer, 1911), presumably because thus more of the morphine reaches the nervous axis (Abel, 1912). The onset is also hastened, and the necessary dose reduced, by cold, and by removal of the cerebrum, which inhibits convulsions. The results are more prompt if the medulla is not destroyed (Githens, 1913).

McGuigan and Ross, 1915, find that the previous injection of morphine sensitizes frogs to strychnine so that strychnine tetanus develops more quickly—provided that a latent period of one-half to two hours elapses between the morphine and strychnine injections. They believe that the tetanizing action is due to an oxidation product of morphine, since an artificially oxidized morphine tetanizes more rapidly. Along the same lines, they explain the usual absence of tetanus in mammals by assuming rapid destruction of the tetanizing substance. The explanation involves some unproven assumptions.

Death.—The tetanus is mixed with paralytic phenomena, the animal lying lax between the spasms. Eventually the paralysis becomes permanent and ends in death.

The *heart* is still beating at this stage and is indeed little affected directly. Death may also occur during a spasm. The convulsive stage may be absent with very large or very small doses.

Recovery.—If recovery occurs, the depressed functions recover in inverse order to their appearance (Witkowski, 1877). This paper also gives the older bibliography of the experimental work with morphine).

Invertebrates do not show typical morphine effects.

Narcotic Symptoms in Human Subjects.—The first effect, produced by doses too small to elicit any other symptoms (5 mg.), consists in diminished sensibility to lasting impressions; especially such as give rise to pain, cough, fatigue, hunger, discomfort, and other disagreeable sensations.

Somewhat larger doses (10 mg. or more) depress the attention and thus weaken the appreciation of other external impressions. A *sudden* stimulus may evoke a normal or exaggerated reflex response; there is even increased acuteness of perception of external impressions (Kraepelin, 1892); but *persistent* or gradual stimuli are neglected. The stimuli are evidently transmitted to the brain, but do not fix the attention. The faculties of concentration, of judgment and of memorizing (Weygandt, 1903) are all seriously disturbed, constituting a narcosis.¹ Through this exclusion of external stimuli, the patient is quieted, and then passes through a dreamy, apathetic, drowsy state, into natural sleep. Exceptionally, the disturbed balance of the brain leads to excitement (especially in cats) and even to delirium.

Larger doses cause a much more extensive depression, the sleep becoming so profound that the patient can be aroused only imperfectly and with difficulty. Eventually the coma and insensibility are complete.

Psychologic Experiments on Man.—Macht and Isaacs, 1916 and 1917, find that 4 to 8 mg. generally produce a primary stimulation, *i.e.*, they shorten the reaction-time. This is often followed after one-half hour by delayed reaction. With larger doses, the primary stimulation is very short and may be absent; and the secondary depression is predominant.

Association (arithmetic) is delayed more readily, and mistakes are more numerous, than with simpler reactions.

Potentiation of the narcosis occurs in most individuals by the addition of narcotine and other opium alkaloids.

Behavior of Rats.—Macht, 1920, studied the influence of opiates on the behavior of rats that had been trained to a maze. He found that morphine, even in minute doses, markedly impaired the memory and the activity. Both series of opium alkaloids were depressant, but the papaverine group much less than the morphine group. Mixtures with the isoquinoline alkaloids appeared less depressant than corresponding doses of morphine alone.

Relative Analgesic Action of Opium Alkaloids.—Morphine is decidedly the strongest hypnotic and analgesic member of the group.

Analgesic Experiments on Man.—Macht, Herman and Levy, 1916, investigated the influence on the sensory threshold by a quantitative method. They find the efficiency highest with morphine; then comes papaverine, then codeine; narcotine, narceine and thebaine are practically not analgesic. However, narcotine had a considerable potentiating action on morphine.

With hypodermic injection, 5 mg. of *morphine* produced no measurable analgesic effect; with 10 mg., the analgesia was marked in two subjects; the third responded by hyperesthesia, especially to larger doses, although all the other narcotic effects were present. With *codeine*, 20 to 25 mg., the analgesia was only slight; with *papaverine*, 40 mg., it was as strong as with 10 mg. of morphine, but slower and shorter; with *narcotine*, 8 mg. was ineffective; 20 to 40 mg. produced first some hyperexcitability; then slight analgesia. Narceine and thebaine, 10 mg., were ineffective. With a mixture of equal

¹ *Narcotics* are substances which stupefy: Opium, alcohol, cannabis, atropine and similar drugs.

parts of morphine and narcotine, containing $3\frac{1}{3}$ mg., the analgesia was almost as great as with 10 mg. of morphine alone. This combination was also effective in the subject who resisted morphine.

Excitant Effects in Man.—Some individuals, particularly among women, are apparently more excited than depressed by morphine. This can perhaps be explained by diminished restraint, rather than by direct stimulation. The same explanation probably holds true also for the flights of imagination which fill the period preceding the sleep.

Effects of the Other Members of the Group.—Codeine and diacetylmorphine are less quieting, and perhaps more excitant and convulsant than morphine. Codeine does not inhibit, but rather increases the convulsions of camphor, etc. (Januschke and Masslow, 1915).

Imagination.—It is self-evident that an unrestrained imagination will take very different directions, according to the individual. In some it will tend directly to sleep; in others, it may even prevent sleep; in some it will be highly unpleasant, whilst others will seek to repeat the experience and thus fall easy victims to the morphine habit. The aphrodisiac effects, which occur in some, and the anaphrodisiac action in others, depend upon this action on the imagination.

Special Senses.—These are not affected directly. They may appear disturbed through the impaired attention, or through the heightened reflex irritability.

Symptoms in the Lower Mammals.—The effects are almost purely depressant (apathy, stupor, analgesia, sleep and coma) in the dog, rabbit, guinea pig, white rat, mouse and sparrow. The acute reflexes are heightened, but firm pressure, which would be much more painful in normal animals, elicits no response. Dogs exhibit a peculiar clumsiness and incoördination in their voluntary movements. They stand and walk unsteadily, and often drag their hind legs ("hyenoid walk," Cl. Bernard). These motor symptoms resemble those of ablation of the motor areas. On the other hand, one often sees convulsions, tremors or choreiform twitches of the limbs. The excitability of the motor areas to electric stimulation is not altered even by the largest doses (Hitzig, 1873). The respiration may at first be very rapid, but is eventually depressed. Vomiting and defecation occur early.

In the cat (and also with the horse, ass, beef, sheep, pig and goat and sometimes in dogs) the coma is preceded by more or less excitement. The cat particularly exhibits a violent mania, races about as if in extreme terror, with prominent eyes and widely dilated pupils, scratching and clawing wildly. Sometimes there are even convulsions. The excitation is combined with psychic depression; for the animal does not avoid obstacles in its career, and there is marked analgesia. The excitant effect on cats is also produced by codeine and thebaine, whilst papaverine and narceine are mainly depressant (G. H. Müller, 1908).

Relative Toxicity for Different Animals.—The tolerance for morphine differs remarkably. Man is by far the most susceptible, the fatal dose for man being no greater than that required for a frog of but $\frac{1}{2000}$ the weight. Pigeons, goats, rabbits and pigs require nearly 100 times the human dose, per kilogram; dogs and cats about 15 times; horse and cow two to four times.

Respiration.—Small and moderate (non-narcotic) doses of morphine (3 to 15 mg. in man) quiet the respiration. The rate is generally moderately slowed (Gscheidlen, 1869), markedly so if it had been rapid; the depth is often rather increased, especially if it had been shallow; the minute volume is usually somewhat decreased, but may be unaltered or even increased; the response to carbon dioxide and asphyxia is greatly diminished. Spasmodic irregularities, dyspneas, and air hunger are removed or allayed. The regular deep respiration thus induced is more favorable to the air-exchange, so that the respiration is more efficient even when it is slower. There is also a special effect on the cough-reflex, which is allayed by quite minute doses (2 mg. of morphine).

Toxic doses produce progressively serious depression of the respiratory center: very marked decrease of excitability, rate, depth, and efficiency; periodic respiration (Filehne; Barbour, 1914) resembling the "Cheyne-

Stokes type," and finally arrest of respiration, before the heart is seriously injured.

Mechanism of the Respiratory Depression.—This probably involves an action analogous to the psychic effects; *i.e.*, inattention to the stimuli that normally influence and entertain respiration. This would be most marked toward persistent stimuli, such as those of cough and carbon dioxide; whilst the response to abrupt stimulation, for instance of the sciatic nerve, may even be increased (S. J. Cohen and McGuigan, 1924). With toxic doses, the apathy would gradually abolish all respiration. In habituation, the organism learns to adapt its indispensable functions to the apathy, and the toxicity is greatly diminished. Different degrees of apathy would also explain the wide variations in the fatal dose for different animals.

Rate and Depth of Respiration.—The effect of morphine, as of most drugs acting on the respiratory center, is mainly on the rate. With small doses, the depth is affected only secondarily, namely, increased in the attempt to compensate for the slowed rate, especially if the respiration was previously superficial (Issekutz, 1911). The effects, therefore, resemble those of section of both vagi: this suggests that the effect might be due to blocking of the normal augmentor vagus impulses; but this is not the correct explanation, for morphine does not block the response to electric stimulation of the vagi, and it also causes a further slowing after both vagi have been divided (Cushny, 1913).

Relation to Dosage.—With dogs and rabbits, Macht, 1915, found that small doses (0.1 mg. per Kg.) markedly slowed the rate, but somewhat increased the minute-volume and alveolar ventilation; but the response of the center to CO₂ was somewhat decreased. Full doses (1 to 5 mg. per Kg.) diminished the rate, minute-volume, alveolar ventilation, and response to CO₂.

Quickening of Respiration.—This is seen occasionally with therapeutic doses in man (Higgins and Means, 1915) and occurs at certain stages in animals.

In the dog, the hypodermic injection of morphine first causes a quickening of respiration (perhaps through nausea) followed in fifteen minutes by the typical slowing (Mayor, 1908). *In frogs*, the slowing is succeeded by quickening, just prior to the convulsive stage. A *secondary quickening* is also seen in rabbits (Filehne, 1879; Cerna, 1892) but never in man.

Diminished Sensibility to Asphyxia.—In normal animals, excess of carbon dioxide and deficiency of oxygen increase the depth and rate of respiration. Morphine greatly dulls this response (A. Loewy, 1890; Henderson and Scarbrough, 1910; Lindhard, 1911; Cushny, 1913; Cushny and Lieb, 1915); apnea is very easily produced and very persistent (Filehne, 1879); the blood becomes very venous (Filehne and Kionka, 1895). Schmidt and Harer, 1923, and Schmidt, 1924, attribute the diminished response to CO₂ to slowing of active expiration.

Respiratory Reflexes.—The effects of morphine vary for the different reflexes. In general, it tends to increase the sensibility to inhibitory and spinal reflexes, and has little effect on acute augmentory reflexes (Cushny, 1913; Dooley and Andrews, 1923; Cohen and McGuigan, 1924).

Other Opium Alkaloids on the Respiration.—The effects of the morphine derivatives, codeine, heroine, dionine, etc., are essentially the same as those of morphine (Issekutz, 1911). Contrary claims have been due mainly to insufficient acquaintance with the actions of morphine. In man, the respiratory effects of 5 mg. of heroine correspond almost quantitatively to those of 15 mg. of morphine (Higgins and Means, 1915).

Codeine has the material advantage of relative freedom from undesirable side actions and is therefore preferable in cough. Heroine has no real advantage; it is at least as liable as morphine to induce habit formation; and it is much more toxic (Harnack, 1899). Morphine is much more effective than its derivatives in quieting dyspnea.

The alkaloids of the papaverine group generally stimulate the respiratory center; so that opium is rather less depressant to the respiration than would be expected from its morphine content (Macht, 1915).

Diacetyl-morphine (Heroine) on Respiration.—This derivative was introduced by Dreser, 1898, with the claim that therapeutic doses lessen the cough reflex and slow

the respiration; but that the inspirations are deepened and more powerful, so that the alveolar air is more effectively ventilated. Independent workers, however, have shown that there is no real difference from morphine (Fraenkel, Harnack, Lewandowsky, Santesson, Winternitz, 1899; Issekutz, 1911; Cushny, 1913).

Codeine.—Whilst therapeutic doses (1 to 2 mg. per kilogram, for rabbits) agreed with morphine, convulsive doses (20 mg. per kilogram) increased the ventilation and the CO₂ response (Macht, 1915).

Bronchial Muscles.—These are slightly relaxed by therapeutic doses of morphine, and more powerfully by papaverine and narcotine (Pal, 1913; Macht, 1915); whereas large doses of morphine, codeine, dionine, and especially heroine, narcotine and thebaine, produce marked constriction. Higgins and Means, 1915, observed bronchial constriction in man with 15 mg. of morphine or 5 mg. of heroine. The relaxation may play a part in the relief of bronchial spasm (*asthma*); whilst the constriction may contribute to the asphyxia of toxic doses.

The effects are peripheral, for they occur on excised bronchial muscle (relaxation, Trendelenburg, 1912) as well as in pithed (constriction, Jackson, 1914, 1915, and 1916) and in intact animals (relaxation with small, constriction with large doses; Brodie and Dixon, 1903). The constrictor action is not antagonized by atropine and must therefore be on the muscle or myoneural junction. It can be overcome by powerful dilator (sympathetic) stimulation (epinephrine, hordenine, Jackson, 1914 and 1915).

The combination of morphine and narcotine in dilator concentration gives *less* dilation than ether alone (Macht, 1915). This is similar to the behavior of the coronary action.

Bronchial Secretion.—Unless there is nausea, the secretion of mucus appears diminished; particularly in bronchitis. This may be explained largely by the suppression of cough, permitting a longer sojourn of the mucus in the bronchi, with consequent removal of its water by absorption and drying; but there may also be a central depression, analogous to that of the salivary secretion, for a decrease of tracheal secretion has been demonstrated in animals (Rossbach, 1882).

Circulation.—*Therapeutic doses* of morphine or its derivatives do not affect the circulation materially. In man, there is generally an (indirect) increase of *pulse rate* immediately after an injection; this is quickly followed by persistent moderate slowing, with increased fulness and force (stimulation of vagus center). The blood pressure, after a short rise, may remain level (Anderes, 1913), or falls slightly (Guinard, 1895), through the slowing, and perhaps through incipient depression of the vasomotor center. The cutaneous vessels are markedly flushed.

With *toxic doses*, the fall of blood pressure is more marked (central vasomotor depression), and the pulse becomes weak, varying in rate, and often arrhythmic (stimulation of vagus center and disturbed cardiac conduction).

The heart muscle suffers indirectly, by the low blood pressure and asphyxia (hence danger in cardiac insufficiency, especially when combined with dyspnea). Ordinarily the circulation remains fairly good, until death occurs by paralysis of respiration. Direct depression of the heart is produced only when morphine, or especially its derivatives, are perfused directly through the heart.

Hering, 1915, believes that the increased vagus tone resulting from large doses may indirectly produce ventricular automatism, or even fibrillation, especially in pathologic hearts tending in that direction.

Vagus Center and Cardiac Conduction.—Dogs show the same phenomena in more marked degree. The preliminary acceleration is due to nausea. The typical slowing

does not occur after section of the vagi, and is therefore central. It occurs with very small doses, increases with larger doses, and passes into arrhythmia (van Egmond, 1911; Anderes, 1913). Electrocardiograms also show central vagus stimulation (Einthoven; Cohn, 1913); and sinus-auricular and auriculo-ventricular heart-block, separate or combined, removable by atropine (Eyster and Meek, 1912, 1913). The reflex excitability of the vagus center is also increased (Jackson and Ewing, 1914).

The effect on the pulse rate is inconstant in cats, absent in rabbits (Egmond). Anderes found constant slowing in rabbits, the vagus stimulation being partly central, partly peripheral through decrease of the negative thoracic pressure.

Morphine sensitizes the vagus center to *epinephrine* (Heinekamp, 1919).

The cardio-inhibitory center of the turtle is stimulated by perfusing morphine through the medullary circulation (Bush, 1920).

Cardiac Muscle.—On the Langendorff excised *mammalian heart*, morphine and all its derivatives first increase the rate and amplitude; this is followed by decrease, and finally systolic standstill (Vinci, 1907).

The heart of dogs shows only depression with morphine or heroine; and heroine is also purely depressant to the heart of rabbits, and is 2 to 4 times as toxic as morphine (Arbuzow, 1917).

The rate of the perfused, atropinized *frog's heart* is quickened by dilute, slowed by more concentrated solutions of all the papaveraceous alkaloids; morphine being the least deleterious (Hale, 1909). Lippens, 1908, found peronine highly toxic for the turtle's heart. Narcotine is the most toxic of the opium alkaloids, for the heart (Macht, 1915). Papaverine lowers the cardiac tone (Pal); this is followed by considerable tachycardia (Renon and Desbouis, 1914).

The *tonus-waves of turtles' auricles* are augmented by morphine, depressed by papaverine and benzyl alcohol (C. D. Snyder and Andrus, 1919).

Cardiac Ganglia.—These show degenerative histologic lesions, similar to those of alcohol or chloroform (Lissauer, 1914).

Coronary Circulation.—This is quickened, by dilation of the coronary vessels, by most of the opium alkaloids. The action is most marked with narcotine and papaverine, slight with morphine, very slight with codeine, heroine or pantopium, and absent with narceine and thebaine (Macht, 1915).

Vasomotor Effects.—These have not been satisfactorily investigated. Gscheidlen, 1869, found that the center is not completely paralyzed even in advanced poisoning; stimulation of the spinal cord still gives a rise. The venous *pressure* is not changed by moderate doses, slightly lowered by toxic doses, indicating vasodilation (Capps and Matthews, 1913).

Cerebral Circulation.—The effects are small and inconstant with ordinary doses. Huerthle, 1889, found sometimes an increase, sometimes a decrease, of the flow. Aliprandi, 1905, describes a brief constriction, followed by lasting dilation. Frankfurter and Hirschfeld, 1910, describe an initial increase of brain volume, followed by decrease, the latter probably due to the fall in general blood pressure.

Action on Skin.—Morphine and its esters have a direct mild irritant action on the skin, resulting in erythema, itching and wheals. These effects are marked with local application to the scarified skin, and occur to some degree after the internal administration of therapeutic doses.

Circulation of the Skin; Diaphoretic Action.—The cutaneous vessels are specifically dilated even by small doses. The skin is reddened, warm, and the perspiration increased. This action is utilized, in the form of Dover's powder (Pulvis Ipecac et Opii, 0.5 Gm. at night) for the "abortion" of colds. In susceptible individuals, the cutaneous dilation may give rise to exanthemata. With toxic doses the skin becomes pale (vasodilation of the splanchnic area), and cyanotic (asphyxia).

Other Poisons Which May Produce Erythema on Systemic Administration are: atropine, quinine, chloral, barbital, benzol derivatives (antipyrine, cinchophen, salicylates, aspirin, etc.), iodides, bromides, sera, etc.

Wheals.—The local application of solutions of morphine or any of its esters to the scarified skin results in the production of an urticarial wheal (Philipsson, 1899; Toisk and Hari, 1903; Jadassohn and Rothe, 1914; Sollmann, 1917). Similar wheals are produced by histamine, peptone, emetine, and calcium chloride (Sollmann and Pilcher, 1917).

The susceptibility to wheal formation is the same in addicts as in normal individuals; so that tolerance is not acquired by habituation (Pilcher and Sollmann, 1923). This wheal formation is responsible for the itching and probably for the sneezing that are sometimes noted in morphine-poisoning. The pruritus was described by the Greeks, but seems to have fallen into oblivion until quite recently (Francis Adams, 1830; Edinburgh Med. and Surg. Jour., 1: 315).

Conjunctival Reaction to Ethylmorphine (Dionine).—The direct application of a 1 to 5 per cent. solution or ointment produces burning pain, hyperemia, and acute edema of the lids and conjunctiva, which disappears without any ill effects. This reaction is used in ophthalmology for the removal of old inflammatory products.

The edema, which is ascribed to vascular congestion, appears in a few minutes and lasts for several hours. There is also some more persistent local anesthesia. The pupils are at first constricted, and the intraocular tension is raised (Toczyski, 1912). The edema does not occur in rabbits, but readily in dogs or cats (Axenfeld, 1905).

Benzoyl-morphine (peronine) is said to act in the same way; but the effect does not occur with morphine, codeine, heroine, or any of the natural opium alkaloids.

Effect on Pupils.—In man (not in animals) even small, scarcely analgesic doses of morphine constrict the pupils. The miosis is due to a stronger constrictor (oculomotor) tone; for it disappears when the oculomotor endings are paralyzed by atropine; whilst it is scarcely affected by cocaine, which stimulates the sympathetic endings. The action is central, for it is not produced by local application. It has been suggested that morphine depresses the inhibitory impulses which normally keep the oculomotor tone in abeyance (Meyer and Gottlieb). There is a fairly lasting rise of intraocular pressure (Myashita, 1913). Ethyl-morphine produces a shorter rise.

The oculomotor center (pupillo-constrictor) appears to be normally in a state of partial inhibition through a variety of sensory impulses. When these are diminished—as by sleep, narcosis, and in a specific manner by morphine—the oculomotor tone increases, and the pupils contract. When the inhibitory impulses are reinforced—as by emotion, electric stimulation of the cerebral cortex, asphyxia, etc.—the oculomotor tone is diminished, and the pupils dilate. That this type of mydriasis is not due to stimulation of the sympathetic (dilator) center, is shown by the fact that it occurs after division of the cervical sympathetic nerve (Braunstein, 1894).

Local Application of Morphine to Eye.—Ganter, 1924, claims that 1 per cent. solution produces spasm of accommodation, even after atropine. This agrees with the general tonus effect on smooth muscle. The pupil is not changed by local application, because the sphincter and dilator tonus are both stimulated.

Pupil Changes in Animals.—In cats, the pupils are dilated, in conformity with the general excitement. In dogs, the effect is variable, but generally dilator.

Spinal Cord.—Morphine and all the members of the group increase the spinal reflexes.

Large doses, in frogs, produce convulsions which are indistinguishable from those caused by strychnine. Mammals generally die from the respiratory depression before the convulsant stage can develop; but the smaller mammals may exhibit muscular stiffness and tremors. Convulsions are sometimes seen, even in man, when toxic doses (3 grains) are taken (A. Gordon, 1915; Keen). In dogs, the *intraspinal* (subarachnoid) injection of morphine produces marked convulsions (McGuigan and Ross, 1915).

A *tabetic patient* responded by marked increase of spinal reflexes to a toxic dose (2 grains) of morphine (Orsnato, 1918).

The convulsant action is especially strong in *thebaine*, so that this is generally placed in the strychnine group.

The spinal stimulation would seem to contraindicate the use of morphine in convulsant conditions of spinal origin, as in strychnine poisoning. Practically, however, the analgesic effect may offset this disadvantage; nor does the theoretical objection hold against convulsions that are not spinal.

Sensory Nerves.—Opium and its alkaloids have no action whatever on the sensory endings, or on the peripheral sensory nerves, for the site of application is no more affected than other regions of the body (Jolly and Hilsmann, 1874). Their local use is therefore irrational. Any apparent success is largely psychical; although there may be some central analgesia, since morphine is readily absorbed from wounds and mucous membranes, and to a slight extent even from the unbroken skin. With the time-honored "Lead and Opium Wash," the precipitate formed by the lead with the gums and meconic acid furnishes a soothing protection. (The morphine is not precipitated by the lead.)

A slight local analgesic effect was reported by Macht, Johnson and Ballinger, 1916, and confirmed by Sollmann, 1917 (endermic method). This, however, is so slight, brief and superficial that it is doubtful whether it has any part in the therapeutic analgesia.

Curare Action.—All the members of the group, when applied directly to a muscle preparation, exert a weak and slow curare action: If the motor nerve is stimulated with a tetanizing current, the muscle responds with a series of rapid separate contractions, instead of a fused tetanus. Larger doses paralyze the muscle-nerve endings completely. Diacetyl morphine acts more powerfully than morphine or codeine; but the action is too weak to be observed in intact mammals (Hale, 1909).

Urinary Bladder.—Toxic doses of morphine produce spasm of the vesical sphincter, leading to distention of the bladder and constant but ineffective desire for micturition. This sometimes occurs in the therapeutic use (Czapek and Wassermann, 1914). In guinea pigs the distention may rupture the bladder (Tappeiner, 1899).

The effect is apparently the result of a depression of a detrusor center in the sacral cord; and this produces reflexly a reciprocal spasm of the sphincter. The effect is diminished by habituation (Ikoma, 1924).

Other Opium Alkaloids.—The other phenanthrene alkaloids also produce powerful contraction on intravenous injection in dogs (D. E. Jackson, 1916). The isoquinoline alkaloids (papaverine) relax (Macht, 1918).

Straub's Mouse Test.—White mice respond to the hypodermic injection of morphine (0.02 mg.) or its esters by a characteristic S shaped stiff erection of the tail. The same effect is produced by other convulsants, but generally only with larger doses (Rassers, 1916), for instance by nicotine, 1 mg. per 15 Gm. mouse (Jensen and Runry, 1918).

With all these drugs the phenomenon appears to be due to intense tenesmus of the anal (and bladder) sphincters, originating in the medulla and transmitted through the pelvic nerves (Van Leersum, 1918). Heinekamp, 1922, refers it to stimulation of the spinal cord. It does not appear to be a direct effect on the muscle, as was believed by Macht, 1920.

Ureter.—The phenanthrene (morphine) alkaloids increase the contractions and tonus, whereas the isoquinolines (papaverine) inhibit the contractions and relax the tone. With the combined alkaloids (pantopium) the inhibitory action predominates (Macht, 1916). This would aid the analgesic action in renal colic. Opium would be more effective than morphine.

Seminal Ducts.—These react like the ureter (Macht, 1916).

Uterus.—Morphine probably tends to delay the progress of labor, by its psychic sedative action, largely by preventing the reinforcement of labor pains by the contraction of the abdominal muscles (Barbour and Copenhaver, 1916). It has practically no effect on the normal uterine contractions in animals, *in situ* (Barbour, 1915). When applied directly to the excised uterus, the tone is somewhat increased (Barbour and Copenhaver, 1915); but this would have no clinical bearing.

Nausea, Emesis, and Anti-emetic Action.—Morphine tends to produce nausea and vomiting, and thus to disturb digestion. The effect is independent of the mode of administration, the action being central.

The severity varies greatly in different individuals. In some cases it is so serious, and accompanied by so much depression, as to preclude the use of the drug. It may sometimes be lessened by bromide or by atropine (I. Simon, 1907).

With large doses, the emesis is followed by diminished susceptibility to vomiting. This action is also mainly central (Leake, 1922).

Site of the Emetic Action.—Eggleston and Hatcher, 1915, showed that this is essentially central; for it occurs when all afferent impulses from the digestive tract are excluded; and it is also evoked when very small quantities of morphine or acetyl-morphine are applied directly to the floor of the fourth ventricle (Hatcher and Weiss, 1923).

It may conceivably be aided by reflexes from the gastric spasm; for atropine appears to diminish the emetic tendency. There is no evidence of local gastric irritation, although the alkaloid is rapidly excreted into the stomach. Vomiting occurs more readily with hypodermic than with intravenous injection; probably because the latter depresses the vomiting center too rapidly.

The emesis is produced by absolutely pure samples, and is therefore not due to contamination with apomorphine (even prolonged boiling does not convert morphine into apomorphine, (Feinberg, 1913)).

Relative Emetic Action of Opium Alkaloids.—Morphine is more nauseant and emetic than the other isolated alkaloids (Macht, 1916). Opinions differ as to the position of the combined alkaloids. Eggleston and Hatcher, 1915, believe that the emetic effect of pantopon and narcophine is more powerful than would correspond to their morphine content. As narcotine alone is not emetic, it would be conceived as sensitizing the center to morphine. Macht, Herman and Levy, 1916, incline to the opposite conclusion.

Salivary Secretion.—The nausea, as usual, is accompanied by salivation. In the absence of nausea, the mouth is dry and the patient thirsty, from depression of the salivary center (V. E. Henderson, 1910).

The *appetite* is diminished, through the lesser perception of hunger, and through the gastric derangement.

Gastric Secretion.—Morphine starts the gastric secretion in the empty stomach (therefore contraindicated in gastric ulcer), but is said to diminish the secretion when the stomach contains food (Chiari, 1915). It also increases the pancreatic secretion. Opium increases gastric secretion, but causes a lasting decrease of pancreatic flow (Bickel and Pincussohn, 1907; O. Cohnheim and Modrakowski, 1911). In chronic morphinism, gastric secretion is said to be abolished (Hitzig).

Antemetic Action.—Dogs, after a primary emesis, do not respond to irritant emetics or apomorphine. This has been attributed to paralysis of the vomiting center; but it could also be explained by the firm contraction of the cardiac sphincter (Magnus, 1908); for morphine, codeine, or heroine are antemetic in doses which are not narcotic, whilst chloral or urethane, to prevent vomiting, must be exhibited to full narcotic action (v. Issekutz, 1912; Ruth, 1913). Papaverine is not antemetic (Ruth).

Constipative Action.—Morphine produces constipation, and is one of the most effective means of arresting all kinds of diarrheas. Small doses suffice for this purpose. Opiates are even somewhat more effective than the dose of morphine contained in them. The constipative effect is an undesirable side-effect in the analgesic use of the opiates, but is valuable for quieting peristalsis in acute inflammations of the intestines or peritoneum.

Mechanism of the Constipative Effect.—This involves several quite distinct actions on the different parts of the alimentary tract. The most important elements are:

(1) *Persistent spasmodic closure of the gastric sphincters*, particularly the prepyloric sphincter. This slows very greatly the entrance of food into the intestines, and therefore minimizes the mechanical stimulus to peristalsis, and thereby rests an irritated intestine. The action is peripheral.

(2) *Inattention to the rectal sensations*, and therefore decreased responsiveness to the defecation reflex. This also furnishes prompt relief in the tenesmus of diarrhea. The action is largely psychic.

(3) *The direct effects on the intestinal movements* appear to vary with conditions, and to be generally of subordinate importance. The normal time of passage through the small intestines is usually a little slowed, about to the degree that would be expected from the slowed entrance of the food. The direct effects have been described discordantly. Sometimes there is marked slowing, due probably to diminished response to the distensive stimulus of peristalsis. This is perhaps more marked in the colon than in the small intestines. Marked quieting of the peristalsis of the small intestines is produced in some varieties of acute enteritis, for instance in colocynth diarrhea. Under other conditions, however, the direct effects on the intestine may consist in increase of tone and of the peristalsis. This may occur with small doses and is the regular result of large doses in animals, so that dogs, for instance, respond by catharsis; but this is unusual in man.

All the intestinal effects are peripheral.

Relative Share of the Actions in the Constipative Effect.—This doubtless varies with conditions. In normal man, the rectal stasis causes apparently the largest delay; and this is also the main element in the prompt relief of diarrheas. The gastric stasis is however also important; and is indeed the main element in resting and protecting the intestines. The importance of the direct intestinal action cannot be estimated from the present data.

Comparison of Opium Alkaloids.—The morphine esters act similarly; acetyl-morphine being perhaps somewhat more, and codeine considerably less active than morphine. The alkaloids of the isoquinoline group (papaverine etc.) depress smooth muscle and therefore tend directly to diminish peristalsis. Opiates are distinctly more effective than would correspond to their morphine content; mainly because of the additive effect of the other alkaloids, and partly perhaps because of the slower absorption and more prolonged local and central action.

Historical.—Although the constipative action of the opiates has long been known, their analysis had to await the development of suitable methods of studying peristalsis. The older writers (discussed by Magnus, 1910) assumed depression of the local reflex which was assigned to the Auerbach and Meissner plexuses; or central stimulation of the inhibitory splanchnic fibers (Nothnagel, 1882). Neither theory was satisfactory. Experiments on excised intestines failed to explain the actions. A genuine advance was made by the application of Cannon's bismuth x-ray method, first by Magnus, 1906 and 1908. This showed especially the importance of the gastric contracture, which had however been described by Herich, 1901 and by Baas, 1904. The further analysis of the intestinal effects requires operative methods which are still incomplete. Interest in work with excised intestine has been revived by the use of distended segments, introduced especially through P. Trendelenburg, 1917.

Bibliography.—Uhlmann and Abelin, 1920, cite 314 titles.

The Roentgen Studies of Magnus.—Magnus investigated the constipative action on the quasi-physiological diarrhea that can be maintained in cats by an exclusive milk diet. This diarrhea is very effectively stopped by morphine. The remedial action is equally pronounced when the intestinal nerves have been divided so that the action is certainly peripheral. On the *excised intestine*, however, morphine increases peristalsis (except with enormous doses), indicating that its constipating effect is not due to peripheral intestinal depression.

To solve the riddle, Magnus investigated the passage of the alimentary contents by the Bismuth x-ray method of Cannon. He now observed that morphine acts exclusively on the stomach, producing prolonged contracture of the sphincter antri pylori, as also of the pyloric and cardiac sphincters. As a result, the food remains for hours in the fundus, the complete evacuation occupying twenty-five hours instead of the normal three hours. The intestines thereby are granted a very large amount of physiological rest, the food entering very slowly and gradually, being more perfectly macerated and digested, and presumably relatively aseptic. This furnishes the whole explanation of

the constipating action in milk-diarrhea; for the same method shows that the movements of the small intestine are scarcely affected by the morphine, whilst those of the large intestine, as also the defecation of enemata, are quite unaffected by the drug. Nor has morphine any constipating action in experimental diarrhea from certain irritant cathartics, viz., senna, castor oil, or magnesia.

Entirely analogous phenomena are observed in the dog (Magnus; E. Zunz, 1909), and in the human subject. They are probably a highly important factor in the therapeutic effect. Magnus himself, however, suggested that morphine may possibly have further indirect actions on peristalsis by modifying intestinal secretion or absorption.

Colocynth Diarrhea.—This surmise was confirmed by the results of his pupil, Padtberg, 1911, in colocynth diarrhea. This drug produces exudation and increased movements throughout the alimentary tract. Both effects are antagonized by morphine (and much more by opium), even when the food is already in the intestine. The action of morphine in colocynth diarrhea is therefore different from its action in milk, senna, castor oil or magnesia diarrhea, in which morphine would not affect the progress of the food after this has reached the intestine.

Other Opium Alkaloids on Colocynth Diarrhea.—Takahashi, 1914, found that codeine acts similarly to morphine but weaker. Mixtures of morphine and codeine act stronger than either alone (potentiation), so that constipation occurs by combining one-fourth of the minimal active dose of morphine with one-fortieth to one-four hundredth of the minimal active dose of codeine. Equal parts of the two alkaloids constitute the best ratio. The other alkaloids do not seem to contribute, but rather to interfere; so that Pantopium, for instance, is inferior. Codeine also potentiates the gastric spasm, but only with much larger doses than are needed in colocynth. When used alone, the codeine does not produce gastric spasm.

Morphine on Gastric Digestion.—The retention of the food causes the digestion of meat to take place mainly in the pre-pyloric portion of the stomach, instead of the antrum and the duodenum (Zunz, 1921). This furnishes an index of the relative gastric effects of the opiates.

Relative Efficiency of Opiates on Gastric Contracture.—By the digestive index and by x-ray observations, only the morphine-esters produce the prepyloric spasm; with codeine the action is relatively feeble. The isoquinoline alkaloids (papaverine, etc.) are ineffective. Opium is more active than would correspond to its morphine content, probably because it is in less absorbable form (Zunz, 1921; Le Fevre de Arrie, 1918, 1921).

Direct Delay in Small Intestines.—One source of the confusion in the x-ray experiments is the time of administration of the opiate with reference to the food. Gordonoff, 1925, for instance, confirmed on dogs that when the opiate is administered with the food, the passage through the small intestines occurs in the normal time; but the gastric spasm retained the food in the stomach for $5\frac{1}{2}$ hours; so that the morphine effect had already waned. If the administration of the morphine was deferred till the food had entered the intestines, a marked delay resulted.

He found the effects of codeine similar to those of morphine, both on the stomach and on the intestines; and their mixture produced a simple addition of effects.

Roentgen Observations in Man.—These show delay in the passage of the food through all parts of the digestive tract; but the relative share of these appears to be quite inconstant even with normal subjects. Zehbe, 1913, reported that the time of the total sojourn of the food was nearly doubled by the opiates; more by opium and pantopium than by morphine and narcophine. That in the stomach and small intestines was lengthened each by about a third. The main effect, however, was on the colon and rectum. The defecation-reflex is delayed or suppressed (Stierlin and Schapiro, 1912; Schapiro, 1913; Mahlo, 1913).

On the other hand, Pancoast and Hopkins, 1915, observed the main delay in the small intestines; but little in the colon: the defecation-reflex was not observed. Small doses were more effective than large. Hypodermic and oral administration produced the same results.

Roentgen Observations on Chickens.—Steinmetzer, 1924, reports a quieting effect on the movements of the crop and gizzard; persistent spasm of a zone in the stomach; and no slowing of the intestinal progression.

Permanent Fistula.—These permit direct observations of peristaltic activity, without anesthetics. Plant and Miller, 1923, experimented on dogs, with doses corresponding to those used on man (0.1 to 0.5 mg. of morphine per kilogram, equivalent to $\frac{1}{10}$ to $\frac{1}{2}$ grains per man). These produced marked increase of the tonus and peristalsis of the small intestines. This was much more marked in denervated loops; it was not decreased by habituation. The stomach showed marked relaxation and decreased amplitude of contractions.

The morphine esters acted in the same directions; acetyl-morphine was somewhat stronger; codeine much weaker; the isoquinoline alkaloids had less effect on both stomach and intestines.

Abdominal Window.—Katsch, 1913, sewed a celluloid window into the abdomen of rabbits, which permitted a view of the cecum. When the animals had recovered, morphine in large doses (10 mg. per Kg) was administered, and this was followed by very marked slowing of the rate of peristaltic waves in the cecum, from 2.4 to 0.1 per minute. With the same method, Gordonoff, 1925, found more often stimulation; illustrating the variability of the response and the caution that is necessary in generalizing from a few observations.

Excised Intestine.—Simple suspension, by the Magnus method, as well as the distention method of Trendelenburg, has given confusing contradictory and negative results that seem at present irreconcilable. The views of Uhlmann and Abelin, 1920, are perhaps the most widely accepted at the moment. They hold that the effects on the small intestines are essentially similar in excised intestines and in living animals; namely that very small doses depress the peristalsis; slightly larger doses stimulate the movements; and still larger doses produce a maximal stimulation, followed by paralysis. The peristaltic movements are much more susceptible than the pendulum movements of the longitudinal muscle; and the latter is depressed without stimulation. They also believe that the differences between morphine and the opiates are merely quantitative.

It is difficult, however, to explain the discordant results of other workers by this schema. Le Barre, 1923, believes that the choline-content of the intestines has a large influence.

Gall-bladder and Bile Flow.—Large doses of morphine increase the tone of the sphincter of the biliary papilla, and thus hinder the flow of bile (Reach, 1914). Lieb and McWhorter, 1915, state that the musculature of the bile-bladder is not affected; but Macht, 1917, claims that the gall-bladder reacts to the opium alkaloids like the ureter, *i.e.*, that it is stimulated by morphine, depressed by papaverine.

Metabolism.—The output of CO_2 , and to a lesser degree of urinary nitrogen, are materially decreased, mainly by the muscular quiet; in prolonged experiments also by the digestive derangement. The CO_2 content of the blood rises, through the defective respiration. The *urine* often contains *reducing substances*, partly morphine-glycuronic acid (P. Mayer, 1899), partly glucose from the asphyxia. The flow of urine is said to be decreased (Ginsberg, 1912). The body *temperature* is lowered through diminished heat production.

Lessened CO_2 Output.—That this is due to muscular depression is shown by the fact that cats exhibit an increase (Boeck and Bauer, 1874), and this is also the result in other animals with the more stimulant members of the group, as codeine. In man, however, the oxygen consumption is not altered, whilst the CO_2 production is decreased. The paradox is not explained (Higgins and Means, 1915).

Ratio of Urea to Total Nitrogen.—This is not altered.

Alkali Reserve.—Large doses of morphine would be expected to produce asphyxial acidosis. Smaller doses (10 mg. per Kg for dogs), however, appear to increase the alkali reserve for several hours (Hjort and Taylor, 1919). The *urine* becomes strongly alkaline, by the excretion of carbonate, after narcotic doses in dogs; rabbits' urine does not show any change of reaction (Underhill *et al*, 1917).

Habituated Animals.—These do not show the depression of basal metabolism and the tendency to acidosis (Schoen, 1924).

Growth.—The phenomena will be discussed under *Chronic Opiumism*.

Hyperglycemia.—Large doses of morphine produce considerable hyperglycemia, presumably due partly to the defective respiration. In dogs, the hypodermic injection of 10 mg. per kg. increases the blood sugar, on the average, by 60 per cent. in $\frac{1}{2}$ hour and 77 per cent. in $1\frac{1}{2}$ hours (E. L. Ross, 1918). A peculiar reducing substance in human urine is described by Spitta, 1908.

The morphine hyperglycemia is much greater after partial destruction of the pancreas (Auer and Kleiner, 1917).

Insulin lowers the blood sugar level as much as in other hyperglycemias (Stewart and Rogoff, 1923).

Relation to Adrenals.—Stewart and Rogoff, 1921 and 1922, showed that morphine hyperglycemia differs essentially from asphyxial, pique and ether hyperglycemia; in that the reaction to morphine is decidedly less if the adrenal glands have been removed; whilst this does not affect the other hyperglycemias.

Temperature.—The fall (which is sometimes preceded by a slight rise) may be as great as 2°C. with large doses; the extent depending, however, more upon idiosyncrasy than upon the dose. The cooling is particularly great if the animal is kept in cold surroundings. With small doses, the fall may be explained by increased heat loss from cutaneous vasodilation; but with large doses it is due mainly to diminished heat production, and finally to circulatory collapse. The heat production may be reduced by 80 per cent. in extreme cases, reaching its minimum in the third hour. The heat loss is diminished (up to 20 per cent.), partly through the effort of the heat centers to compensate for the diminished production, partly through the depressed circulation (Reichert, 1901).

Regulation of Blood Volume.—Morphine hinders the transfer of injected saline solution from the blood to the tissues (Bogert, Underhill and Mendel, 1916).

Leucocytes.—These are diminished in acute and chronic morphine poisoning (Cloetta, 1903). The injection of morphine inhibits the migration of leucocytes in inflamed frog's mesentery (Ikeda, 1916).

Morphine also diminishes phagocytosis *in vitro* (Arkin, 1913); but the concentrations would be very different from those obtaining clinically.

Protozoa.—The papaverine group is very toxic to these organisms; whereas the morphine group is relatively ineffective (Macht and Fisher, 1917, Bills and Macht, 1924). *Trypanosoma brucei* is killed *in vitro* by both groups, but especially by the papaverine group. *In vivo* (rats) both groups are ineffective (Macht and Weiner, 1918). The amebicidal action of emetine, which is also an isoquinoline derivative, prompted Pick and Wasicky, 1915, to suggest the trial of papaverine against amebic dysentery; but it does not seem to have been successful.

Absorption, Fate and Excretion.—Morphine is rapidly absorbed from all mucous surfaces, and from the abraded skin; but scarcely, if at all, from the intact skin. It disappears from the blood, being partly fixed in the organs, and largely destroyed, so that only a fraction can be recovered at autopsy. A part is excreted unchanged. In acute poisoning with large doses, administered hypodermically to dogs, one to two-thirds of the morphine can be recovered from the feces. The urine participates in the excretion, usually to a smaller degree. The destruction is much more complete in habituated animals, thus accounting partly for the increased tolerance for morphine.

Some of the morphine is said to be excreted by the milk and to cause morphinism in sucklings. It also passes through the placental circulation to the fetus, sometimes killing the latter *in utero* (Jung, 1914).

The investigation of the fate of morphine is of great scientific, as well as of practical toxicologic interest. Unfortunately it is beset with considerable difficulties. The methods of isolation are complicated, and the more or less firm combination and partial alteration of the morphine in the body render its quantitative isolation in pure form practically impossible. Marquis, 1896, believed that it exists in the tissues in three different forms.

Disappearance from the Blood.—The morphine usually ceases to be demonstrable within twenty minutes, although it is not destroyed by the blood (Cloetta, 1903). It must therefore have passed into the tissues.

Excretion by the Urine.—The conclusions as to the importance of the urinary excretion appear to differ with the methods of isolation. The more recent data indicate that it may exceed the fecal excretion (Takayanagi, 1924). Kaufmann-Asser, 1913, found that dogs and rabbits excreted by urine 3 to 23 per cent. of the morphine in acute poisoning; and to 39 per cent. in chronic poisoning. Kaufmann found it quantitatively in less than two up to thirty-six hours; negative in fifty hours.

Excretion by Milk.—Contrary to the usual statement, Koledwijn, 1910, found that this does not occur (in cows and goats). The subject requires investigation.

Excretion by Saliva.—Rosenthal, 1893, showed its presence in man, after 0.05 Gm. per day.

Gastric Excretion.—This was discovered by Marmé, 1883; but it occurs only in traces, and has no practical significance (Hatcher, 1925). Alt, 1880, believed the gastric excretion to be so extensive, that the re-absorbed morphine would contribute materially to the toxicity. Accordingly, gastric lavage was practiced for many years, after hypodermic as well as after oral administration, and also after diacetyl morphine. Langer,

1912, Kleiner, 1913). However, Hatcher could find only traces of morphine in the stomach, after hypodermic administration of toxic doses, in man as well as in animals.

Excretion by Intestine.—Marquis found morphine in the large intestine one hour after intravenous injection; in the small intestine only after two hours. The large intestine contains the larger amount. This indicates that morphine is excreted by the mucosa of the whole alimentary tract. With oral administration, the morphine may reach the intestine directly, within half an hour (Kauzmann). The bile may contain traces in twenty-five minutes, but is generally negative (Kauzmann). The intestinal excretion is increased by *intestinal irritants* (quillaja senega, alcohol), even when the morphine has been administered hypodermically (McCrudden, 1910).

In dogs, it is said to be diminished by vegetable diet, (Valenti, 1914).

Quantity Excreted by the Feces.—In non-habituated animals, one-fourth to one-third of the administered morphine can be recovered from the feces (Cloetta, 1903; Tamura, 1920). Faust, 1900, found that non-habituated dogs excreted by the feces 66 per cent. of the morphine which had been injected hypodermically.

With repeated injection, as the animals became habituated, the feces contained less and less morphine (26 per cent. after twenty-one to twenty-four days; 8 per cent. after twenty-nine to thirty-two days; none after forty days); although the later doses were up to 50 times as large as the earlier doses. It is evident, therefore, that the power of the organism to destroy morphine is greatly enhanced by habituation.

Presence in the Tissues.—These contain only a fraction of the morphine—for the most part mere traces. The largest quantity is usually found in the liver and in the contents of the alimentary canal (Kauzmann, 1868; Marquis, 1896). The brain of poisoned animals is very poor in morphine although *in vitro*, brain substance fixes the alkaloid much better than liver pulp (Cloetta, 1903).

The Distribution of the Morphine in Various Organs.—This is described for cats and rabbits by Homburger and Münch, 1916; for rabbits by van Rijn, 1908.

Quantity of Morphine Recovered from the Tissues.—Cloetta, 1903, succeeded in recovering about one-third of the injected morphine from the entire bodies of non-habituated rats and pigeons killed in five to twenty-four hours after the injection of large doses of morphine. The same quantity was recovered from animals which had been habituated, but left without morphine for two days prior to the final injection (to permit the complete elimination of retained morphine). This indicates that the destruction is not a rapid process, even in habituated animals.

Destruction of Morphine in the Body.—The facts described in the preceding section leave no doubt that the morphine is largely destroyed; but as to the place and manner of this destruction, the evidence is incomplete. It indicates that the morphine may be destroyed in various organs, and more actively in habituated animals.

Tauber, 1890, could not demonstrate any destruction on perfusing morphine through excised liver or kidney. Cloetta, 1903, claims the disappearance of one-sixth to one-third of the morphine digested with oxygenated emulsions of lung, liver, and especially brain; no destruction with filtered extracts; so that the action is not due to soluble ferments, but presumably oxidative. The destruction is increased in habituated animals. Albanese, 1909, found practically no destruction by liver pulp, from either normal or habituated animals; but marked destruction during abstinence following habituation. Other organs showed similar but weaker destruction. Dorencourt, 1913, again claims that morphine is destroyed by liver *in vitro*, and that this is increased by habituation. (Theories of decomposition: Spitta, 1908.)

Gottlieb claims that the administration of *thyroid* prevents the destruction of morphine in white rats.

Fate in Chick-embryos.—If morphine is injected into fertilized eggs, which are then incubated, no destruction of morphine or its derivatives occurs if the embryo dies before it is half developed. If the development is completed, heroine is destroyed absolutely; morphine very largely, codeine and dionine not at all. The destruction therefore takes place only after a certain development, perhaps of the nervous system, has been reached. The alkyl groups protect the morphine against oxidation, just as they do in the adult organism, while the acetyl groups are evidently easily separated (Grueter, 1916).

Fate in Frogs.—In these, the destruction is very small, and no tolerance is acquired. The excretion is very slow, extending over eight days, and occurs exclusively through the alimentary tract (B. Frenkel, 1910).

Recovery after Burial.—This has been investigated amongst others, by Homberger and Munch, 1916, and Palet, 1919. The latter obtained positive tests after 7 months.

Fate of Codeine.—This behaves quite differently from morphine: about 80 per cent. is excreted unchanged, mainly in the urine, but somewhat also in the feces (Tauber, 1892). Repeated administration does not

increase its destruction, nor does it appear to produce tolerance in animals (Bouma, 1903).

Heroine.—The greater part is excreted unchanged in the urine; some also in the feces. A part is destroyed and this destruction is greatly increased in habituation (Langer, 1912).

Odorous Substances.—The substances which give the characteristic odor to opium are excreted largely by the urine, and also in the breath, sweat and milk.

Toxicology.—*Acute Symptoms of Morphine and Opium Poisoning*.—Suicidal and accidental poisoning by morphine or opium is common, and familiarity with its successive symptoms is therefore important. The following description of the morphine effects applies equally to opium (with ten times the dose); except that the symptoms do not appear quite (but almost) as promptly.

Moderate Therapeutic Doses (5 to 15 mg.; $\frac{1}{12}$ to $\frac{1}{4}$ gr. of morphine).—The symptoms set in promptly (five to ten minutes after hypodermic, fifteen to thirty minutes after oral administration). They begin with slight flushing of face, sensation of warmth and comfort, lassitude, giddiness, dreamy state, with free imagination but confused intelligence; mouth dry and thirsty.

The patient becomes sleepy; skin pale; respiration and pulse slowed; pupils constricted. Nausea and vomiting are exceptional with this dosage.

In a short time—the sooner, the larger the dose—a natural sleep sets in, lasting six to eight hours or more; the patient commonly awakens refreshed.

Intravenous Injection.—If the injection accidentally enters a vein, there is tinnitus, tachycardia, fainting, but usually rapid recovery.

Larger Therapeutic Doses (20 to 30 mg.; $\frac{1}{3}$ to $\frac{1}{2}$ gr.).—The initial symptoms are the same. Sleep occurs more promptly and is more profound. On awakening there is usually some confusion, nausea, anorexia, and constipation.

Toxic Doses (100 to 300 mg.; $1\frac{1}{2}$ to 5 gr.).—The initial symptoms are as described. The somnolence deepens rapidly into sleep and coma; severe symptoms being generally conspicuous in five to ten minutes after hypodermic, or fifteen to forty minutes after oral administration; rarely delayed for one or two hours.

In the earlier stages of the coma, the patient can be partially aroused to a confused consciousness, but relapses promptly into lethargy.

As the coma deepens (*i.e.*, almost always within two hours, and often in half an hour after taking the poison), the patient can not be roused, the reflexes disappear, the muscles relax, the jaw drops. The miosis becomes extreme ("pin-point pupil"); the skin cyanotic; fall of temperature; respiration very slow, irregular, often Cheyne-Stokes; pulse slow, feeble and often irregular. Convulsions are rare in adults, more common in infants; they are sometimes violent, but rarely if ever tetanic.

The respiration stops before the heart. The pupils almost always dilate as the terminal asphyxia sets in. (With heroine, death is due to the convulsions; Langer, 1912.)

The time of death is usually seven to twelve hours; but sometimes two hours or even less. Survival over twelve hours indicates a good prognosis.

Autopsy findings are not characteristic. There are only the common asphyxial lesions: Cerebral and meningeal congestion, sometimes with serous effusion; lungs

hyperemic and sometimes edematous; general venous congestion; rarely intestinal or cerebral ecchymoses.

Ordinary Fatal Dose.—With morphine, this is 0.2 to 0.4 Gm. (3 to 6 gr.); with opium, 3 Gm. (45 gr.). There is, however, considerable idiosyncrasy, and 60 mg. (1 gr.) of morphine must be regarded as dangerous. With 250 mg. (4 gr.) the prognosis is unfavorable, even under treatment, although patients have been saved after 4 Gm. (60 gr.) of morphine.

Recovery.—This may occur even after asphyxial convulsions. The respiration and pulse improve, the coma becomes lighter, and passes into a very prolonged sleep, often lasting for one or two days. On awakening, the patient is troubled with headache, constipation and digestive disturbances, often vomiting, itching, impotence of the bladder; exceptionally excessive depression. Sometimes the recovery is interrupted by a serious relapse, perhaps through the reabsorption of morphine from the intestine.

Idiosyncrasies.—Infants are highly susceptible to morphine; as to older children, there is difference of opinion. The female sex, and patients weakened by disease, succumb relatively easily. On the other hand, large doses are well tolerated in diabetes, in delirium tremens and in tetanus. In fever, morphine is sometimes exciting; in neurotic patients it may cause insomnia and delirium, instead of sleep. Nausea and vomiting are very pronounced in some individuals. Urticaria has been observed. Itching of the skin, especially of the nose, is a rather common symptom in poisoning. These idiosyncrasies should be remembered in the therapeutic use of the drug.

Death has been reported from almost incredibly small doses. Lewin cites two fatalities in children from 0.3 mg. ($\frac{1}{200}$ gr.) of opium. In adults, 0.2 Gm. (3 gr.) of opium ($\frac{1}{2}$ gr. of morphine), is credited with a death. The great variation in the susceptibility of different animals has been described, man being by far the most susceptible.

Hypersusceptibility of Infants.—Young animals are said to be more susceptible than adults, with the exception of cats. Doebeli, 1911, from a clinical and experimental investigation, concludes that the hypersensitivity, both in the human and in animals, applies only to the age before weaning, older children following the ordinary rule. This, he finds, is also the opinion of most pediatricists. The special susceptibility of sucklings is perhaps explained by the observation of Hunt, 1910, that a milk diet greatly increases the toxicity of morphine (for mice). The hypersusceptibility exists only for the narcotic action, and is, therefore, insignificant for codeine.

Influence of Thyroid and Iodides.—Hunt, 1905 and 1907, found that feeding with thyroid or iodides increases the susceptibility of mice, rats and guinea pigs to morphine. Githens and Meltzer, 1913, find in rabbits that iodide increases the morphine depression but lessens the tetanic effect, and therefore the fatality.

Adrenalectomy on Morphine Tolerance.—It has been claimed (Lewis, and Scott) that adrenalectomy rendered rats much more susceptible to the lethal effects of morphine. Rogoff, 1925, showed that this was based on inadequate estimates of the natural mortality after this operation, and that the susceptibility to morphine is not altered.

Diagnosis of Morphine or Opium Poisoning.—A prompt diagnosis is very important for proper treatment. The coma is the most conspicuous symptom, and its gradual development is characteristic. In advanced poisoning, it may be difficult to distinguish the morphine coma from other forms. The symmetrical pin-point pupils are important, but it must be

remembered that these dilate as death approaches (asphyxia). The odor is characteristic of opium poisoning.

Treatment of Acute Morphine and Opium Poisoning.—If the opiate was taken by mouth, the first indication is to *empty the stomach*. If narcosis has already set in, emetics may act too slowly, and it may be necessary to employ a stomach-tube. The best *chemic antidote* is *potassium permanganate*, about 0.5 Gm. per liter (5 gr. per quart) by lavage; or orally, 0.1 Gm. ($1\frac{1}{2}$ gr.) in a tumbler of water. Tannin is not very effective.

The patient should be *kept awake* as far as possible and in *constant movement*, since this contributes to the better tone of the medullary center. *Reflex stimulants* may be employed, such as *cold ablutions*, the inhalation of *ammonia* in the form of smelling salts, hypodermic injections of ether, etc. Caffeine should be administered, preferably in the form of strong, black, hot *coffee*. *Atropine* may be valuable if the dose of 1.5 mg. ($\frac{1}{40}$ gr.) is not exceeded. The patient should be kept *warm*. If the breathing shows signs of failing, artificial respiration should be supplied. *Oxygen* inhalation is also useful in the later stages (periodic respiration and anoxemia); the rate of respiration being increased, and the blood-pressure improved (Clark and Hamill).

When the danger is over, the *constipation* which usually follows should be relieved by cathartics and enemata.

Permanganate.—De Buscher (1904, 1905) found this effective in rabbits, even when it was administered three hours after the morphine; it was much less successful with dogs. It was quite ineffective if the morphine was given subcutaneously. Nothing could be expected from the hypodermic injection of permanganate, since this would be destroyed before entering the circulation.

Respiratory Stimulants.—Variable results are reported by different investigators. If the morphine asphyxia is interpreted as inattention to the CO_2 stimulus, a removal of this psychic fog would be required to restore permanently the excitability of the centers. No drug has yet been found quite successful for this purpose; the "improvement" being usually confined to an acute and temporary reaction. The discordant conclusions of a few workers may be quoted in illustration: Voegelin and Wiggers, 1918: Caffeine, moderate doses, marked improvement; atropine, slight improvement; camphor and epinephrine, doubtful. Meissner, 1923 (rabbits): improvement by ether or atropine hypodermically, camphor or cocaine intravenously. No improvement by caffeine, strychnine, epinephrine and aspidospermine. Schmidt and Harer, 1923 (dogs and cats): Caffeine, marked increase of rate and depth of respiration; aided by digitalis; camphor, variable; atropine, ineffective; CO_2 inhalation, dangerous. Haskell et al, 1924: Caffeine, in wide range of doses, unfavorable.

Atropine.—This has been used extensively and somewhat indiscriminately in the treatment of morphine poisoning. It may be a dangerous remedy. The most conspicuous antagonistic actions of these two poisons are on the pupil, heart-rate, psychic processes, secretions, etc.—i.e., upon functions which are of subordinate importance in dangerous cases of poisoning. Any useful antagonism must be sought in their actions on the circulation, respiration, and metabolism. The effects of morphine and atropine on these functions are antagonistic only with certain stages; whilst more severe grades are actually synergistic. The later paralytic effects of atropine coincide with those of morphine; whilst in the last stages of morphine poisoning the centers are too greatly depressed to respond to the slow and weak stimulation of atropine. *The usefulness of this antidote exists therefore only if moderate doses of atropine are given in moderate morphine poisoning (or vice versa).* This conclusion is supported by several series of experiments on animals. As a practical deduction, the atropine should be given hypodermically in the dose of 1.5 mg. ($\frac{1}{40}$ gr.) and this should *not* be repeated. It is fair to state, however, that this is not the universal opinion. For instance, Roch, 1907, advises 2 mg., frequently repeated, until the pupils begin to dilate.

Cocaine.—A general antagonism exists also between morphine and small doses of cocaine especially as regards the effects on temperature and metabolism. Larger doses

are synergistic, and as the susceptibility to cocaine is variable, the hypodermic dose of 0.01 Gm. ($\frac{1}{8}$ gr.) should not be exceeded.

Acute Heroine Poisoning.—Animals are killed by the convulsions; if these are prevented by etherization, almost double the fatal dose may be survived (Langer, 1912).

The literature of fatal heroine poisoning is reviewed by McNally, 1917.

Chronic Opiumism.—*Etiology.*—Opium, morphine, and heroine addictions are unfortunately widely prevalent and together with the cocaine habit (and to a much less extent of "hashish") they constitute a serious menace to civilization. All these drugs produce at first a feeling of well-being, relief and contentment, of stimulation and freedom of imagination, and of ease and facilitation of mental effort. These agreeable actions vary in degree in different individuals, and therefore all do not fall their victims with equal readiness; women and neurotic and dissipated individuals are especially in danger, if they become acquainted with the effects of these drugs.

The majority of the heroine and cocaine addicts begin the use through curiosity or dissipation (Drysdale, 1915; McIver and Price, 1916; Hubbard, 1920; Kolb and DuMez 1924); but prior to the restriction of the Harrison Narcotic Law, "patent medicines" (cough, consumption, diarrhea, and catarrh "cures," etc.) were responsible for many cases (A.M.A. Report, 1920, J.A.M.A., vol. 74, page 1324). Physicians must also be on their guard in prescribing these drugs, even in acute conditions.

The continued use of opiates will lead to the habit, or disease, in practically every one, and is therefore excusable only in exceptional conditions, such as hopeless, painful diseases (cancer, etc.). The very susceptible acquire the addiction in 10 days of continuous use; and there is little chance of escape if the drugs are used daily for 3 to 5 weeks (Hubbard, 1920).

Historical.—While the therapeutic use of opium dates back of Hippocrates, its habitual use seems to be of more recent origin. The first authentic records fall in the beginning of the sixteenth century. It would seem that its use is much older in India than in Turkey, and that the Mohammedans learned it through the conquest of the former country. Their acquaintance with cannabis indica is of much earlier date. The existence of the opium habit was at first confined to the Orient; its introduction into Europe and America is of modern date—it began in the United States about 1860.

Prevalence of Opium and Cocaine Addiction.—Accurate estimates are naturally impossible; but the consideration of various data justifies the conclusion that the expense and inconvenience of obtaining the drugs illegally, against the provisions of the anti-narcotic laws, have produced a marked decrease in the number of confirmed addicts. Kolb and DuMez, 1924, estimated the number of these in the United States as 264,000 in 1900, and as 110,000 at present. This is, of course, still a very serious figure. The evil has only been checked, not abolished. The same cause has practically driven out the less easily obtainable opiates used by smoking and by mouth, and led to the substitution of the more compact "heroine," which is now proscribed by law. Intensive cocaine addiction has also practically vanished because of the difficulty of obtaining supplies.

The United States narcotic laws have been very successful in regulating the legitimate trade in the narcotic drugs; probably only an insignificant proportion of the illegitimate supply comes from licensed dealers (Du Mez, 1924).

The further improvement in the narcotic situation depends partly on the success of police in dealing with smugglers and illegitimate dealers; on a popular understanding of the seriousness of starting the addiction; and on methods of treating confirmed addicts.

Opium Habit in Children.—This is unfortunately not at all rare. It is usually started by the indiscriminate employment of paregoric and other soothing syrups. They present the typical symptoms. Withdrawal of the medicine is followed by restlessness, wakefulness, and every indication of suffering and distress. The treatment would be mainly hygienic.

Forms of Opium Habit.—The drugs are introduced by all possible channels: by the mouth, hypodermically, by smoking, by suppositories; and heroine, like cocaine, by snuffing. The effects are similar in all cases.

At present addicts in the United States confine themselves almost exclusively to morphine and heroine, and use these mainly hypodermically; probably because of the more abrupt and therefore more noticeable response. Those who have become accustomed to the hypodermic method do not readily change to the oral use. The needle may be attached to a medicine dropper; sometimes the alkaloids are rubbed in the scarified skin. Heroine is also often "snuffed."

Comparison of Morphine and Its Esters.—In principle, all morphine esters are presumably capable of producing addiction; but practically the difference between them is very large. This depends on the quantitative response: the more powerful is the narcotic effect of the alkaloid, the more easily is the habit induced and carried on, and the more difficult is it to break. Heroine is rather more powerful than morphine, and the addiction is consequently somewhat more serious. The narcotic action of codeine is so slight that it is not very tempting to addicts, and really narcotic doses would be inconvenient to administer, and disproportionately expensive, so long as its sale is restricted. If restrictions were removed, however, so that it could be procured in unlimited quantities the situation might become very different. With medicinal doses of codeine, the psychic effects are so slight that they would scarcely be recognized by the patient; and there is therefore no temptation to increase the dosage; and the codeine can be withdrawn without much reaction on the part of the patient.

Heroine Addiction.—The phenomena are indistinguishable from those of morphine, and the treatment presents identical difficulties and dangers (Manguat and Blondel, 1903; Conar and Buvat, 1904; Farr, 1915; McIver and Price, 1916). The snuffing causes rhinitis (J. Phillips, 1912). Fatalities from overdosage are not uncommon.

Codeine Addiction.—The rarity of this may be judged by the report of Watson, 1922, that replies from 700 physicians, including sanatoria and prisons, do not record a single case of codeine-addiction. Only three cases are found in the literature, and these were so mild that they could be broken in a few days without marked abstinence symptoms. The dose recorded was 2 Gm. per day (cf. also Pelz, 1905; Petteys).

Practically no fatalities from codeine are on record, and the fatal dose is not known. Small doses may cause symptoms if there is idiosyncrasy.

Derivatives of codeine with more marked narcotic action produce addiction ("eukodal" and "parakodin;" Biberfeld, 1920 and 1921). The acquired tolerance does not extend to the convulsant action.

Smoking.—This is mainly practised in the Orient. Smoking opium (chandoe) is prepared by the Chinese, by a complicated process of roasting, and repeated extraction and evaporation. Its morphine content is about the same as that of ordinary opium. It has been claimed that the opium smoke does not contain morphine (e.g., Moissan, 1892; Hartwich and Simon, 1903); but Pott, 1912, has proved that morphine is indeed the active constituent. It has been said that Orientals are less injured by opium; but this is mainly because, in smoking, smaller quantities are consumed, with longer intermissions. The hypdermic method is now becoming the more popular, and with it, the Chinese present the same phenomena as Europeans (A. S. Rochester, 1900). The Chinese government has been making serious and fairly successful efforts to suppress the opium evil.

Effects of Opiate Addiction.—The immediate effects of morphine are essentially the same as in unhabituated individuals; but the response varies quantitatively, and somewhat qualitatively, because of acquired tolerance, and of the imminence of "abstinence-symptoms." These differ materially as regards the occasional opiate debauchee, and the steady addict.

Intermittent and Continuous Addicts.—The occasional user, for instance the opium-smoker, usually pushes the dosage to the toxic point, and thus obtains the dreams and the deep sleep. The steady consumer does not carry the dosage to that stage; partly because he has acquired tolerance; partly because of the side-effects; and partly because it would be impossible for him to work while under the toxic influence. Most patients whose addiction started with the therapeutic use of opiates have never experienced the imaginative toxic effects, but only the analgesia and euphoria; their first recognition of the addiction dates often from the withdrawal symptoms.

Euphoria.—Confirmed addicts generally use opiates rather as stimulants, or as the only apparent means of escape from the intense discomfort, nervousness, depression, and violent craving that follow the withholding of the accustomed dosage. These are quite analogous to intense hunger or thirst, and increase in intensity for several days, to a degree that is beyond the unassisted strength of most patients; especially when they dispose over the means of relief, *i.e.*, further dosage of the opiates (E. L. Bishop, 1913, 1920).

Acquired Tolerance.—The continued use of morphine or heroine leads to the gradual development of very considerable tolerance to the narcotic and toxic effects. This starts before addiction becomes confirmed. Addicts who aim to produce narcotic dreams are therefore driven to the use of ever-increasing doses, sometimes 10 or 20 times more than would be fatal to an unaccustomed individual. The tolerance, however, is never absolute, and death by accidental or intentional overdosage is the most frequent "excitus letalis" of morphinists.

On the other hand, patients who take morphine only as a stimulant are not so likely to increase their dosage beyond a definite, more moderate amount, soon ascertained by experience; and find it possible to resist or discontinue temporary increases beyond this point (Bishop); precisely as some smokers keep themselves on a fairly definite allowance whereas others are constantly increasing theirs.

The daily consumption of either morphine, heroine or cocaine ranges between 0.3 to 4 grams; but it is generally above 0.4 grams and would usually be between 1 to 2 grams, if supplies were obtainable (McIver and Price 1916; Kolb and Du Mez, 1924; Wholey, 1912, heroine). Even larger doses are claimed by patients; but their statements are often unreliable, since they are made in the hope that the drug will be withdrawn more gradually. The high tolerance diminishes if the drug is discontinued, but is readily re-acquired; and some degree of toleration persists long after the discontinuance.

The tolerance is explained partly by a very considerable increase in the power of the organism to destroy morphine; but since the destruction proceeds more slowly than the absorption, there must also be an acquired tolerance to the action of morphine. This does not extend to all the effects, but only to those that involve conscious or subconscious psychic activity; and to the respiration, which may presumably be included in these. No "antitoxin" is formed.

Duration of Tolerance.—This would be expected to vary with individuals, if psychic factors are prominent. Bishop, 1913, states that the tolerance persists unimpaired after seven months of abstinence. In animals on the other hand, the tolerance begins to diminish within ten days after withdrawal (Biberfeld, 1917).

Tolerance in Animals.—This can be induced in dogs (Faust), rabbits, goats, rats and pigeons (Cloetta, 1903). Frogs seem to become more susceptible.

Drug-reaction of Fish.—Goldfish (not minnows), when placed in a "graduated tank," rapidly develop preference for water containing alcohol, cocaine, morphine and certain other substances (Shefford, 1918). However, this is probably a sensory skin phenomenon, and is not analogous to the psychic craving of human drug habits.

The Explanation of Acquired Tolerance to Morphine.—This has been the subject of many investigations and theories. Marmé, 1883, aimed to show that morphine is transformed in the body into oxydimorphine, to which he attributed actions precisely the reverse of morphine. It would thus explain both the tolerance, and the abstinence symptoms. This theory has only historical interest, since Donath, 1886, and Marquis, 1896, have shown that oxydimorphine is not formed; and, moreover, the properties of this substance do not agree with the assumption of Marmé.

Another theory which may be dismissed is the formation of an antitoxin. Hirsch-laff, 1902, claimed that the serum of habituated animals is protective; but his experiments are discredited by the negative results of Morgenroth, 1903, of Cloetta, 1903, and of Pellini and Greenfield, 1920.

The increased destruction of morphine (Faust) and of heroine (Langer) in habituated animals must be a factor in the protection, but can not explain it completely. The experiments of Cloetta and of Ruebsamen, 1908, indicate that this destruction is a relatively slow process, so that the tissues must in the meantime be exposed to a large amount of morphine.

van Egmond, 1911, found that habituation to the toxic effect does not diminish the susceptibility to the central vagus stimulation. In dogs, the respiratory center becomes habituated to 1800 times the initial minimum effective dose; the pupil (dilator) reaction also becomes habituated. The order in which centers become irresponsive in morphine habituation are: pupil; emesis; defecation; narcosis; respiratory center. The gastric sphincters habituate slowly and imperfectly; the vagus center not at all. These differences in centers show that habituation is not a matter of destruction. Rabbits do not become habituated to morphine (as judged by narcosis and respiratory center (Van Dongen, 1915)).

Langer, 1912, also states that the acquired tolerance of dogs to the narcotic action of heroine does not extend to its convulsive effects. This persistence of some of the effects proves that the disappearance of others can not be due to destruction of the alkaloid.

Biberfeld, 1915, found no difference in the lipid content of the brains of normal and habituated animals.

Habituation also fails to diminish the susceptibility to the skin-reaction for morphine (Pilcher and Sollmann, 1924).

Crossed Tolerance.—Dogs habituated to morphine also show marked tolerance toward heroine and codeine, as regards the respiratory effects; slight as to equilibrium; none as to heart or peristalsis. They have not acquired toleration toward cannabis or chloral (H. B. Myers, 1915).

Biberfeld, 1916, confirms the absence of tolerance of morphine-habituated animals to scopolamine, cocaine and veronal and claims that there is none even against heroine.

On the other hand, Blair, 1919, believes that heroine addicts readily acquire tolerance to scopolamine; and that it apparently acts somewhat as a substitute.

Mental Phenomena.—The life of the addict is dominated by the abstinence symptoms that start when the effect of the dosage begins to wear off; by the consequent need of obtaining the drug at any cost; and often by the fear of detection. If the supply is regular, the addicts may appear quite normal; so much so that the addiction may be kept secret for many years, and the addict may occupy responsible positions. Close observation, however, would generally reveal signs of the addiction; especially variability of moods, depressed or stimulated, according to the interval since the last dose.

Opiate debauches doubtless accentuate the weaknesses of moral character from which they originate. They tend to make their victims

slothful, apathetic and unreliable. They do not lead to the more active crimes, as cocaine may; except in so far as crime may be necessary for obtaining the drug.

The addicts of inherently good character, if they take the drug solely to ward off the intolerable depression, are not so seriously affected. Their will-power and self-reliance is weakened, as by any other enslaving self-indulgence, and the agony of drug-deprivation drives them to deception and more serious crimes when their supply is threatened; but outside of this, their character and mental faculties are said to remain practically normal. A large part of the traditional depravity of the addicts exists in the minds of the public, rather than in life. This pariah-attitude makes it more difficult for the addicts to lead a normal life, and thus tends to drive them into the very vices of which they are accused (Bishop).

Physicians should look upon drug addicts as patients with a nervous disease. Like other nervous patients, they must be treated with firmness, but also with sympathy and kindness.

Physical Phenomena of Opiate Addiction.—The moderate use of opiates may not produce any definite physical deteriorations. Animals at least may even gain in weight, presumably by being less active. With more severe addiction, the digestion becomes seriously disturbed; obstinate constipation alternating later with equally obstinate diarrhea, loss of appetite alternating with voracious hunger and thirst, and polyuria. The patient loses weight rapidly and suffers from marasmus and cachexia.¹

The *skin* becomes hard, pale, dry and rough; sometimes of a peculiar waxy appearance. The nails, teeth and hair are also diseased. The condition of the integument is rendered worse by the local effects of the injections when the drug is used hypodermically. The whole skin may be mottled with scars and marks of recent or older injections, and abscesses are often produced through want of cleanliness.

The *pupils* are usually contracted. The pupillary and accommodation movements are affected. The *heart* may become irregular. *Albuminuria*, *glycosuria* and *amenorrhea* are frequent. The *sexual functions* are lessened (functional impotence, sterility), but usually return on withdrawal (Wholey, 1912). *Fevers* resembling simplex, intermittent, and typhoid are seen. The *motor-nervous system* shows considerable change: nervous tremors, increased reflex irritability, etc. These conditions sooner or later weaken the *resisting powers* of the patient, so that he falls an easy prey to some other ailment, and thus rarely reaches old age. However, the habit may persist for over thirty years (McIver and Price).

Metabolism.—Rats habituated to morphine show a decrease of gas metabolism and increase of respiratory quotient and increased sensitivity to oxygen deprivation, similar to thyroidectomized animals—this on drug-free days, when their psychic and motor behavior is normal. If the morphine is long continued, the animals become cachectic, with increase of metabolism (F. Hildebrandt, 1922).

Growth and Body Weight.—Morphine, heroine and codeine fed to rats continuously for several months, in doses corresponding to about $2\frac{1}{2}$ grains per day, for a man, produced increase of body weight. With codeine this is continuous; but with morphine, it is followed after some time, by a sharp and progressive steady decline. No abstinence craving or anguish was discernible on temporary withdrawal (Sollmann, 1924).

Withdrawal Symptoms.—The withdrawal of morphine from those accustomed to its use leads to a train of very severe effects, the severity

¹ These are two ill-defined terms. The former, marasmus, signifying a continued low condition of the nutrition and a wasting of the flesh without apparent organic cause. Cachexia also indicates a wasting of the body, with some striking change in the features, which are usually pinched and yellow.

being proportional to the duration of the addiction, the dosage that has been used, the rapidity with which the drug is withdrawn, and inverse to the general resistance, vigor and will-power of the patient.

In the early stages of addiction, withdrawal results in more or less restlessness, weakness and depression. These are endurable, and disappear in a few days, if the drug is withheld.

Uneasiness, restlessness, depression and weakness are also the earliest withdrawal symptoms in confirmed addicts. They become more and more intense, leading to almost uncontrollable craving for the drug, which may pass into real mania.

Other early symptoms are spasmodic yawning and sneezing; coryza and lachrymation; and hoarseness. The pupils dilate again. Most conspicuous are muscular twitchings and violent pains or "*cramps*," sometimes in the abdomen, more commonly in the legs; also headache and other neuralgias. The extremities are cold, the head congested. *Insomnia* is a very constant symptom; the patients are very irritable and excitable. This condition may culminate in delirium or acute mania, often suicidal. Women often have hysteric attacks. The *digestion* is profoundly disturbed, presenting the symptoms of a violent functional gastroenteritis. The most dangerous phenomenon is sudden *collapse*, ushered in by irregular and weak pulse, alternating between extremes of rapidity and slowness, cold sweat, and general prostration; and sometimes ending fatally by heart-failure. This collapse, if severe, demands the prompt injection of a moderate dose of morphine, which generally causes the symptoms to disappear.

The withdrawal symptoms are practically absent if the patient is rendered delirious by scopolamine (Wagner and Riewel, 1905). This suggests that they are mainly of psychic origin, *i.e.*, quasi-hysterical reactions to a balked imperative desire. This is confirmed by the absence of any notable withdrawal symptoms in the case of rats (Sollmann, 1924). The theory that the symptoms are due to the production of toxic substances (Marmé, 1883; Valento, 1914) is contradicted by the results of Pellini and Greenfield, 1924.

Diagnosis of Opiate Addiction.—This often requires careful observation: Pin-point pupils and needle marks are valuable indications; the failure of the ordinary dose of morphine to produce drowsiness or analgesia; the occurrence of withdrawal symptoms when the supply is stopped by confinement; the presence of morphine in the stools and urine.

Treatment of Opium and Other Drug Habits.—The prime indication, as in all diseases, is the removal of the cause, the withdrawal of the drug. This must be done under medical supervision, best in special institutions, for the patients have neither the will power, nor the physical resistance to carry it through unaided; attempts at self-treatment are generally unsuccessful, and always dangerous. In fact, the closest surveillance of the patient is indispensable, both to prevent clandestine continuance of the drug, and to control the withdrawal symptoms. The main object, therefore, is to withdraw the drug without danger or too great agony to the patient. When the drug has been completely stopped, even for a few days, the intense craving for it disappears, and the patient may be considered cured, although still in need of tonic treatment.

Unfortunately, the cure is often not permanent. The experience of the morphine euphoria remains, and the patients are likely to succumb

again, sooner or later; to resort to it for the relief of any stress or ailment; and the addiction develops very rapidly if the drug is resumed. It is therefore also necessary to be especially cautious in the therapeutic use of opiates on ex-addicts. Those who were treated against their full consent naturally relapse on the first favorable occasion. These remarks apply equally to cocaine and other serious drug habits; and the treatment of these is identical.

Methods of Withdrawal.—Attempts at “insensible withdrawal,” by very gradual diminution of the dose, amounts to useless and protracted agony; the sensations of the patient gauge the dose with surprising accuracy, and their patience reaches its end long before the drug.

Ambulatory treatment is also so often inefficient, and is so liable to fraud, that it is rarely justifiable (S. D. Hubbard, 1920). Advertised *Morphine cures* are generally thinly disguised solutions of morphine, and are used by addicts as a convenient source of supply of the drug.

Rapid and abrupt withdrawal, preferably under hospitalization, are by far the most effective methods. Either is successful under proper conditions. The preference depends mainly on the special experience of the physician. The abrupt method is simpler, but is likely to place a greater tax on the patient. •

Preparation of Patient.—E. S. Bishop, 1920, points out that the suffering of the patient is much smaller, and the chances of permanent success are much greater, if the withdrawal is attempted only when the patient is in the best physical and mental condition, because his need for the drug is then less imperative, and because he can withstand the discomfort more bravely. This may require a preliminary period of training, to obtain the best possible health, and to establish the patient's confidence. Unless this is done, suffering and incompetence may, in advanced cases, persist for weeks and months.

Rapid withdrawal is generally preferable if the patient can be supervised. With this method, the drug is reduced as rapidly as can be borne by the patient without producing very violent reaction.

It is better to begin by reducing the number, rather than the size of the doses (Bishop). The withdrawal may be completed within ten to fourteen days. Very hot baths relieve the restlessness and insomnia. The latter is one of the most difficult features; and often requires a hypnotic (barbital, phenobarbital, or full doses of bromide). Salicylates or cinchophen may be used against the “pains” (McIver and Price, 1916). The bowels should be kept loose. The treatment is effective and not excessively difficult (Drysdale, 1915).

Interval and Dosage.—E. S. Bishop, 1920, states that there is an almost mathematical relation between the size of the dose and the interval before craving sets in; that is, if the dosage is doubled, the number of administrations may be halved.

Abrupt Withdrawal.—Unless the patient is perfectly prepared, this entails severe suffering, and some danger. However, when skillfully managed, good results may be obtained in nearly all cases, without other medication than catharsis (S. D. Hubbard, 1920). The patient must be closely watched. If withdrawal symptoms become dangerous, they may be controlled by 0.015 to 0.03 Gm. of morphine.

Drug-adjuncts to Morphine Withdrawal.—The withdrawal symptoms of all drug addictions can be greatly diminished by diverting the attention, by cathartics or nauseants; or more effectively, by inducing a mild delir-

ium and amnesia ("twilight sleep") by scopolamine or atropine, for 2 or 3 days (M. K. Lott, 1901; Wagner and Riewel, 1905).

Details.—The treatment consists in absolute withdrawal of the drug, and in administering hypodermically a mixture of scopolamine hydrobromide, 0.3 mg. ($\frac{1}{200}$ gr.); atropine sulphate, 0.1 mg. ($\frac{1}{600}$ gr.), and water 1.5 c.c. (25 minims). The first dose, which is usually without results, is repeated in one-half to two hours, and again in one and one-half hours, and then every one-half to two hours, until the full scopolamine effect is indicated by dry throat, flushed face, dilated pupils, restlessness, and mild delirium. The patient is maintained continuously in this state for three or four days, by repeating the injection every two to six hours, reducing the individual dose to half, if possible. Constant, careful and skilled watching of the patient is indispensable. If the pulse (which remains ordinarily of normal character, with a rate of 60 to 70) should fall below 50, or rise above 110, the treatment is intermitted, and a very little morphine given.

The second day usually produces some abstinence symptoms (violent attacks of sneezing and some gastro-intestinal phenomena), but these are rarely of sufficient severity to require special attention.

The patient can be about the room throughout the treatment, and receives "fever diet." The delirium is usually mild and busy, the patient being mainly engaged in picking imaginary insects, etc.

At the end of the third day the injections are stopped, to see whether craving for the drug will return. Should this occur, the treatment is continued for another day. This is rarely required.

The Lambert-Towns Method, described by A. Lambert, 1909 and 1913, involves the same principles, since it uses essentially hyoscyamus and belladonna, together with severe catharsis which also serves to distract the attention of the patient. (Details in J.A.M.A., 1911, v. 56, p. 503; 1913, v. 60, p. 1933.) Collapse sometimes occurs (Wholey, 1915). Bishop considers the active catharsis as detrimental to the patient.

Pilocarpine has also been employed.

Scleth, 1916, advises a method including scopolamine, pilocarpine and ethylmorphine.

Substitution of Other Habit-drugs.—Withdrawal of opiates may be made less distressing by substituting other habit-drugs; but this is rarely justifiable since the end-result is usually merely to condemn the patient to an additional drug habit.

The After-treatment.—This is important with all methods. The patient should receive tonics, nutritious food, and rest for several weeks. *Insomnia* is rather troublesome at first, and should be relieved by giving chloral and bromide for two or three nights. The bowels should be kept clear, both before and after the treatment.

The "recovered" patient must be protected as much as possible against pain and other circumstances which would tempt him to the resumption of the drug. Psychotherapy may be useful to prevent recurrence.

Legislation against Drug Habit.—The real cure of drug habits lies in the enforcement of appropriate legislation. The Harrison Law reduced the sale of opiates and cocaine to half (Wilbert, 1916); but there is a great deal of smuggling that is difficult to suppress. This is partly excused by the inadequate provision for the proper treatment of addicts.

Heroin is so particularly liable to abuse, and the medical need for it is so superficial, that its importation has been prohibited.

Legitimate Consumption.—The Health Committee of the League of Nations (1924) estimates the present maximal medical requirements per head per year as 450 mg. of opium (raw or manufactured into alkaloids) and 7 mg. of cocaine.

Therapeutic Uses.—Morphine and Opium are used mainly to *lessen pain, to procure sleep, to check peristalsis, to suppress cough, to ease dyspnea, to facilitate anesthesia, and to secure muscular quiet.* These indications arise in a great variety of diseases; and since the action of the opiates is certain and highly effective, their field of usefulness is extensive and important. However, they must be used with discretion. It should be remembered that the relief is generally only symptomatic and may some-

times interfere with the natural processes of repair, or obscure the observation of the progress of the disease.¹ The danger of habit formation restricts their employment in neurotic individuals and in chronic diseases (except when these are hopeless). The habit danger can be somewhat avoided if the morphine is administered only by the physician, with somewhat impressive formalities of asepsis, and not intrusted to the patient himself. The side actions (constipation, nausea, gastric disturbance, and occasional excitement) may also interfere with the usefulness. Even with these restrictions, however, the range of usefulness of the opiates is still very wide.

Pain.—Morphine surpasses in efficiency all other analgesics, particularly for persistent pain. Its use is generally aimed to dull, rather than to abolish the sensibility; and for this purpose relatively small doses suffice. Morphine by hypodermic injection is to be preferred, 5 to 15 mg. ($\frac{1}{12}$ to $\frac{1}{4}$ gr.) according to severity, and repeated as necessary. Local application is irrational, although it is still somewhat used (H. C. Wood, Jr., 1916).

Insomnia.—Morphine should be avoided, if possible, especially in nervous insomnia and in psychic excitement. It may be needed if the insomnia is caused by pain, cough, or dyspnea; and small doses (5 mg. or $\frac{1}{12}$ gr.) may be employed to reduce the dosage, and thus the side actions, of other hypnotics (*f.i.*, the circulatory depression of chloral).

Diarrhea.—Opiates are very effective in arresting the excessive peristalsis in acute intestinal catarrh. If the intestines are first cleared of toxic and irritant material by a cathartic, the rest afforded by opiates favors the subsidence of the inflammation. Tincture of Opium by mouth (0.5 c.c. or 10 drops) deserves the preference. If the opiates are given while the *materies morbi* are still in the intestine, they may do harm, even when they give symptomatic relief.

Opium is also useful in the constipation and colic of *lead poisoning*, by relaxing the intestinal spasm. In *peritonitis* it relieves the pain, both directly and by lessening peristalsis; but the disguise of the symptoms may be surgically objectionable. In *biliary and renal colic*, Morphine (15 mg. or $\frac{1}{4}$ gr.) is given hypodermically, to lessen the suffering (usually with 1 mg. atropine, which relaxes the ducts).

Cough.—The opiates check cough by lowering the reflex irritability of the respiratory center. Small doses suffice for this purpose—by mouth, Morphine 5 mg. or $\frac{1}{12}$ gr.; Tr. Opii $\frac{1}{2}$ c.c. or 10 drops; Codeine 30 mg. or $\frac{1}{2}$ gr.; Heroin 5 mg. or $\frac{1}{12}$ gr. (children above one year, $\frac{1}{2}$ mg. or $\frac{1}{120}$ gr.; below one year, $\frac{1}{4}$ mg. or $\frac{1}{240}$ gr.); Dionine 15 mg. or $\frac{1}{4}$ gr. Codeine deserves preference, since it produces the desired effect with less side actions, and without habit formation.

The use of opiates as "sedative expectorants" in bronchitis and phthisis requires judgment. They are indicated when the cough is mainly irritative; and contraindicated when it is required for the expulsion of excessive mucus. Even then, however, they may be needed to produce sleep.

Asthma and Dyspnea.—Morphine (15 mg. or $\frac{1}{4}$ gr., hypodermically) often relieves this condition, by quieting the patient, by allaying the "air hunger" and anxiety; and by improving the efficiency of the respiration, rendering shallow breathing deeper, and convulsive respiration regular. Morphine should be avoided in asthma, for fear of habit-formation.

¹ Cushny, 1914, aptly points out that the avoidance of opiates for fear of obscuring the diagnosis is a confession of deficient diagnostic technic; it should not be necessary to make the diagnosis at the expense of exhausting pain.

It might also lead to addiction in cardiac dyspnea. It is useful in acute respiratory disease, for instance pneumonia or pleurisy: deleterious depression need scarcely be feared from therapeutic doses.

Morphine in "Gassing" by Chlorine and Other Volatile Irritants.—Morphine not only dulls the agonizing "air-hunger," but tends to save life by quieting the patient and thus diminishing the use of oxygen and the production of carbon dioxide. Hjort and Taylor, 1919, claim that it also prolongs the maintenance of alkali reserve.

Colds.—The diaphoretic action is utilized for aborting colds; generally as Pulv. Ipecac et Opii, 0.5 Gm. or $7\frac{1}{2}$ gr.

Anesthesia.—Morphine in safe doses does not induce complete insensibility, but it is an efficient synergistic to other anesthetics (10 mg. or $\frac{1}{6}$ gr., hypodermically; see under "Ether," also under "Scopolamine"). Morphine is similarly useful for distracting the patient's attention from operations under local anesthesia.

Hemorrhage.—Morphine favors the arrest of hemorrhage by quieting the patient, thus keeping the blood pressure low, and permitting the formation of the clot. It is especially valuable when the hemorrhage is in an inaccessible situation, *f.i.*, the pulmonary hemorrhage of phthisis. The depressant effect on the respiration enjoins caution in the use of larger doses, especially in severe hemorrhage, cardiac disease, and other debilitating conditions.

Convulsions.—Since morphine increases reflex excitability, it can not compare with ether, chloral or chloroform for suppressing tetanus or other spinal convulsions; but its analgesic effect may justify its use as an adjuvant. The depressant action on the respiratory center must be borne in mind (Dreyfus, 1914).

Eclampsia.—Large doses of morphine have been recommended (15 mg. hypodermically, every hour until the respiration drops to 8 or 10 per minute). This generally arrests the convulsions; and it is claimed that labor often proceeds spontaneously (McPherson, 1917).

Psychic and motor exaltations, e.g., delirium tremens or atropine poisoning, are controlled only by very large doses, the danger of which offsets the problematic benefit.

Emesis.—Morphine is employed as an ant-emetic, but the doses which can be safely prescribed are often ineffective.

Diabetes.—Large doses of opium, morphine or codeine appear to benefit some otherwise intractable cases; but the ultimate results are not brilliant. The effects are probably indirect, by slowing the absorption of sugar from the alimentary tract.

Experimental Glycosurias.—The opium alkaloids have no effect on the hyperglycemia resulting from the conversion of hepatic glycogen (epinephrine or piqûre); but they have an inhibitory action on alimentary hyperglycemia (Klercker, 1914). This indicates that the action is on the alimentary canal, presumably by the gastric delay slowing the digestion and absorption of the carbohydrates, and thus preventing the sudden flooding of the organism with sugar (Macleod, 1914). Morphine delays the disappearance of injected dextrose from the circulation of dogs, although it facilitates its excretion by the urine (Kleiner and Meltzer, 1916). It must therefore hinder the passage of sugar from the blood into the tissues.

Clinical Evidence.—Good clinical observers claim that the thirst, polyuria, glycosuria, and itching of the skin are all markedly diminished. Part of this action must be attributed to the analgesic effect, while the influence on the glycosuria is probably due to its action on digestion, and is produced in the same way as by limitation of the diet or by nauseants. On the whole, opiophagic diabetics die earlier than others. Codeine has been used instead, but without any marked advantages.

Dosage of Opiates for Children.—This is best adjusted to the weight: with children above ten months, the weight (in pounds) is divided by 150; below ten months, by 300. The adult dose is multiplied by the fractions thus obtained (Doebeli, 1912).

Regulations for the Prescribing of Narcotics.—In the United States, physicians who prescribe narcotics must be registered with the Department of Internal Revenue, and comply with regulations furnished by that department, which are designed to restrict the illegitimate supplies of these drugs. Severe penalties attach to the violations of these rules.

Form of the Prescriptions.—These are written on ordinary blanks, *not* on special forms. They must contain the following data: (a) The full name and address of the patient; (b) the full name, address and registry number of the prescriber, and (c) the date of issue. The signature must be in ink or indelible pencil. Narcotic prescriptions cannot be given over the telephone. They cannot be refilled or partly filled. A physician is permitted to prescribe only for patients whom he attends in person.

Prescriptions for continuous use must have further inscriptions explaining the facts or the "exception" under which they come: for incurable diseases they may be marked, "Exception I, Article 117;" if for addicts under the special restrictions provided in "Exception 2, Article 117" (Treasury Decision 3426).

Scope of the Regulations.—These include opium or coca leaves, or any compound, manufacture, salt or preparation thereof, even though they are not narcotic, for instance apomorphine and papaverine. It does not include the synthetic local anesthetics.

Exemptions.—Certain articles are specifically exempted, and may be prescribed without formality, or bought without prescription, for legitimate uses. The more important of these exemptions are: Tr. Opii Camph.; Mixt. Glycyrrh. Co.; Lotio Opii et Plumbi; and all preparations for application on the skin, if they contain ingredients that would render them unfit for internal use.

Conditions against Which Narcotics May Be Prescribed.—These include, (a) all acute conditions, at the discretion of the prescriber; (b) incurable diseases (cancer, advanced tuberculosis, etc.) under certain restrictions; (c) the treatment of addicts, narrowly restricted.

Dispensing and Administration of Narcotics by Physicians.—Subject to the preceding paragraph, physicians may personally administer single or occasional doses away from their office, without formality or record. Otherwise, however, a record must be kept, in the manner provided in the regulations.

Recapitulation of the Chief Differences of the Morphine Derivatives.

—The actions of all morphine derivatives are quantitatively identical, so long as they involve only changes in the outlying side-chains (R. Stockman, 1891). Even the quantitative differences are not of very great practical importance.

Morphine produces the strongest narcotic, analgesic, hypnotic and intestinal effects, and the weakest stimulation. It causes the greatest derangement of digestion; and, with heroine, is most apt to induce addiction.

Codeine (Methyl-morphine) is less narcotic, less constipating, and less apt to induce a habit or tolerance. It has some advantage in the treatment of cough. Bastedo uses 15 to 30 mg., but Fraenkel, 1899, claims that at least 40 to 60 mg. are required to affect cough. This dosage is some-

what quieting, but not narcotic, and scarcely analgesic. Larger dosage produces restlessness instead of quieting. The susceptibility is the same for all ages (Doebeli, 1911).

It increases the spinal *reflexes* more than morphine (v. Schroeder, 1883). Frank-further and Hirschfeld, 1910, claim a greater dilation of the *cerebral vessels* (without rise of blood pressure).

Dionine (Ethyl-morphine) seems to stand intermediate between morphine and codeine, in all respects. Mering advises it in cough. Lindenmayr, 1912, uses it in colds, 0.05 Gm. before retiring. It sometimes causes itching of the skin (Seifert, *Nebenwirk.*, 1915, p. 61). It has a special action on the conjunctiva (edema).

Heroine (Diacetyl-morphine) approaches still more to morphine, of which it shares all the disadvantages, and over which it has no serious advantage. Bastedo finds it inferior to codeine (Side actions, Seifert, *Nebenwirk.*, 1915, p. 69).

Severe poisoning has been reported from 2 to 8 mg. ($\frac{1}{32}$ – $\frac{1}{8}$ gr.). The government services are contemplating its abandonment; and prohibition of its manufacture is being agitated.

Thebaine (dimethyl-morphine) is so markedly convulsant that it may be placed in the strychnine group (Cl. Bernard; Stockman and Dott).

Structure of Opium Alkaloids.—These belong to two groups, those containing a phenanthrene nucleus (morphine and its esters); and those derived from isoquinoline (papaverine, narcotine, narceine). The difference in the nuclei is shown in the diagram.

Phenanthrene nucleus

Isoquinoline nucleus

Structure of Morphine and Its Derivatives.—Morphine is a complex derivative of phenanthrene. It contains two OH groups (one phenolic, the other alcoholic) in which substitutions can be made, either by alkyl or acid radicals.

The more important alkyl esters are the monomethyl (Codeine), dimethyl (Thebaine) and ethyl (Dionine). Heroine is the di-acetyl derivative.

The nature of the radicals—whether acid or alcoholic, aromatic or aliphatic—is not of great importance. Replacement of a single H (codeine, dionine) diminishes the narcotic actions and increases the respiratory and tetanic action, and the toxicity for animals. When both OH groups are replaced by acids (heroine) the narcotic action is stronger than for codeine, the tetanic action is weaker than with morphine.

Comparative Activity of the Two Groups.—The alkaloids of both the groups are more or less narcotic and convulsant. The essential differences are in the peripheral actions on all kinds of smooth muscle: Their contractions and tonus are stimulated by the phenanthrene group (morphine and its esters), and depressed by the isoquinoline group (papaverine, etc.). This applies to the intestines, bile ducts, vas deferens, bronchioles and blood vessels. Macht, 1918, attributes the stimulation to the pyridine radical of the phenanthrene group; the depression to the benzyl radical of the isoquinoline group.

Convulsant-narcotic Series.—In general, the narcotic actions on the brain, on the one hand, and the stimulant action on the cord and medulla on the other, are in inverse ratio; morphine being the most narcotic and least convulsant, and thebaine the most convulsant and least narcotic; the other morphine esters and the isoquinoline alkaloids being intermediate. Claude Bernard arranged them in the order of: Morphine, codeine, narcotine, papaverine, laudanose, thebaine. Buergi, 1914, places them as: Morphine, papaverine, codeine, narcotine, narceine, thebaine.

Meconic Acid.—This has no effect in the doses which would be administered in opium. Larger doses produce narcosis, muscular fibrillation; medullary convulsions; diarrhea; curare action (Barth, 1912).

Papaverine.—This is discussed in a separate section.

Narcotine.—The peripheral actions appear to be similar to papaverine, but weaker (Pal, 1914). Macht, 1915, found, contrary to Straub, that it is quite toxic to the heart, respiration and other functions.

Narceine.—The peripheral actions resemble narcotine (Pal, 1914).

Differences between Morphine and Opium ; Opium Alkaloid Mixtures.

While the actions of opium are essentially those of its principal alkaloid, morphine, there are various differences, especially quantitative. These are due partly to the mechanical action of the gums and resins, which delay absorption, and thus increase the local and diminish the central actions. In the main, however, the differences are due to the presence of the minor alkaloids, which modify the effects of morphine; for similar differences exist in mixtures of the alkaloids, natural (Pantopium) or artificial (Narcophine, Laudanons).

The precise differences between the actions of morphine, opium and the mixed alkaloids are still under dispute. The statements of different (and sometimes of the same) observers are so contradictory that it is often impossible to judge them (Literature, E. Buergi, 1914).

Claimed Therapeutic Advantages.—It is asserted that opium and the alkaloid mixtures, for a given degree of analgesic and cough-sedative action, cause less depression of respiration and less nausea; that their action, though slower, is more prolonged. It is also claimed that opium and pantopium are more efficient in checking diarrhea; while at the same time, it is stated that pantopium is not as constipating for normal individuals.

Before considering these actions in detail, it is necessary to describe the nature of the commercial products which have been largely used in the investigations.

Pantopon (Pantopium Hydrochloricum).—This consists of the isolated alkaloids of opium in their natural proportions. It was introduced by Sahli. Discounting the early extravagant claims, it has the advantage that the absence of gums and resins insures prompt absorption and makes it much more suitable for hypodermic injection. The pharmacologic data on pantopium are reviewed by Barth, 1912; Schwentner, 1912; Watkyn-Thomas, 1913. Severe poisoning from 0.04 Gm. is reported by Voigt, 1911. The side actions are quoted by Seifert, *Nebenwirk.*, 1915, p. 81.

Artificial Mixtures.—Since it is unlikely that all the alkaloids are therapeutically useful, and that they occur naturally in the optimal proportions, there exists a field for artificial mixtures. Faust, 1912, introduced mixtures of the principal opium alkaloids under the name of "*Laudanons*." The proportions appear to be merely arbitrary. A more scientific attempt has been made by W. Straub in the introduction of Narcophine.

Narcophine.—W. Straub and Caesar, 1912, investigated the modifications produced by a variety of mixtures of opium alkaloids. They found narcotine the most important alkaloid in the combination; claiming that doses of narcotine, which were ineffective alone, modified the actions of morphine, so as to increase the toxicity and narcotic effect, and at the same time diminish the respiratory depression; that a mixture of equal parts of the two alkaloids was the optimal proportion and fully represented the advantages of opium; that the other alkaloids of opium had less effect and introduced complex modifications which render them undesirable. These claims have been both confirmed and contradicted, clinically and experimentally. Meissner, 1913 and 1914, failed to confirm the synergism in the most important effects, viz., the respiratory and psychic;

Straub's reply, 1913, is not quite convincing. Under the circumstances, judgment must be suspended.

Potentiation of Toxic Action.—Issekutz, 1912, found that the toxicity of mixtures of morphine and its esters corresponds to simple addition, but that mixtures of these with the isoquinoline alkaloids shows marked potentiation. This has been confirmed by W. Straub and Caesar, 1912, who claim that doses of narcotine, which are in themselves inactive, double the toxicity of morphine for mice. This synergism may be considered as established; but it has little bearing on the therapeutic use.

Analgesic Action.—The statements are contradictory, as might be expected from the difficulty of making quantitative observations on a subjective condition. As yet, the claims of superior analgesic or narcotic action are not fully established. The sedative action on cough comes under the same category.

Straub claims a marked increase of narcotic action by narcotine, in that the morphine excitement of cats is prevented. (This, however, is a very variable condition, which is greatly influenced by external conditions.) Macht, Herman and Levy, 1916, also claim a synergistic decreased sensitiveness to cutaneous pain in human subjects; and Macht and Isaacs, 1917, find a greater delay in the reaction-time. On the other hand, it is very suggestive that the clinical doses of narcophine and pantopium are strictly equivalent to their morphine content. Zeelen, 1910 and 1911, found only simple summation in the narcotic (and tetanizing) action of the various opium alkaloids. Meissner also failed to confirm Straub.

Respiratory Action.—Straub asserts that the respiratory center in rabbits (as judged by response to CO₂ stimulation) is much less depressed by narcophine than by morphine. This is contradicted by Meissner. Straub's statements appear self-contradictory, since he also claims that the toxicity, which generally depends on respiratory depression, is increased. However, Macht, 1915, confirms that the minor opium alkaloids stimulate respiration, and thus antagonize somewhat the morphine depression.

Circulation.—The data are scanty. Macht, 1915, finds that morphine-narcotine mixtures dilate the coronary vessels much less than either alkaloid alone; and that Pantopon and Laudanon have practically no effect on the coronary circulation.

Gastric Disturbance.—It is quite generally asserted that the combinations are less liable to produce nausea and vomiting; but quantitative differences of this kind are difficult to judge, clinically. It is possible, though not proven, that there may be a slight difference, since morphine itself stimulates the vomiting center more than any other opium alkaloid.

Constipating Action.—This has been discussed under morphine.

Ureter and Gall-bladder.—The depressant action of the isoquinoline alkaloids would make the combined alkaloids more effective than morphine in ureteral and biliary colic (Macht, *et al.*).

The synergism of morphine with scopolamine and with the anesthetics and hypnotics will be discussed in connection with those drugs.

PREPARATIONS—OPIUM

* *Opium*, U.S.P., B.P. (Meconium, Thebaicum).—The dried milky juice exuding from the incised unripe seed-capsules of the poppy, *Papaver somniferum*. Brown masses or powder, of peculiar odor and bitter taste. Contains a number of alkaloids, the most important being morphine (about 10 per cent.). *Dose*, 0.06 Gm., 1 gr., U.S.P. (equivalent to 6 mg. or $\frac{1}{10}$ gr. morphine); 0.03 to 0.12 Gm., $\frac{1}{2}$ to 2 gr., B.P. Maximum dose, 0.2 Gm., 3 gr.

Opium was mentioned by Theophrastus, third century B.C. An interesting account of its history is given by Macht, 1915. The history of the opium preparations is also interesting (Wilbert, 1916). Laudanum is said to have been originated by Paracelsus (1493-1541), but as a solid aqueous extract; paregoric by Le Mort of Leyden, early in the eighteenth century. Sydenham's laudanum (*Vinum Opii*) is derived from a formula of Sydenham (1624-1689). *Tr. Opii Deodorati* was originated by Robiquet (1780-1840), and Robt. Hare, 1827; *Mist. Glycyrrh. Co.* by Dr. B. J. Barton of Philadelphia, about 1814.

The opium poppy is cultivated in Asia and Egypt; it can be raised in the United States, but the cost of labor renders the production of opium unprofitable. The capsules (especially before ripening, Caesar and Lorey, 1902) and seed also contain the alkaloids. They are not present in the fresh plant, but are produced by the action of oxidases on the latex (Stockberger, 1916).

The seeds yield 50 per cent. of a bland fixed oil which may be used like olive oil.

The usual percentage of the other alkaloids in opium is: Codeine, 0.2 to 0.7 per cent.; Thebaine, 0.15 per cent.; Narceine, 0.02 to 0.7 per cent.; Narcotine, 1.3 to 10 per cent.;

Papaverine, 1 per cent. (absent in some sorts; Van Italie and Kerbosch, 191c). The development of these alkaloids in the growth of the plant is interesting (Kerbosch, 1910).

Opium also contains a number of other minor alkaloids; meconic acid (2.5 to 5.5 per cent.), lactic acid, gums, resins, fats, odorous principles. No starch or tannin.

Opium Pulveratum (Opium Pulv.), U.S.P.; Powdered Opium.—Light brown powder, yielding 10 per cent. of anhydrous morphine. *Dose*, 0.06 Gm., 1 gr., U.S.P.

Opium Granulatum, U.S.P.—This is employed in manufacturing.

Ext. Opii Liq., B.P.—0.75 per cent. of morphine, 3.75 per cent. of the Dry Extract, in 20 per cent. alcohol. *Dose*, 0.3 to 1.8 c.c., 5 to 30 minims, B.P.

Ext. Opii Sicc., B.P.—A powdered extract, 1 Gm. representing 2 Gm. of the drug, or 20 per cent. of morphine. *Dose*, 0.03 Gm., $\frac{1}{2}$ gr., U.S.P.; 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P. Maximum dose, 0.15 Gm., $2\frac{1}{2}$ gr.

Lin. Opii, B.P.—Equal parts of Tr. Opii and Lin. Sapon.

Lotio Opii Et Plumbi, N.F.; Lead and Opium Wash.—Lead acetate, 4.5 Gm.; Tinct. Opium, 9 c.c.; Water, q.s., 250 c.c.

* *Mistura Glycyrrhizæ Composita* (Mist. Glycyrrh. Co.), U.S.P. (Brown Mixture).—The adult *dose*, 10 c.c., $2\frac{1}{2}$ drachms, of this mixture contains 1.2 c.c. of Paregoric or 5 mg., $\frac{1}{4}$ gr. of opium; and 2.5 mg., $\frac{1}{24}$ gr., of Tartar Emetic; also a little Sp. Aether. Nit. It is a popular expectorant, but needlessly complex.

(*Pil. Plumb. C. Opio*, see Index.)

Pil. Sap. Co., B.P.—20 per cent. of Opium. *Dose*, 0.12 to 0.25 Gm., 2 to 4 gr., B.P.

Pulv. Cret. Arom. C. Opio, B.P.—25 per cent. of Opium. *Dose*, 0.6 to 4 Gm., 10 to 60 gr., B.P.

* *Pulvis Ipecacuanhæ et Opii* (Pulv. Ipecac. et Opii), U.S.P.; *Pulv. Ipecac. Co.*, B.P. (Dover's Powder; Opium et Ipecac. Pulv. Co., P.I.).—Contains 10 per cent. each of Opium and Ipecac with Lactose, U.S.P., or Potass. Sulphate, B.P. (It was introduced by Thomas Dover, 1742, as a diaphoretic in gout.) *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P. Maximum dose, 1.5 Gm., 20 gr.

(*Pulv. Kino Co.*, see Index.)

Pulv. Opii Co., B.P.—10 per cent. of Opium, with aromatics. *Dose*, 0.3 to 1 Gm., 5 to 15 gr., B.P.

(*Supp. Plumbi Co.*, B.P., see Index.)

* *Tr. Opii*, U.S.P., B.P.; Tincture of Opium (Laudanum).—10 per cent. of opium, or 1 per cent. of morphine, in diluted alcohol. The U.S.P. tincture is prepared by extracting the opium with water, digesting the percolate with paraffin to remove some of the odorous constituents, and adding about 20 per cent. of alcohol to the filtrate. It takes the place of the *Tinct. Opii Deodorati*, which was formerly official. Miscible with water or alcohol. *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, repeated; single, 1.2 to 1.8 c.c., 20 to 30 minims, B.P. Maximum dose, 2 c.c., 30 minims.

Tr. Opii Ammon., B.P.—0.1 per cent. of Morphine, with Anise oil, Benzoic acid and Ammonia. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

* *Tinctura Opii Camphorata* (Tr. Opii Camph.), U.S.P.; *Tr. Camphor. Co.*, B.P.—(Paregoric; Opium Tinctura Benzoica, P.I.).—0.4 per cent., each, of opium, benzoic acid, camphor, and anise oil, U.S.P. The B.P. contains the same ingredients with 0.5 per cent. of opium. The preparation is used especially for children. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P. 4 c.c. contains 16 mg., $\frac{1}{4}$ gr., of opium or 1.6 mg., $\frac{1}{40}$ gr., of morphine, U.S.P. (20 mg., $\frac{1}{3}$ gr., of opium or 2 mg., $\frac{1}{20}$ gr., of morphine, B.P.).

(*Ung. Gall. C. Opio*, B.P., see Index.)

(*Ung. Myrrh. C. Opio*, B.P., see Index.)

Pantopon (*Pantopium Hydrochloricum*).—A purified mixture of opium alkaloids, containing 50 per cent. of morphine. Sol. in water. *Dose*, 5 to 20 mg., $\frac{1}{2}$ to $\frac{1}{3}$ gr., by mouth or hypodermically.

Narcophine; Morphine-narcotine meconate.—About 33 per cent. of morphine. Sol. in water. *Dose*, three times that of morphine.

PREPARATIONS—MORPHINE

* Morphine and its salts occur as odorless, bitter white powders or colorless crystals. They are incompatible with alkalis, tannins, iodides and other precipitants of alkaloids. *Dose*, 8 mg., $\frac{1}{8}$ gr., U.S.P.; 8 to 30 mg., $\frac{1}{8}$ to $\frac{1}{2}$ gr., B.P. The rectal dose is the same; the hypodermic about two-thirds of the oral. Maximal single dose, 30 mg., $\frac{1}{2}$ gr. The actions begin in about five minutes on hypodermic administration. Solutions are said to decompose rather readily when heated above 60°C. (Welmans, 1908).

Moulds in solutions of morphine often come from the cork. These are probably harmless even when injected. They are prevented by adding a small piece of camphor (Norgaard, 1920).

Morphina, $C_{17}H_{19}NO_3 \cdot H_2O$.—Very slightly sol. in water (1:3,340); slightly sol. in alc. (1:210); sol. in lime-water (1:100).

Morph. Acet., B.P., $C_{17}H_{19}NO_3 \cdot C_2H_3O_2 \cdot 3H_2O$.—Freely sol. in water (1:2.5). Loses acetic acid on exposure to air.

* *Morphina Hydrochloridum* (Morph. Hydrochl.), U.S.P., B. P., $C_{17}H_{19}NO_3 \cdot HCl \cdot 3H_2O$.—Sol. in water (1:17.5) or alc. (1:52).

* *Morph. Sulph.*, U.S.P., $(C_{17}H_{19}NO_3)_2 \cdot H_2SO_4 \cdot 5H_2O$.—Sol. in water (1:15.5); slightly sol. in alc. (1:565).

Morph. Tart., B.P., $(C_{17}H_{19}NO_3)_2 \cdot C_4H_6O_6 \cdot 3H_2O$.—Sol. in water (1:11).

Inj. Morph. Hyp., B.P.—2.5 per cent. of tartrate. Dose, 0.3 to 0.6 c.c., 5 to 10 minims, B.P.

Liq. Morph. Acet., B.P.—1 per cent. Dose, 0.6 to 3.6 c.c., 10 to 60 minims, B.P.

Liq. Morph. Tart., B.P.—1 per cent. Dose, 0.6 to 3.6 c.c., 10 to 60 minims, B.P.

Supp. Morph., B.P.—0.017 Gm., $\frac{1}{4}$ gr.

Tr. Chlorof. et Morph. Co., B.P.—Chlorof., 7.5 per cent.; Morph., 1 per cent.; Acid. Hydrocyan. Dil., 5 per cent.; with Capsicum, Cannabis Indica and Peppermint. Dose, 0.3 to 1 c.c., 5 to 15 minims, B.P. Used in colic.

Troch. Morph., B.P.—2 mg., $\frac{1}{30}$ gr.

Troch. Morph. et Ipecac., B.P.—2 mg., $\frac{1}{30}$ gr., of Morphine; 6 mg., $\frac{1}{10}$ gr., of Ipecac.

PREPARATIONS—MORPHINE DERIVATIVES

These resemble the morphine salts in physical characters and incompatibilities; they are further incompatible with strong acids or alkalis.

Aethylmorph. Hydrochl., U.S.P. (Dionine), $C_{17}H_{17}NO(OH)(OC_2H_5) \cdot HCl \cdot 2H_2O$.—White or yellowish, odorless, microcrystalline powder. Freely sol. in water (1:8); sol. in alc. (1:22). Dose, 15 mg., $\frac{1}{4}$ gr., U.S.P.; Locally, 10 to 20 per cent. Maximum dose, 50 mg., $\frac{3}{4}$ gr.

Diacetylmorphina (Heroin).—Very slightly sol. in water (1:1,700); sol. in alc. (1:31).

Diamorph. Hydrochl., B.P. (Heroin Hydrochloride), $C_{17}H_{17}(C_2H_3O_2)_2 \cdot NO \cdot HCl \cdot H_2O$.—Freely sol. in water (1:2); sol. in alc. Dose, 2.5 to 8 mg., $\frac{1}{25}$ to $\frac{1}{8}$ gr., B.P. Maximum dose, 10 mg., $\frac{1}{6}$ gr.

Codeina, U.S.P., B.P., $C_{17}H_{19}(CH_3)NO_3 \cdot H_2O$.—Slightly sol. in water (1:120); freely sol. in alc. (1:2). Dose, 30 mg., $\frac{1}{2}$ gr., U.S.P.; 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P.

* *Codein. Phosph.*, U.S.P., B.P., $C_{18}H_{21}NO_3 \cdot H_3PO_4 \cdot 2H_2O$.—67 per cent. of anhydrous codeine. Freely sol. in water (1:2.3); slightly sol. in alc. (1:325). Dose, 30 mg., $\frac{1}{2}$ gr., U.S.P.; 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P. Maximum dose, 0.1 Gm., $1\frac{1}{2}$ gr.

Syr. Codein. Phosph., B.P.—0.5 per cent. Dose, 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms, B.P.

* *Codein. Sulph.*, U.S.P., $(C_{18}H_{21}NO_3)_2 \cdot H_2SO_4 \cdot 5H_2O$.—Sol. in water (1:30); very slightly sol. in alc. (1:1,280). Dose, 30 mg., $\frac{1}{2}$ gr., U.S.P.

Papaverin. Sulph., N.N.R., $(C_{20}H_{21}O_4N)_2 \cdot H_2SO_4$.—Sol. in water or alc. Dose 30 to 80 mg., $\frac{1}{2}$ to $1\frac{1}{4}$ gr.

PAPAVERINE

This was recommended as an analgesic by Baxt, 1809, and Macht, 1915; but its central effects are insignificant (Pal). Its toxicity is low. Bouchet claimed that 1 Gm. produced no effects on man.

Its important peripheral actions have been investigated mainly by Pal, 1913, 1914. He found that it relaxes the tonus of all smooth muscle, especially when this has been spasmodically contracted, and this without paralyzing the contractility of the muscle; *f.i.*, he claimed that it lowers intestinal tonus without interfering with normal peristalsis or producing constipation; that small doses lower abnormally high blood pressure, whilst it requires much larger doses to lower the normal pressure. Macht, 1910, claimed that it lowers blood pressure, mainly by peripheral vasodilator action, especially in the splanchnic area. The coronary circulation is increased. Small doses slow the heart, with tendency to stronger contractions.

G. Rosenow, 1920, found a moderate lowering of the vein-pressure in patients with arterial hypertension; no change in the healthy.

Popper claims that the isoquinoline alkaloids relax the longitudinal coat of the intestines; the phenanthrenes the circular coat.

Macht, Herman and Levy, 1916, find that 40 mg. hypodermically, in man, produces marked analgesia with some vasodilation, fall of blood pressure and slight constipation.

Further discussion of the papaverine effects on protozoa, auricular tonus-waves, etc. may be found under opium.

Therapeutic Use of Papaverine.—Pal advises its use in gastric and intestinal spasms and colics, and in spastic constipation (30 to 80 mg. by mouth or hypodermic; 5 to 30 mg. by vein. Stoerk, 1915, employs it against the tenesmus of bacterial dysentery (0.06 Gm., three times daily, continued as long as required). It has also been tried, with less reason, in hypertension, angina pectoris; vomiting, gastric crises; asthma and pertussis (Pal; Popper, 1914; L. Levy, 1914). It is a local anesthetic, and has been used on the cornea as solution of 4 to 10 per cent. Macht, 1916, finds that papaverine relaxes the tone of the ureter, without inhibiting the peristalsis. Gerathy and Macht, 1916, use its injection by ureteral catheter, against the colic of ureteral calculi (5 c.c. of 2 per cent. P.HCl). The gall-bladder and the seminal ducts are also relaxed (Macht, 1919).

Commercial papaverine contains considerable cryptopin, to which most of its chemical tests are due (Pictet and Kramers, 1910). In general, however, the quality of commercial opium alkaloids is satisfactory (Warren, 1915).

Fate of Papaverine.—It is probably extensively destroyed in the body, since neither papaverine nor any immediate decomposition products have been recovered from the organs or excreta after its hypodermic administration (Zahn, 1915).

An extensive *Bibliography* of papaverine is given in Merck's Reports, 1914, 28: 74.

Tetra-Hydro-Papaveroline.—Laidlaw, 1910, found that this inhibits the tone of unstripped muscle, dilates the bronchioles and blood vessels, and lowers blood pressure, while at the same time stimulating the heart. It is relatively non-toxic. Marshall, 1912, tried it clinically in arteriosclerosis, but found it practically inefficient—probably because it is too easily oxidized.

PROTOPINE GROUP

The curare and muscular actions of the opiates were first described by v. Engel, 1890, for the protopine group—certain unimportant alkaloids (protopine, cryptopine, chelidonine, homochelidonine, and chelerythrine) which occur in opium, but especially in other Papaveraceous plants (*Sanguinaria* or Bloodroot; and *Chelidonium* or *Celandine*; *Bocconia*, etc.). These alkaloids share also the depressant morphine action on the heart (Hale). They are said to paralyze the sensory endings like cocaine. The respiration is stimulated.

CHELDONINE

This is the most promising member of the protopine group. It is chemically related to papaverine, containing the benzyl-isoquinoline group. It therefore depresses all smooth muscle and has a low toxicity. It deserves clinical trial against spasm and colic of smooth muscle, asthma, etc., *i.e.*, in the same fields as benzyl benzoate (Hanzlik).

Central Actions.—H. Meyer, 1892, found that it produces, in frogs, descending depression of the central nervous system, similar to morphine, but without spinal stimulation. Mammals also respond by analgesia and sleep, without marked depression of reflexes.

The respiration is unaffected by therapeutic doses; moderately slowed by large doses. Toxic doses cause coma, without nausea or vomiting; finally, the vasomotor center becomes paralyzed.

Peripheral Actions of Chelidonine.—These have been investigated especially by Hanzlik, 1915, 1921. Like other isoquinoline alkaloids (narcotine, papaverine), it depresses all kinds of smooth muscle. The effect appears to be directly on the muscle substance, since it antagonizes not only pilocarpine, but also histamine, peptone, anaphylaxis, epinephrine and even barium; while these do not remove chelidonine depression.

Large doses depress cardiac muscle, slowing and dilating the heart. (Meyer erroneously attributed this to vagus stimulation.)

Skeletal muscle is also depressed (Hanzlik), and Meyer described paralysis of sensory and motor-endings. It has no effect on nerve-trunks, even in high concentrations.

Chelidonina Sulphas.—Freely soluble in water. Incompatible with chlorides. Dose, about 0.2 Gm., 3 gr.

Chelidonium Juice.—This is an acrid irritant, applied in folk-medicine to remove warts. The acrid principle has not been isolated. *Chelidonium* also contains berberine.

SANGUINARIA (BLOODROOT)

This has been used as a nauseant, usually as the 10 per cent. acidulated tincture (dose, 1 c.c., 15 min.).

Sanguinaria contains sanguinarine (Reports, Council Pharm. and Chem., 1911, 60) and other alkaloids (Kozniowski, 1910). It is irritant, but requires further pharmacological investigation.

BENZYL BENZOATE AND OTHER BENZYL ESTERS

The hypothesis that the benzyl radical is responsible for the tonus-depression of smooth muscle by papaverin, suggested to Macht, 1918, the trial of the simpler benzyl esters. Benzyl benzoate and acetate were found to relax excised smooth muscle from various organs. On this basis, they were tried clinically in colics or spasmodic conditions of smooth muscle.

More thorough investigation, however, showed that clinical doses, by mouth, are entirely without effect, for instance on the blood-pressure. Larger doses (also of benzyl alcohol) produce only local irritation, *i.e.*, vomiting and diarrhea (Gruber, 1923; bibliography). If injected parenterally, the benzyl compounds depress the heart and the respiration, and increase the urine flow (Gruber, 1925), without depressing the smooth muscle in those organs against whose overactivity the drug had been especially advised, *i.e.*, the uterus, intestines, stomach and bronchi (Mason and Pieck, 1920). The toxicity of the benzyl esters is low, since they are converted into hippuric acid.

The most extensive use of benzyl benzoate has been as an analgesic in functional dysmenorrhea (Litzenberg, 1919). The apparently beneficial results can probably be explained partly by suggestion, partly by reflexes from the taste and from the gastro-intestinal irritation. It is without effect on arterial hypertension, if the observations are properly controlled (Gruber, 1924; bibliography).

Nielsen and Higgins, 1921 and 1922, reported positive results (quieting of peristalsis; lowering of blood pressure; depression of the respiration) for intravenous injection of suspensions of various insoluble benzyl esters; but their results may be attributable to the colloidal precipitation of their esters. This does not seem to have been adequately checked.

The soluble sodium salts of the benzyl esters (sodium benzyl-succinate and sodium di-benzyl phosphate) are also ineffective by mouth, in clinical doses. Larger doses, administered parenterally to animals, generally depress the respiration and raise the blood-pressure (Gruber, 1925).

Hydrolysis.—The rate of hydrolysis by alkalies would be of some importance for the local effects in the intestines, and for absorption. Volwiler and Vliet, 1921, found the amount of hydrolysis in 4 hours to be 3 per cent. for the salicylate; 15, 18 and 23 per cent. for the benzoate, stearate and cinnamate, 40, 50 and 60 per cent. for the acetate, succinate and fumarate.

PREPARATIONS

Benzylis Benzoas, N.N.R.; Benzyl Benzoate, $C_6H_5COOCH_2C_6H_5$.—A colorless; oily liquid, of faint odor and disagreeable, sharp taste. Insoluble in water or glycerin; freely soluble in alcohol and fat solvents. Best prescribed as the commercial 20 per cent. alcoholic solutions or emulsions, usually flavored with aromatics (Spir. Anise). The dosage is 1 to 10 c.c. ($\frac{1}{4}$ to 2 teaspoons) of the 20 per cent. solution, in cold water, 3 or 4 times daily.

Benzaldehydum (Benzald.), U.S.P.; Benzaldehyde, C_6H_5CHO .—A colorless or yellowish, refractive liquid; odor resembling oil of bitter almonds; taste, aromatic and burning. Soluble in about 350 parts of water; miscible with alc., ether, fixed and volatile oils. Dose, 0.03 c.c., $\frac{1}{2}$ minim, U.S.P. Antispasmodic and anesthetic. A saturated sol.

(0.2 per cent.) relaxes the tonus and inhibits the contraction of smooth muscles. Small doses do not lower blood pressure. As local anesthetic it is inferior to benzyl alcohol, since its solutions rapidly oxidize to benzoic acid (Macht, 1919).

HYDRASTIS

Hydrastis (Golden Seal) has few, if any, rational indications. It is employed empirically as a bitter stomachic; to check internal hemorrhage; and locally in catarrhal conditions, especially of the genito-urinary tract.

Constituents.—Hydrastis contains at least three alkaloids, berberine, 1.5 to 4 per cent.; hydrastine, at least 2.5 per cent. (U.S.P.), and canadine a derivative of berberine. There is also some resinous matter, etc.

Hydrastine.—This is an isoquinoline derivative, closely related to some of the minor opium alkaloids, narcotine, laudanose and papaverine. Narcotine is methoxy-hydrastine, an H of hydrastine being replaced by OCH_3 .

By oxidation both give analogous artificial alkaloids, which are somewhat important:

Berberine, $\text{C}_{20}\text{H}_{17}\text{NO}_4$ (structure, Faltis, 1910) is an intensely yellow and bitter alkaloid, of wide occurrence, which gives the color and taste to a large number of "golden" roots and barks (Berberis, Xanthoxylon, Coptis, etc.).

Actions of Hydrastis.—An extensive study of hydrastis and its alkaloids was made by Bunge, 1895. This gives the literature to that time. Of later papers, mention may be made of those of Fellner, 1906; Williams, 1908; and Laidlaw, 1910. The effects of the drug and of its different alkaloids are qualitatively similar.

Central Nervous System.—Hydrastine produces convulsive effects analogous to those of strychnine. These are also obtained with the fluidextract. The derivatives hydrastinine and cotarnine have a purely depressant action, producing death by respiratory paralysis (Laidlaw). There is no narcosis.

Circulation.—From the experimental results, it seems that the effects of hydrastis and its alkaloids and derivatives on the circulation are too uncertain to be therapeutically useful. The clinical evidence also appears insufficient to establish their value. Frey, 1909, found that hydrastinine had no effect on pulmonary hemorrhage; and Hanzlik, 1918, showed that hydrastis and its alkaloids, including hydrastinine, are not styptic on ordinary wounds, either with local or systemic administration; but they rather tend to increase the bleeding. The effects of hydrastis on the circulation are variable, and the description of different investigators are discordant.

Williams obtained no effects with hypodermic or oral administration, even with very large doses. Intravenously the fluidextract, hydrastine and berberine produced the same results; considerable fall of blood pressure, followed with small doses by a slight and short rise. With large doses, the pressure remained low. These effects were predominantly cardiac (myocardiograms and oncometer); this overshadowed any possible vasomotor changes.

The vasomotor center is not directly affected by moderate doses of hydrastis, hydrastine, berberine, hydrastinine or cotarnine, but may be stimulated indirectly through respiratory depression, convulsive phenomena or cardiac arrest (Pilcher and Sollmann, 1915).

With toxic doses, there is vasomotor paralysis, and paralysis of vagus endings. Excised organs show some vasodilation.

On the scarified skin, hydrastine (1:1,000) produces some blanching (Sollmann and Pilcher).

Hydrastine is related to the protopine group, and therefore depresses the cardiac and skeletal muscle, and has a weak local anesthetic action.

Hydrastinine also causes some primary fall but a larger rise (about 15 mm.) maintained for over fifteen minutes; the heart rate is slowed. This rise is also predominantly cardiac, but there is a stimulation of the arterial muscle, not prevented by paralyzing

the nerve endings with ergotoxine. Kurdinowski, 1904, interprets its actions rather differently.

Uterine Actions.—Fellner, 1906; Kehrer, 1907, and Lieb, 1914, showed that hydrastis, hydrastine, hydrastinine and cotarnine increase the tonus and excite rhythmic contractions of the uterus, both in the excised organ and in living animals. This has been confirmed by the subsequent workers; also for the surviving human uterus (Ruebsamen and Kligermann, 1912). High concentrations relax (Wendling, 1915). Berberine has similar effects (Marek, 1911). La Torre, 1912, examined histologically the uteri of animals treated with hydrastinine. The muscular layers were contracted and thickened, compressing the larger vessels, and thereby probably decreasing the blood supply of the mucosa. Laidlaw found the stimulant action of hydrastinine and cotarnine constant in the excised organ, but varying with conditions during life. These actions resemble those of the pituitary and ergot principles; but hydrastis does not act on the intestine, and very slightly on the bladder. Synthetic hydrastine appears to be rather more stimulant than the natural alkaloid (Wendling, 1915).

The bronchioles are not markedly affected in pithed animals (D. E. Jackson, 1914).

Actions of Berberine and Canadine.—Berberine acts as a simple bitter in small doses. Its bitter taste and the yellow stain which it produces on linen, render it objectionable in the therapeutic use of hydrastis. Berberine is about seven times as active as hydrastine on the circulation; and as hydrastis contains about one and one-half times as much berberine, about 85 per cent. of the circulatory effect is due to this alkaloid. Large doses lower the temperature, increase peristalsis, and kill by central paralysis (Curci, 1892). It is not excreted, being probably oxidized completely (Berg).

Canadine resembles morphine somewhat in its action. It is present in too small a quantity to be of practical importance. It occurs also in xanthoxylum, where its actions have been studied by Laidlaw, 1913.

PREPARATIONS

Hydrastis, U.S.P.; *Hydrast. Rhiz.*, B.P. (Golden Seal).—The dried rhizome and roots of *Hydrastis canadensis*, yielding not less than 2.5 per cent. of ether-soluble alkaloids, U.S.P. *Dose*, 2 Gm., 30 gr., U.S.P.

Hydrastis was employed by the Indians, mainly as a pigment, but also as medicine. It was introduced by the eclectics about the end of the eighteenth century. The plant is becoming rare, but is easily cultivated (Henkel and Klugh, 1908).

Fldext. Hydrastis, U.S.P.; *Ext. Hydrast. Liq.*, B.P.—2 per cent. of ether-soluble alkaloids, $\frac{2}{3}$ alcohol, $\frac{1}{10}$ glycerin, U.S.P. *Dose*, 2 c.c., 30 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P.

Tr. Hydrast., B.P.—10 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Hydrastina, $C_{21}H_{21}NO_6$.—White prisms. Almost insol. in water. *Dose*, 10 mg., $\frac{1}{6}$ gr.

Hydrastin. Hydrochl., $C_{21}H_{21}NO_6.HCl$.—White powder. Very sol. in water or alc. *Dose*, 10 mg., $\frac{1}{6}$ gr. Maximum dose, 0.1 Gm., 1 $\frac{1}{2}$ gr.

Locally, for conjunctivitis, 0.1–0.5 per cent.; for gonorrhea, 0.25–0.5 per cent.

Hydrastinin. Hydrochl., $C_{11}H_{11}NO_2.HCl$.—Light yellowish needles or powder. Very sol. in water or alc. Its aqueous solution, especially when highly diluted, shows a blue efflorescence. *Dose*, 30 mg., $\frac{1}{2}$ gr.

COTARNINE

Cotarnine salts (marketed under the name of *stypticine* and *styptol*) have been tried locally and systemically, to arrest bleeding, especially in menstrual disorders. Their employment was based on very weak clinical and experimental data, which do not stand critical examination. It has no rational use.

Use Against Hemorrhage.—The older data were discussed rather fully in the 1917 edition of the Manual. Since then, careful experiments by Hanzlik, 1918, have demonstrated that cotarnine is not a local hemostatic. Systemically, it tends to lower blood-pressure, and thus indirectly somewhat decreases bleeding.

General Symptoms.—K. Molr, 1905, found that 0.1 to 0.2 Gm. per kilogram, in rabbits, dogs or cats produced only some lassitude and drowsiness. Larger doses had a

pronounced sedative action, especially in cats and dogs. Ataxia was also pronounced. With fatal doses, these effects were followed by some excitement, then progressive paralysis till death. Toward the end, the respiration became very slow and shallow, sometimes interrupted by asphyxial convulsions.

Laidlaw, 1910, on guinea pigs, describes indefinite depression of the central nervous system and death by paralysis of the respiratory center. Relatively small doses slowed the respiration, without change of depth.

Fatal Dose.—This ranges from about 0.1 Gm. per kilogram for guinea pigs (Laidlaw) to 0.3 to 0.4 Gm. per kilogram for rabbits, and even higher for dogs and cats (Mohr).

Uterine Contractions.—Kehrer, 1907, found that cotarnine stimulates the uterus, both excised and *in situ*, pregnant or non-pregnant; increasing the contractions and tonus. This has been confirmed for the excised organ by all subsequent workers (Laidlaw, 1910; Ruebsamen and Kligermann, 1912; Lieb, 1914). The results *in situ* are contradictory. Kehrer's stimulant effects were obtained with cats. With a pregnant rabbit, Mohr, 1905, obtained no stimulation. Laidlaw, 1910, also found the results on living rabbits negative, whilst the excised organ responded. La Torre, 1912, observed no histologic evidence of contraction, such as is seen after ergot and hydrastinine. Chiappe and Ravano found that the pregnancy of guinea pigs was not affected by toxic doses; and that even fatal doses produced no uterine abnormalities.

The clinical data are in harmony with these negative results. All reporters agree that cotarnine never provokes uterine pains, even in late pregnancy; that it does not hasten the involution of the uterus; and that it has no influence on postpartum hemorrhage.

Mohr claimed that cotarnine depresses the excitability of the uterus to hypogastric stimulation; but his conclusion appears to be based on a single very imperfect experiment with enormous doses, and must therefore be rejected.

It appears, from all this, that cotarnine stimulates the excised uterus, on local contact; but that, with systemic administration, the uterus does not respond, at least in rabbits; and certainly not with therapeutic doses in the human.

Other Smooth Muscles.—Offergeld quotes contraction of the intestines and bladder; but Laidlaw found the bladder irresponsive.

Systemic Circulation.—Intravenous injection produces variable changes in the blood pressure; sometimes a fall; or a momentary fall followed by a slight rise (Kehrer, 1907; Laidlaw, 1910; Lieb, 1914). If the vagi were divided, the rise is more prominent (Pilcher and Sollmann, 1915). The vasomotor center is not affected directly, but may be stimulated by the slowed respiration (Pilcher and Sollmann); and this probably accounts for the rise. The fall of pressure appears to be cardiac; for the Langendorff heart is slowed and weakened (Laidlaw). Kehrer and Heinz also consider the fall cardiac.

This diminished output of the heart has been credited with causing a hemostatic effect; but this is most improbable. There is no evidence that it occurs with therapeutic doses; and even with the experimental doses, it is too slight and especially too evanescent, to influence a persistent hemorrhage.

Direct Action on Systemic Arterioles.—All the earlier investigators (Falk, Marfori and Ronsse) affirm that cotarnine has no effect on the arterioles, with systemic administration. This has been confirmed by the negative results of perfusion experiments (Laidlaw, *leg.*). The positive results of direct contact with strong solutions have no bearing on this. Cotarnine does not produce the gangrene changes characteristic of ergot (Mohr).

Coagulation of Blood.—This is not affected, whether the cotarnine is added directly to the blood, or injected into the animal (Laidlaw; Marfori).

Dosage and Administration.—The cotarnine salts were used by mouth or hypodermically. The intramuscular dose is 0.25 to 0.5 Gm., as 10 or 20 per cent. solution, repeated daily as needed. The injections are not irritant. By mouth, the dosage is from 0.05 to 0.1 Gm. four to five times daily.

Side Actions.—None have been reported from oral administration or from hypodermic injections of 0.5 Gm. Offergeld found some lassitude with 0.7 Gm. and a single case of temporary collapse with 0.65 Gm. by intramuscular injection.

Cotarninae Chloridum (Cotarn, Chlor.), U.S.P. (Stypticine), $C_{12}H_{14}O_8NCl \cdot H_2O$.—Odorless, bitter, yellow, crystalline powder. Very sol. in water or alc., yielding yellow solutions. *Dose*, 0.06 Gm., 1 gr., U.S.P.

CANNABIS

The tops of the hemp plant are somewhat of a pharmacologic curiosity. They contain resinous constituents (cannabinol) which produce a peculiar psychic exaltation. Cannabis is employed as an intoxicant in the Orient. Therapeutically, it is used empirically (Extract 0.01 Gm., $\frac{1}{6}$ gr.) as an adjuvant to other drugs in nervous headaches, and as a coloring agent for corn remedies. The drug is of uncertain activity, and has no rational indication.

Intoxicant Action in Man.—The oriental use of Cannabis antedates history. It was introduced in Western medicine about the middle of the nineteenth century. When used as an intoxicant, the tops or resins are made into a confection or smoked with tobacco. Effective doses (2 gr. of solid extract of the Indian or American drug) produce after about an hour a state of partial inebriety and confusion, with happy and humorous tendencies. Ideas pass rapidly but disconnectedly, so that the time seems very long. The subject often has hallucinations of double personality. The exaltation, which seems to be much more marked in orientals, is succeeded by some irritability, dozing, and complete recovery in five or six hours. The effects are modified by individual disposition and surroundings (Hamilton, Lescotier and Perkins, 1913; A. Schneider, 1923). It is stated that the drug is not fatal even in very large doses, but experience on dogs certainly shows that it presents some danger. The habit to which it gives rise shows less effect upon the alimentary canal and less marasmus than does morphine, but more often psychic alterations, dullness, or mania. The clinical side actions are described by Seifert, *Nebenwirk.*, 1915, p. 149.

Cannabis smoking is becoming prevalent in Mexico and is said to be a national menace in Brazil. "Smokers nearly always become imbecile in time" (T. S. Blair, 1919).

Effects on Animals.—Dogs (Dixon, 1899) exhibit a decided narcotic effect. After a preliminary ataxia, excitement, and nausea, the animals usually fall into a deep and prolonged sleep, during which the sensation of pain is much diminished, whilst the reflexes persist. Some animals show acute mania; a fatal ending is not rare from doses which are ineffective in other animals, the same preparation being used. Considerable idiosyncrasy exists, and the action is fairly independent of the dose. The effects can not be obtained by hypodermic administration (on account of the non-absorption of the resin).

Rabbits seem absolutely insusceptible to the narcotic action of cannabis.

PREPARATIONS

Cannabis, U.S.P.; *Cannabis Indica*, B.P.; Cannabis, Indian Hemp (Hashish, Bhang, Guaza, Gangja, Charas, Momeka, Marihuana, etc.).

The dried flowering tops of the pistillate plant of *Cannabis sativa*. The B.P. requires that it be grown in India; the U.S.P. permits any origin, but provides that the activity must be confirmed by testing its narcotic effects on dogs (Houghton and Hamilton, 1907; U.S.P. IX). This is necessary since different samples vary greatly, and are liable to deteriorate rapidly. If the Indian drug is preferred, *Cannabis Indica* may be specified; if the American, *Cannabis Americana*. American grown Cannabis produces identical effects (Houghton and Hamilton, 1907 and 1908), but is generally only half as active (Eckler and Miller, 1912). The preparations, however, are brought to the same degree activity.

The American Drug Manufacturers' Association (1921) believe that its therapeutic use is not enough to justify the trouble of standardization.

The *active ingredient* is a resin, *cannabinol* (Fraenkel, 1903), $C_{21}H_{30}O_2$, which presents the appearance of a thick reddish yellow oil, soluble in petroleum ether, etc. (not identical with the commercial "cannabinol"). This changes by oxidation to an inactive black pitch. The change accounts for the deterioration which the drug and its preparations undergo in keeping. The deterioration can be prevented by excluding the air (Marshall, 1909).

However, there is some question as to the instability of the ordinary drug. H. C. Hamilton, 1918, claims that crude drug samples that had been on the shelves for at least 14 to 17 years still showed 70 per cent. of the bio-assay activity of the "standard" recent drugs; and that nine year old extract has apparently not lost in activity.

Cannabis also contains a volatile oil (terpenes), paraffin, pitch, etc., which are not concerned in its action. There is no specific alkaloid, but the extracts may give alkaloid reaction from the formation of choline and trimethylamine. These are not connected with the action. The fresh extract has a beautiful green color (if prepared without excessive heat), due to chlorophyll. The active principle is completely extracted by alcohol, but is insoluble in water.

The pretended *Isolated Principles* on the market under various names are generally quite inactive (S. A. Matthews, 1908).

Ext. Cannabis (Ext. Cannab.), U.S.P.; *Ext. Cannabis Ind.*, B.P.—A pilular alcoholic extract, about 25 times as strong as the fluidextract (U.S.P.). *Dose*, 15 mg., $\frac{1}{4}$ gr., U.S.P.; 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P. Maximum dose, 0.1 Gm., $1\frac{1}{2}$ gr.

Fldext. Cannabis, U.S.P.—*Dose*, 0.1 c.c., $1\frac{1}{2}$ minims, U.S.P.

Tr. Cannabis Ind., B.P.—5 per cent. of extract. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

PISCIDIA (JAMAICA DOGWOOD)

This drug produces ataxia similar to cannabis (Pittenger and Ewe, 1919; bioassay), and was introduced as a sedative, hypnotic and analgesic (Ott, 1883; Nagle, 1881). However, it is practically useless (Tyrode and Nelson, 1905).

It contains a crystalline non-nitrogenous principle, "piscidin;" but this does not seem to be the bearer of the ataxic action (Pittenger and Ewe).

LACTUCARIUM—DRIED LETTUCE JUICE

The dried milk juice of wild lettuce, *Lactuca virosa*, was introduced by Dr. Coxe of Philadelphia in 1799 as a sedative. The average dose is 1 Gm., 15 gr. Lettuce had some reputation as a hypnotic in ancient times, but it is probably undeserved. Kelterborn took 12 Gm. of Lactucarium without any effects. No active principle has been determined.

LUPULIN AND HOPS

These act as bitters, and have some popular but exaggerated reputation as hypnotics. The average dose of hops is 2 Gm., 30 gr.; of lupulin, 0.5 Gm., 8 gr. Hops are the dried pistillate flowers of *Humulus Lupulus*. The active principles are contained in small glands, which can be separated as a powder, and constitute the *Lupulin*.

Two acids (α and β -*lupulinic acids*) are present. They stimulate the respiratory and vagus centers; this is followed by depression. They also depress the cardiac muscle. Lupulin contains a further, unknown, constituent which is insoluble in water and is a strong cardiac poison. Power, Tutin and Rogerson, 1913, also found a trace of alkaloid. All these, however, are not active when administered by the stomach, and are therefore not concerned in the action of the drug.

LOCO DISEASE

Horses, cattle and sheep on the Western stock ranches are subject to this peculiar disease, which bears some resemblance to drug habits. The symptoms consist in motor incoördination, forced movements, misjudgment of distance, stupidity, apparent hallucinations. In the chronic form there is emaciation. Death is preceded by coma and convulsions.

The cause of these conditions is obscure. It is generally attributed to feeding on certain leguminous plants ("loco weeds"—especially *Astragalus*). C. D. Marsh, 1909, claims to have reproduced the condition (nervous symptoms, etc., with exudative meningitis, anemia, etc.) experimentally by very long-continued feeding with these plants; but H. T. Marshall, 1914, considers the results in conclusive, and believes that there is no distinct loco disease; and that the name covers a variety of conditions—malnutrition, parasitism, etc.—unconnected with the loco weed.

CORYDALIS CAVA

F. Peters, 1904: The alkaloids produce a peculiar narcotic action, including a typical cataleptic condition; so that the animal does not move spontaneously, but remains in any condition in which it is placed.

COCAINE GROUP; LOCAL ANESTHETICS

Actions and Uses.—The alkaloid cocaine is important mainly as a local anesthetic, paralyzing the sensory nerve fibrils on direct application. With dilute solutions, its action may be confined to these; but higher concentrations paralyze all other nerve fibers, and, indeed, all protoplasm. It also causes local vaso-constriction. The pupils are dilated through stimulation of the sympathetic pupillo-dilator mechanism, both central and peripheral.

When cocaine is absorbed in sufficient quantity, it produces complex systemic actions, involving stimulation and paralysis of various parts of the central nervous system. These are mainly of toxicologic and scientific interest. Its continued use leads to the formation of a habit, resembling morphinism.

Analogous local anesthetics are produced by a variety of synthetic bases, which may be used as substitutes for cocaine; such as Procaine (novocaine), alypine, beta-eucaine, apothesine, benzyl alcohol, phenylcarbinol, stovaine; also tropacocaine and quinine-urea hydrochloride. Potassium salts are anesthetic under suitable conditions.

Historical.—Cocaine is derived from the leaves of *Erythroxylon Coca*, a tree indigenous to Peru, Chile and Bolivia. The leaves were chewed from time immemorial by the natives to relieve hunger and fatigue, and to produce a psychic stimulation, somewhat after the manner of caffeine. It is now cultivated in other tropical countries.

In Europe, trials with the leaves gave disappointing results. The discoverers of cocaine (Woehler; Niemann and Lossen, 1860) incidentally described its benumbing action on the tongue, but without realizing its significance. As late as 1880, a British medical commission reported on the drug as merely a poor substitute for caffeine (further details, J. U. Lloyd, 1911, "History of Vegetable Drugs," and 1913, J. Am. Pharm. Assoc., 2:1242). In the same year, Anrep subjected cocaine to a thorough pharmacologic investigation.

In 1884, the Vienna oculist, K. Koller was engaged in general pharmacologic experiments with cocaine, and it occurred to him that the numbing effect on the tongue was really anesthesia. Being interested in ophthalmic anesthesia, he tried the cocaine immediately on the eyes of animals, and then in the clinic, and announced the discovery to the German Ophthalmologic Society (Koller, 1920). Its practical value was at once generally recognized.

Peripheral Nerves.—Local Anesthesia.—Local contact with cocaine paralyzes all forms of nervous tissue, without preceding stimulation. The susceptibility of the various nerve fibers presents marked and characteristic quantitative differences. Sensory fibers are especially easily attacked; and by using appropriate dilutions, the paralysis can be confined strictly to them. With sufficient concentration, the paralysis is as complete as if the nerve fibers had been severed with a knife. If the alkaloid is washed away, or absorbed, the nerve recovers its functions promptly and completely (but very strong solutions may produce neuritis and permanent paralysis).

Since these effects are strictly local it follows that the cocaine must be applied in such a way that an effective concentration will reach the nerve supply of the part which it is desired to affect. This may be accomplished, according to circumstances, by painting a solution on mucous membranes (from which it is very readily absorbed); or by injecting it into or under the skin (infiltration and subcutaneous anesthesia); or around or into the nerve trunk (peri- or intraneural anesthesia); or around the spinal nerve roots (subdural or spinal anesthesia). The intact skin is practically

impermeable to cocaine, although it penetrates slightly if the skin has been soaked (Macht *et al*, 1916).

Duration of Local Action.—The onset and duration of the anesthesia vary with the concentration of the solution, and the method of its application. Roughly speaking, it starts in a few minutes and lasts perhaps ten to thirty minutes, with a single application.

Local Anemia.—As the cocaine is absorbed and thus removed from the site of application, its local action ceases and its systemic and toxic effects start. Since cocaine is rapidly destroyed in the body, the systemic toxicity increases with the rapidity of absorption. It is therefore desirable and often necessary to delay the absorption. This may be done by restricting the local circulation. Cocaine itself tends to do this by producing a local vasoconstriction—an action which is not shared by its substitutes. This vasoconstriction should be reinforced by the addition of epinephrine. In this way, more dilute solutions may be used, and the anesthetic effect is much more prolonged. In suitable situations, the circulation may be slowed by bandages, or arrested by temporarily clamping the arterial blood supply.

Interruption of the circulation was introduced by Corning in 1885. He showed that this makes $\frac{1}{4}$ of $\frac{1}{3}$ per cent. cocaine solution more effective than the 2 to 10 per cent. solutions that were then in vogue; and that it greatly diminishes the danger of poisoning (H. Braun, 1914).

The anemia also favors anesthesia directly; ligation of a large artery in itself produces anesthesia of the nervous end structures.

When a large quantity of dilute cocaine solution is injected under pressure, as in the infiltration anesthesia, the cocaine action is reinforced by anemia, pressure, and edema.

Comparison of Anesthetic Efficiency.—This may be attempted by a number of experimental methods. In transferring the results to clinical problems, the conditions of the clinical use must be borne in mind (Sollmann, 1918).

Intracutaneous Injection (the "wheal" or "quaddel" method of H. Braun), observing either the duration or better the threshold values of the anesthesia. This reproduces practically the conditions of *infiltration and of injection anesthesia*. When combined with epinephrine, it also measures absolute anesthetic efficiency. The ratio by this method is as follows:

Percentage	Intracutaneous Injections	Efficiency Ratio
$\frac{1}{32}$	Cocaine, procaine, tropacocaine and alpine hydrochlorides	1
$\frac{1}{16}$	Beta-eucaine hydrochloride, apothesine	$\frac{1}{2}$
$\frac{1}{8}$	Quinine-urea hydrochloride	$\frac{1}{4}$
$\frac{1}{4}$	Antipyrine, potassium sulphate	$\frac{1}{8}$

The susceptibility of different skin areas varies, even in the same neighborhood, so that discordant results are sometimes obtained.

The solutions should be approximately isotonic (3.5 per cent. or higher, corresponding to 0.55 to 2.5 per cent. NaCl). Stronger and weaker solutions are first

irritant, then anesthetic, even when indifferent salts are used (Braun, 1914). More dilute solutions should have about 0.5 per cent. of KCl added (H. Braun).

Hypodermic Standardization by Dogs.—A method is described by Pittenger, 1921.

Mucous Membranes.—The skin of the frog's foot is most convenient; but rabbit's cornea corresponds more closely to clinical conditions. However, it must be remembered that the absorbability, and therefore the ratios, would differ for various mucosæ. The results on the cornea are as follows:

Percentage	Rabbit's Cornea	Efficiency Ratio
$\frac{1}{2}$	Cocaine and phenacaine (holocaine) hydrochlorides	1
1	Beta-eucaine hydrochloride	$\frac{1}{2}$
2	Tropacocaine, alypine and quinine-urea hydrochloride	$\frac{1}{4}$
4	Apothesine hydrochloride	$\frac{1}{8}$
8	Procaine hydrochloride	$\frac{1}{16}$
10	Antipyrine, KCl	$\frac{1}{20}$

Sensory Nerve Fibers of Frogs.—These may be tested through reflexes. The results correspond to the conditions of "nerve-blocking."

	Sensory Reflex	
$\frac{1}{4}$	Cocaine, procaine, and tropacocaine hydrochlorides	1
$\frac{1}{2}$	Alypine hydrochloride, KCl	$\frac{1}{2}$
2	Quinine-urea hydrochloride	$\frac{1}{8}$
8	Antipyrine	$\frac{1}{32}$

Paralysis of the Motor Fibers of the Excised Nerve Trunks of Frogs.—This gives concordant results of scientific interest; but since these cannot be transferred to sensory paralysis they are of no clinical value.

	Motor Fibers	
$\frac{1}{8}$	Cocaine, procaine and tropacocaine hydrochlorides	1
$\frac{1}{6}$	Alypine hydrochloride	$\frac{3}{4}$
$\frac{1}{4}$	KCl	1
1	Quinine-urea hydrochloride and antipyrine	$\frac{1}{8}$

The Selective Action of Cocaine on Motor and Sensory Fiber.—When a $\frac{1}{2}$ to 2 per cent. solution of cocaine is injected into a mixed nerve, or into the subdural canal, the selective action is very marked, so that there is complete anesthesia, without motor impairment (Alms, 1886). If the contact is prolonged, by stopping the circulation, or if stronger solutions are employed, the motor fibers become paralyzed, so that the difference is merely quantitative. A similar difference in the susceptibility of motor and sensory structures exists also for the alcohol group, aconitine, phenol, hydrocyanic acid and for pressure (Luedvitz); and even for the centrally acting narcotics, ether, etc. It is therefore a characteristic of nervous tissue rather than of cocaine.

Winterstein, 1919, pointed out that these facts do not really establish a selectivity for the sensory fibers; for it is quite conceivable that the muscles might respond to a weaker nerve impulse than the several-linked sensory path. He holds that there is not at present any real evidence of a material difference in the susceptibility of the two kinds of nerve-fibers.

Cocaine is Less Effective in Inflamed Tissues.—This may perhaps be explained by the hyperemia, resulting in more rapid absorption.

Peripheral Paralysis of Special Sense Nerves.—Cocaine abolishes not only the sensation of pain, but other special sensations, if it is suitably applied. Here also there is some selection. *In the skin*, it paralyzes the sense of pain, temperature and tickling, before touch and pressure (Goldscheider). *In the nose*, it abolishes the olfactory sense. *On the tongue*, it destroys the taste for bitter substances, but has less effect on sweet and sour taste, and none on salty taste.

Selective Action on Other Nerves.—When cocaine is applied to the appropriate nerves, it is found that the centrifugal vagus fibers are paralyzed before the centripetal; vasoconstrictor fibers before vasodilator; bronchial constrictors before the dilators, etc. (Dixon, 1904).

Visceral Pain.—The abdominal viscera are sensitive to pain in normal animals; but the sensation is abolished by cocaine, even when small doses (0.7 mg. per kilogram) are injected at a distance; for instance, into the pectoral muscles (Kast and Meltzer, 1906-1909). This special anesthesia lasts about half an hour. The insensitiveness of viscera in surgical operations under cocaine anesthesia is thus explained. The effect is probably central, for the animals are greatly quieted, although general sensation is not impaired.

Nature of Action.—Of this, little is known, except that it is purely functional. No structural changes are discoverable in the nerve fibers.

Carbon Dioxide Production in Nerve.—Niwa, 1919, investigated this on frog's sciatic nerve by the Tashiro method. He found the same effects from cocaine as from the aliphatic narcotics: Subanesthetic concentrations increased the production. With anesthetic concentrations this increase was short or absent, the main phenomenon being decreased production.

Site of Action.—Cocaine can paralyze the nerve fibers anywhere in their course, wherever it is brought into contact with them. When it is applied to mucous membranes or hypodermically, it doubtless selects the portions peripheral to the main trunks, the thinner sheath of the terminal fibrils facilitating its penetration. It is therefore unnecessary to assume a selective action on the histological sensory endings.

Penetration.—It is quite possible that its selective action on different nerve fibers may also depend, in part, on differences in penetration.

Alkalinization.—The addition of sodium bicarbonate increases the efficiency of the local anesthetics 2 to 4 times, for direct application or injection into nerve trunks, and probably for subdural injection and on application to mucous surfaces. This is due to the easier penetration of the free anesthetic bases, as compared with their salts (O. Gros, 1910; A. Laewen, 1910, 1912; Sollmann, 1918). This does not apply to hypodermic and intradermic injections, since these do not require penetration.

For all other purposes, the usual solutions of the anesthetic salts may be mixed with an equal volume of 0.5 per cent. sodium bicarbonate solution, without loss of efficiency, and with a saving of one half of the anesthetic, and correspondingly smaller danger of accidents. These mixtures, however, do not keep well, and must be made just before use (Sollmann, 1918).

Combination of Anesthetics.—The efficiency of mixtures of the local anesthetics corresponds to more or less complete summation without any potentiation (except potassium, see below). That is, if solutions of different anesthetics are diluted until they are "just effective," then a mixture of any two of these solutions will also be "just effective," no more and no less (A. Schmidt, 1913; Sollmann, 1918). There would therefore be little or no practical advantage in such mixtures.

Potassium Synergism.—Potassium salts may give considerable potentiation with the other anesthetics (Hoffmann, A., and Kochmann, 1912, 1914). However, this seems to hold mainly for motor fibers, and not for sensory; and therefore has little practical importance (Sollmann, 1918). One per cent. potassium chloride could be used with some advantage in place of sodium chloride, for making up isotonic anesthetic solutions (H. Braun, 1913).

Epinephrine-anesthetic Combinations.—H. Braun, 1903, confirmed that the anesthetic effect of cocaine injections is greatly improved by the addition of epinephrine (about 1:50,000). The duration of the anesthesia is prolonged for over an hour and therefore the effective concentration can be considerably lowered, and the danger of poisoning almost abolished. These results are due to the vasoconstriction, which practically arrests absorption into the circulation.

On the other hand, the nervousness induced by epinephrine in hypersensitive individuals may make them more susceptible to cocaine-collapse.

The greatest field for the epinephrine combination is in connection with operations involving bleeding. The epinephrine is useless on the intact cornea; and probably also for intravenous or subdural injections (Sollmann, 1918).

Epinephrine is similarly efficient with procaine and apothesine. Its effect is not as pronounced with stovaine, and is practically absent with tropacocaine, since $1\frac{1}{2}$ per cent. of this destroys the vasoconstrictor effect of epinephrine (Smyth, 1911). Beta-eucaine also counteracts epinephrine (Braun, 1914).

Cocaine actually potentiates the epinephrine constriction (Braun, 1914) even with very small concentrations of cocaine (Fischel, 1915). Cocaine therefore increases the pressor effect of epinephrine. This may also result in a marked rise of blood pressure when cocaine is used clinically in connection with epinephrine; and the excessive vasoconstriction may be the factor in the toxicity (E. L. Ross, 1922). The synthetic local anesthetics are also somewhat synergistic to epinephrine (Eggleston and Hatcher, 1919).

Epinephrine is not directly anesthetic either alone or in combination with cocaine; for it does not increase the anesthetic effect when the circulation has previously been arrested; nor does it lower the threshold concentration in wheals, although the duration of the anesthesia is greater for a given concentration (Sollmann, 1918).

Local Vasoconstrictor Action.—The application of cocaine to mucous membranes, particularly the inflamed conjunctiva, constricts the capillaries and small arterioles, resulting in blanching, astringent sensation, and actual contraction of vascular formations, such as polypi. The cocaine substitutes do not possess this action; many of them dilate the vessels (alpine, eucaine, stovaine); procaine has no effect (Impens, 1905; Gros, 1910).

Since the cocaine action is local, it must be peripheral. Perfusion experiments (by the Trendelenburg method), have however given contradicting results. According to Abe, 1920, this depends on the species of frogs: *Rana temporaria* responds with pure dilation, *esculenta* with dilation followed by constriction. The results are the same whether the cocaine is injected into the perfusion fluid, or applied externally to the web. The latter disposes of the suggestion of Heinz, that cocaine acts differently from the outside (constriction) and inside (dilation) of the vessels.

Effect on Capillary Hemorrhage.—Cocaine is distinctly hemostatic; procaine, apothesine, and other synthetic anesthetics tend rather to increase bleeding.

Anesthesia by Ischemia.—Persistent interruption of the blood supply of a part gradually induces anesthesia. However, this requires hours and therefore has no direct share in cocaine anesthesia. Indirectly, limitation of circulation, including local cooling, is important by delaying absorption.

Effect of Temperature on Local Anesthesia.—With the frog's nerve, this differs for the various types of anesthetics; cocaine, salicylamide and monacetine are more effective on cooled nerves; whilst alcohol and chloral are more effective on heated nerves. This is probably connected with differences in solubility, *i.e.*, the "partition-coefficient" (H. Moral, 1918).

General Toxicity to Protoplasm.—Cocaine is a typical, if rather weak, protoplasmic poison, paralyzing all sorts of cells, without producing any gross chemical changes. It is toxic to the lower forms of animal life (infusoria, etc.); but has little effect on bacteria, or on ferments.

Precipitation of Proteins and Astringency.—Neither cocaine nor the synthetic local anesthetics precipitate proteins; they are therefore not astringent in the ordinary sense, nor irritant (Sollmann, 1919; alypine, anesthesine, apothesine (slightly), cocaine, cycloform, holocaine, orthoform-new, procaine, propaesine).

Antiseptic Action.—Benzyl alcohol beta-eucaine and holocaine are antiseptic; cocaine and procaine are not (Macht and Satani, 1920).

Yeast Growth.—This is inhibited by small quantities of cocaine, whilst larger doses accelerate (Somoggi, 1916).

Toxicity for Earthworm and Tadpoles.—This is not parallel to the toxicity for mammals (Sollmann, 1919).

Actions of Cocaine on the Eye.—When cocaine is applied to the conjunctiva, it produces local anesthesia (which may not extend to the iris); local anemia (which extends to the iris, but not to the retina); and sub-maximal dilation of the pupil by peripheral sympathetic stimulation. The mydriasis occurs also on systemic administration. The accommodation is impaired, but the light reflex is preserved; there is some exophthalmos. The intraocular pressure is usually lowered, but may be increased. The mydriasis and its associated phenomena are not produced by most of the cocaine substitutes.

Injury.—Cloudiness and even ulcers of the cornea sometime follow the application of cocaine; they are explainable by the drying, and the irritation of dust and other foreign matters which are not perceived on account of the anesthesia, and the abolition of the winking reflex. The protoplasmic toxicity may have a part in their production.

Relative Irritation of Conjunctiva by Various Anesthetics.—Experimental data are given by Closson, 1914. It is difficult, however, to estimate degrees of irritation on animals.

The Cocaine Mydriasis.—This differs in important respects from the atropine mydriasis; with atropine, the dilation is greater; the light reflex is preserved; the intraocular tension is always raised; exophthalmos is absent. The pupil does not react readily to pilocarpine or muscarine, whilst these constrict the cocaine pupil easily.

These differences point to a different mode of action. In effect, atropine paralyzes the oculomotor (constrictor) endings, whilst cocaine stimulates the sympathetic (dilator) mechanism; for when the sympathetic fibers have degenerated (eight days after extirpation of the superior cervical ganglion) ordinary doses of cocaine cease to be effective (Limbourg, 1892; Schultz, 1899). Dilation may still occur, however, with large doses or under special conditions. Simple (postganglionic) division of the sympathetic does not immediately abolish the cocaine reaction; the stimulation must therefore involve the endings; but since the dilation is not as strong, it would seem that, ordinarily, the pupillo-dilator center is also concerned (Schultz, 1898).

Under ordinary conditions, the cocaine pupil continues to respond to oculomotor stimulation, showing that the constrictor mechanism is not paralyzed. Prolonged application of a 5 per cent. solution, however, also paralyzes the oculomotor endings. In birds' eyes cocaine produces no dilation, whereas in frogs it is very marked.

Cycloplegia.—Strong solutions of cocaine act somewhat on the oculomotor endings, and therefore impair accommodation. This begins in five or ten minutes. The maximum is reached in thirty minutes and lasts ten to fifteen minutes; the normal is restored

in one and one-quarter to two hours. The accommodation is merely disturbed by a drop of 6 per cent. solution; high concentrations paralyze it completely. The mydriasis develops somewhat more slowly and is more lasting (Horovitz, 1912). C. Wood, 1893, advises the addition of cocaine to homatropine, to paralyze accommodation.

Intraocular Pressure.—This may be unchanged, or raised or lowered (Tourriere, 1913). The reduction is probably due to the local vasoconstriction, which would tend to lessen the lymph flow into the chambers. This is partly counteracted by the mydriasis, which leads to obstruction of the lymph channels by the relaxed ciliary muscles (see "Atropine"). This obstruction may predominate, and the pressure may thus be increased, especially glaucoma (Myashita, 1913).

Eucaine and alypine act similarly. Holocaine is said to have provoked acute glaucoma (Gjessing, 1915). Tropacocaine and acocaine are probably inactive (Bollet and Curtil, 1911).

Retinal Vessels.—These are strongly constricted by cocaine (Hirschfelder, 1915). This may be responsible for the occasional occurrence of optic atrophy (Harnack, 1912).

Smooth Muscle.—This is generally first stimulated, then depressed by cocaine, regardless of innervation (constituting a fundamental distinction from epinephrine). The stimulation is therefore not through the sympathetic; nor is it parasympathetic, for it is not prevented by atropine. It must be exerted directly on the muscle. This applies also to the synthetic cocaine substitutes (Waddell, 1917).

The excised ureter is stimulated by both cocaine and procaine; excised intestine (rabbits) is stimulated by small doses of cocaine and depressed by large doses; it is depressed by procaine in all concentrations (Roth, 1917).

The urinary bladder (excised) is stimulated by cocaine, less by the synthetic substitutes. Mixtures of these give simple summation. So does pituitary and epinephrine, the latter being depressant (Waddell, 1917).

Cardiac muscle and the salivary glands are not stimulated (Kuroda, 1915).

Striated Muscle.—Kubota and Macht, 1919, investigated the effects of cocaine and most of the synthetic substances (allocaine S, alypine, apothesine, benzyl alcohol, beta-eucaine, holocaine, procaine, and stovaine). All depress the excitability and contractibility, and hasten fatigue. There was no stimulation, even with small doses.

J. T. Fulton finds that a colored derivative of procaine, with similar actions, produces vital staining confined to the muscle nuclei; and argues from this that the nuclei constitute the "receptive substance"—a rather hazardous deduction.

Motor Endings.—Large doses of cocaine paralyze these in frogs. This curare action would not be seen in intact mammals.

Procaine on Tetanus.—E. Meyer and Weiler, 1916 and 1917, discovered clinically that the intramuscular injection of procaine relaxes traumatic tetanus. This has been further studied by G. Liljestrand and Magnus, 1919. They found that procaine injections ($\frac{1}{2}$ c.c. of 1 per cent. procaine, per Kg.), locally relax various kinds of tonic tetani, although active and reflex movements are not affected. The relaxing effect does not occur, with these doses, if the posterior spinal roots have been cut. Apparently, therefore, the procaine acts in this case by abolishing the sensory impulses, which help to maintain tone and tetanus.

In most cases, however, the action is directly on the muscle fiber; for all local anesthetics, even in very dilute solutions counteract various spasms, such as those of nicotine, guanidine and veratrine, also after curarization or after degeneration of the nerve endings. The antagonism is mutual (Frank and Katz, 1921).

Antagonism of Caffeine Rigor.—Procaine (1:500) prevents caffeine contracture and rigor and the over-production of lactic acid, even in concentrations which do not directly depress the response of the muscle to stimulation. The concentration, however, must increase with that of the caffeine. The action is reversible, *i.e.*, when the procaine is washed away, the muscle again becomes susceptible to the caffeine. Established rigor is not removed. Cocaine acts similarly, but requires considerably higher concentrations; anesthesine is quite effective; atropine lacks this action (Schüller and Athmer, 1921; Schüller, 1925).

Oviduct Secretions of Birds: Cocaine appears to decrease somewhat the albumin and the shell-material (Riddle and King, 1921).

SYSTEMIC ACTIONS

These are rather variable and complex, depending largely upon the dose. Whilst all structures are first stimulated and then paralyzed, the susceptibility to the poison is not uniform. Indeed, some portions

of the nervous system show only stimulation, death occurring before the paralysis of these structures is reached.

Stimulation of Higher Functions.—The first effect is a stimulation of the higher parts of the brain (caffeine action). This is shown in animals by *increased movement* (sometimes “circus movements”). In man there is some *psychic stimulation* and wakefulness. A greater *endurance against fatigue and hunger* is also noticed.

How far this may be due to stimulation after the manner of caffeine, or to narcosis, after the manner of morphine, cannot be stated. It is not at all unlikely that both play a part. In regard to the sensation of hunger, it is also probable that local anesthetization of the stomach aids in the effect.

The resistance to fatigue can be demonstrated with the ergograph.

Another evidence of the stimulating action of cocaine is furnished by the fact that animals to which it has been administered are more difficult to put and to keep under chloroform or other anesthetic. Mosso, 1887, and Airila, 1913, find that 10 to 40 mg. of cocaine, hypodermically, wakens dogs or rabbits from deep chloral sleep. The stimulation is greatest with excitable individuals, and may seriously interfere with operations.

Incoördination, Narcosis, Convulsions.—The stage of stimulation may be very short or even absent. With somewhat larger doses it is usually succeeded by depression, first of the *coördinating functions*. The movements lose their purposive type and become choreic. This is followed by a general *narcosis*; and then by *convulsions*. If the paralysis is rapid, the convulsive stage may not appear.

The Seat of the Convulsions.—This has not been exactly determined. They, like the other effects, are probably descending, and the different convulsive centers may be affected in succession. In some stages at least they seem to reside exclusively in the hind brain. In dogs, they appear to be confined to the cerebral cortex, for Feinberg and Blumenthal, 1887, claim that they do not occur after ablation, nor in new-born animals, in which the cortical motor centers are not yet excitable. Rabbits deprived of the hemispheres do not show the clonic convulsions or respiratory effects; but they do exhibit tonic convulsions and “running movements.” Their resistance to toxic doses is increased (Morita, 1915).

Central Phenomena in Frogs.—These show at first symptoms of stimulation by increase of the voluntary movements and exaggeration of the reflexes, sometimes leading to convulsions. This is followed by paralysis of the whole central nervous system.

Spinal Cord.—In frogs from which the brain has been removed, cocaine causes at first an increase of the reflexes, then convulsions, and finally total paralysis. In intact animals this effect is obscured by the action on the higher centers of the nervous system.

The results of applying cocaine directly to the cord will be considered later.

Respiration.—This is at first accelerated. During the spasms it is irregular. The volume then diminishes. It may assume the Cheyne-Stokes type. Respiratory paralysis is the usual *cause of death*. This is also the first center to fail when the cocaine is applied locally to the fourth ventricle.

Roth, 1917, found that small doses of procaine also increased the respiration; large doses being depressant.

Excised bronchial muscle is somewhat dilated (Trendelenburg, 1912).

Emesis.—The vomiting which frequently occurs in cocaine poisoning is perhaps due to the medullary stimulation, but its mechanism has not been fully investigated.

Circulation.—The effects of cocaine on the general circulation are partly central, partly peripheral. They vary according to the dose, and are also influenced by individual susceptibility.

The typical effects are as follows:

Very small doses diminish the pulse rate, by stimulation of the vagus center (Vulpian, 1884). There is a quick rise of *blood pressure* from stimulation of the vasomotor center; this is followed by a temporary fall due to the slowing.

Moderate doses quicken the pulse, mainly by central and peripheral depression of the vagus (v. Anrep, 1880) with some stimulation of the accelerator center (Mosso, 1887). *The pressure rises* (v. Anrep) from stimulation of the vasomotor center (Berthold, 1885), aided by the faster heart rate. The vasomotor factor is predominant, for the rise is practically absent if the cord is cut.

Large doses cause a great fall of pressure and slow and weak pulse (v. Anrep), from the depression of the medullary centers (collapse) and of the cardiac muscle.

Actions on Heart Rate.—This demands some further discussion: The *slowing* from small doses does not occur if the vagi have been cut, so that it is of central origin. The *quicken*ing from moderate doses is also less marked if the vagi have been divided, so that it is probably due in part to a depression of the vagus center. The vagus ganglia are also depressed, for electrical stimulation of the vagus trunk is only partly successful (v. Anrep, 1880). In the frog these ganglia can be paralyzed completely by the local application of cocaine, but in the intact mammal the paralysis is not complete. Some quickening occurs, however, even when the vagi have been divided, but none is seen if the accelerators have also been cut. The *final slowing* is due to direct paralysis of the muscle, for it is accompanied by weakening of the contraction, and it occurs after atropine, and in the excised heart.

Cocaine also stimulates the cardio-inhibitory center when *perfused through the medulla* of the turtle (Bush, 1920).

The Excised (Langendorff) Mammalian Heart.—This has been investigated by Hedbom, 1899; Kochmann and Daels, 1908; and Prus, 1913. Low concentrations slow and strengthen the contractions; higher concentrations cause slowing and weakening; fatal concentrations give diastolic arrest. Kuroda, 1915, observed no stimulation in excised hearts of mammals or frogs.

The Frog Heart.—Dilutions of cocaine 1:500,000 increase the excursions of Straub hearts; 1:300,000 slows and diminishes the systole; 1:60,000 arrests the ventricle (Kochmann, 1921). Perfusion produced heart-block, which may be prevented by atropine or epinephrine (Kuroda, 1915). The threshold of the non-rhythmic apex to electric stimulation is depressed, and larger doses also lower the height of concentration (Sasaki, 1921). Direct application of 6 per cent. cocaine to the sinus suppresses the nodal rhythm, and therefore arrests the heart, while the same application to the auricles or ventricles does not produce arrest (Maestrini, 1916).

The turtle heart is also stimulated by low and depressed by somewhat higher concentrations (H. G. Bayer, 1885).

Procaine depresses similarly to cocaine (Roth, 1917).

The effects on blood pressure have been described mainly by Ott, 1874; v. Anrep, 1880; Vulpian; Mosso, 1890, and Reichert, 1891. The comparative effects of cocaine and procaine have been investigated on dogs by Kamenzove, 1911. Roth (1917) found that both drugs increase the blood pressure in small doses, and lower it when given in large doses.

Splanchnic Circulation; Influence on "Shock."—The intravenous injection of cocaine has a very pronounced effect on the *splanchnic circulation*. The intestines appear unusually pale. Handling of the viscera and other measures of "shock" which cause a splanchnic dilation and consequent fall of blood pressure in normal animals, have less or no effect after cocaine. Burning and stimulation of the sciatic, which cause a rise of pressure normally, are also ineffective (Crile, 1901). Péré, 1906, on the other hand, claims that local anesthesia (by cocaine, its substitutes, or freezing) does not abolish the depressant reflexes (decrease of muscular work, of sharpness of vision, etc.); these occur from procedures which would ordinarily be painful, even when the sensation of pain is eliminated.

Cerebral Circulation.—This is increased by cocaine, and still more by procaine (Frankfurter and Hirschfeld, 1910). The vessels of the retina and pia mater are constricted (Hirschfelder, 1915).

The urine flow is generally diminished, but sometimes increased, depending mainly on the vasomotor effect.

Temperature.—Cocaine causes a rise of temperature, due essentially to increased heat production, and this largely from muscular excitement (see chapter on "Heat Regulation").

Effects on Metabolism.—In *rabbits*, large doses of cocaine cause rapid loss of weight. The quantity of urine, its specific gravity, and particularly the urea, are diminished,

whilst the incompletely oxidized (extractive) nitrogen is increased. During recovery, the quantity of urine returns promptly to normal or above; the disturbances of the nitrogen metabolism persist for some time (Maestro, 1904).

The effects of *repeated injection on dogs* have been investigated by Underhill and Black, 1912: Doses of 10 mg. (per kilogram) produced no change in fat or nitrogen metabolism; 15 mg. gave a slight impairment of fat utilization, and considerable decrease of body weight; 20 mg. markedly decreased the nitrogen and fat utilization. The nitrogen balance may become negative. Lactic acid excretion was markedly increased in well-fed dogs, but not in starvation—the increase being probably due to the muscular activity. The ammonia output bore little relation to the lactic acid.

Blood-sugar.—This is not changed (cats, 15 to 35 mg. per kilogram), except as a result of excitement (Schaer, 1915).

Sympathetic Stimulation.—The symptoms of cocaine poisoning correspond to stimulation of the sympathetic system; *i.e.*, they are analogous to epinephrine, although the analogy is not perfect. The real synergism of the two drugs extends to these sympathetic effects.

The sympathetic symptoms consist, for instance, in the mydriasis and slight exophthalmos; constriction of the ear-vessels; erection of hair; relaxation of intestines. In rabbits, these are produced by the hypodermic injection of 35-50 mg. of cocaine, or by 10 mg. of cocaine plus 1 mg. of epinephrine (Mills, 1919).

Fate of Cocaine.—This is partly destroyed in the organism, but mainly excreted unchanged in the urine (contrary to the results of Wiechowski, 1901).

Rifatwachdani, 1913, recovered 42 to 85 per cent. from the urine of rabbits after acute poisoning, and all in chronic poisoning. None was present as ecgonine; but if ecgonine itself was injected, 25 per cent. was recovered from the urine. Cocaine left for several hours in a ligatured limb was not destroyed.

Persistence of Effect and Cumulative Action.—Most synthetic local anesthetics are destroyed so rapidly in the body, that the toxicity is much smaller when the drug is introduced slowly. Cocaine and phenacaine (holocaine), however, are not destroyed nearly as promptly (Eggleston and Hatcher, 1919). Mills, 1919, obtained contradictory results with cocaine according to the criteria: No cumulative effects were noted unless injections were repeated in less than $1\frac{1}{4}$ hours, indicating rapid destruction. On the other hand, pupillary effects could be demonstrated after 25 hours, so that the iris must retain the drug for longer periods.

Destruction of Cocaine in Vitro; Sterilization.—Long-continued boiling decomposes cocaine into benzoyl-ecgonine and methyl alcohol. It was therefore believed that solutions could not be sterilized by boiling. In fact, however, the decomposition on boiling half an hour, is insignificant (Merck, 1907; Holbrook, 1912); and even longer boiling only decreases the activity, for the decomposition products are merely inactive and not toxic. Any decomposition on boiling is probably due to alkalinity from the glass (Baumeister, 1917).

Watery solutions of basic cocaine deteriorate rapidly, losing their anesthetic power within 7 hours; and still more rapidly when heated. Basic procaine and alypine are stable in solution (Gros, 1912).

Solutions of cocaine salts are much more stable than basic solutions, but liable to mold. *Procaine solutions* are said to be difficult to sterilize (Ersner, 1917). They turn brown on keeping, but their efficiency or toxicity is not altered, at least for several months. Solutions that have developed a sediment (generally molds) should not be used (Bonar, 1923).

Resistance to Putrefaction.—Positive tests for cocaine were obtained in cadavers even months after death (Palet, 1919).

Benzoyl Ecgonine.—This was found by Stockman, 1886, to resemble caffeine in its central and muscular action. It had no effect on sensory nerves or the pupil.

ACUTE COCAINE POISONING; ETIOLOGY

Toxicity.—This is of special importance, since cocaine poisoning is not a very uncommon occurrence in the therapeutic employment of the drug. Very large amounts are sometimes used in a most careless manner for local anesthesia; and since the absorption is fairly rapid, serious and even fatal results may follow. The susceptibility varies enormously, due partly to the uncertainty of the absorption; partly to the rapidity of destruction; and partly to the varying intensity of the effects.

There seems to be a very considerable psychic element (fright) in some of the "accidents."

Bibliography of Clinical Intoxications.—Eggleston and Hatcher, 1919.

Frequency of Fatalities.—Reliable statistics are not available, but fatalities appear to be much more common than is ordinarily supposed (E. Mayer et al, 1920-1924).

Mistakes in Drugs or Dosage.—A large proportion of the anesthetic accidents (25 per cent. in one series) are due to mistakes in the drugs, concentration and dosage (E. Mayer et al, 1920). These could probably be avoided almost entirely by employing the toxic drugs only as tablets, colored by a distinctive dye; so that the tint of the solution would inform the surgeon of the nature and concentration of the drug.

Safe and Toxic Dosage of Local Anesthetics.—All the commonly used local anesthetics have produced fatal accidents. These depend not only upon the absolute dose, but also on the rate of absorption, on idiosyncrasy, and on other conditions. The Local Anesthetic Committee of the American Medical Association has made recommendations (E. Mayer, 1924), which should minimize the accidents. The following are the most important:

Procaine appears the safest of the more widely used local anesthetics and may be employed for subcutaneous and submucosal injections; but the concentration should not exceed 1 per cent.

Cocaine and butyn should not be injected under the skin or mucous membranes, but restricted to surface-application. The total quantity of cocaine should not exceed 0.06 to 0.1 Gm. (1 to 1½ grains).

The patient should be recumbent, if the operation permits. With nervous patients, it is advisable to inject morphine fifteen minutes before the local anesthetic, and to delay the start of the operation till twenty minutes after the injection of the local anesthetic (Mayer et al, 1920).

Urethral injections are especially dangerous, and should be avoided if there is trauma or stricture.

Strict attention should be given to prevent the confusion of procaine and cocaine. The solutions should be kept in different kinds of bottles. Cocaine solution may be distinguished by tinting with sodium fluorescein, 1 mg. per Gm. of cocaine. This would also show the concentration of the solution.

The ordinary fatal dose of cocaine is considered to be about 1.2 Gm. (18 gr.) (Kunkel; Watson-Williams, 1924); but death has been reported from 0.02 (⅓ grain); and serious poisoning from 2 drops of a 4 per cent. solution (5 mg.) on the conjunctiva, and with three drops of ½ per cent. cocaine (1 mg.) in a tonsil operation (Mayer). In other cases, very large doses produced no effect (bibliography, Roth, 1917).

Dilution slows the absorption of cocaine and insures its thorough utilization, and thus economizes its use. Solutions above 1 per cent. should not be used for hypodermic injection. With solutions of ½ per cent. and proper precaution, Reclus considers 0.2 Gm. quite safe.

Safe Operations.—In open wounds or body cavities or other surfaces from which any excess will be removed when the operation is completed, the total quantity of cocaine is practically immaterial if dilute solutions (0.1 to 0.2 per cent.) are employed; for only a small fraction will be actually absorbed.

Dangerous Operations.—Cocaine is especially dangerous when 2 to 10 per cent. solutions are injected into closed mucous or serous cavities, such as the urethra, bladder, scrotal sac, etc. Very severe poisoning has repeatedly followed after urethral injection of 1 Gm. in 5 to 20 per cent. solution, in one case even after 7 c.c. of 1 per cent. (0.07 Gm.). Indeed, a fairly large number of toxic cases are reported from 0.01 to 0.05 Gm. in 5 to 20 per cent. solution (Weigand; H. Braun, 1914).

Tonsil operations, when cocaine is injected, show many more fatalities than operations on the nose (Mayer).

The toxicity is increased by severe hemorrhage, also by chloral narcosis; probably by interference with the activity of the liver (Eggleston and Hatcher).

Procaine proved fatal in a tonsil operation with 4 c.c. of $\frac{3}{4}$ per cent. (0.03 Gm.), injected with epinephrine (Mayer).

Toxic Symptoms.—These are very similar for cocaine and the synthetic substitutes, procaine, apothesine, butyn, etc. (Mayer, 1924). Fatal cases run a very rapid course, with anxiety, sudden fainting, extreme pallor, dyspnea, sometimes brief convulsions, arrest of respiration and death generally in a few minutes.

With smaller doses or slower absorption there is confusion, laughter, vertigo, motor excitement; quickened pulse and palpitation; irregular respiration; pallor; chill, with sweat and rise of internal temperature; dilated pupils and exophthalmos; nausea; vomiting and abdominal pain; great anxiety; disturbance of cutaneous sensation (worms under skin; etc.); finally delirium, dyspnea and Cheyne-Stokes respiration, convulsions, unconsciousness; and death by collapse and asphyxia.

However, if the death has not occurred within a few minutes, the patient will almost always recover. Unconsciousness and Cheyne-Stokes respiration may persist for 1 or 2 hours. Recovery may be followed by more lasting psychic depression and melancholia.

Symptoms in Animals.—These symptoms of acute clinical intoxications by the local anesthetics are closely paralleled by animals, especially cats (Eggleston and Hatcher, 1919):

Intravenous injection of fatal doses produces almost instant extensor spasm, fixation of the respiration, and sudden cessation of the heart.

Sublethal intravenous injections cause immediate stimulation of the respiration and abrupt fall of blood pressure of cardiac origin; the heart-rate being inconstant, but generally slowed. The respiration may be temporarily arrested.

Within a minute, the heart begins to improve and the blood pressure rises; the respiratory stimulation diminishes; there may be brief but severe clonic convulsions. Within five minutes the animals may be apparently normal.

As the doses approach the fatal, the convulsions are more prolonged, and recovery is slower; especially after cocaine (Eggleston and Hatcher, 1919).

Treatment of Poisoning by Local Anesthetics.—If the drug has been taken by mouth, evacuation and chemic antidotes are indicated. If the anesthetic was injected, absorption should be checked by ligation, epinephrine or cooling. Whatever delays death is likely to save the life, in view of the rapid destruction of these drugs. Hypnotics (sodium-barbital and paraldehyde) are very efficient in animals, including monkeys (Tatum and Collins, 1926).

If symptoms have developed, the head should be lowered; collapse treated by aromatic ammonia and caffeine; convulsions allayed by ether or chloral. The use of epinephrine or morphine is not advised.

If there is any disturbance of breathing, artificial respiration should be practiced at once; and cardiac massage if the circulation fails (Mayer commission, 1924).

Calcium injection, which had been advised as an antidote, does not decrease the toxicity of cocaine (Soma Weiss, 1923).

Efficiency of Artificial Respiration in Animals.—This raises the M.F.D. for rabbits from 100 to 300–350 mg per Kg.; the M.F.D. for cats (35 mg. per Kg.) is not raised, but the heart continues to beat efficiently for hours (Atkinson and Tatum, 1925).

Toxicity on Repeated Administration.—Animals that have recovered from toxic doses show a diminished resistance to lethal doses; this is probably due to toxic injury of the tissues, liver and other, that normally destroy the cocaine (Atkinson and Tatum, 1925).

CHRONIC COCAINE POISONING

This bears considerable resemblance to the morphine habit. It is unfortunately on the increase, especially amongst negroes, prostitutes, and the criminal classes (see under "Morphine Habit").

The **immediate effects** consist in a sense of elation and increased mental and physical vigor. The excitement may rise to delusions and mania. These stimulant effects are *succeeded by depression*, tremors, with pale face, and sunken and unsteady eyes (Owens, 1912).

The **chronic effects** are similar to those of the morphine habit, with more severe psychic disturbance—insomnia, hallucinations, apathy, melancholia, suicidal mania. (For Cocaine Psychoses, see Vallon and Bessiere, 1914.) The pupils are inconstant. A very considerable *tolerance* is acquired, so that the daily hypodermic consumption often reaches 2.5 Gm., sometimes even 10 Gm. (Grode, 1912). Animals do not become tolerant (Grode, 1913). Chouppe, 1889, claims that morphinists are relatively tolerant to cocaine. Sudden withdrawal leads to *abstinence symptoms* very similar to those of morphine.

With cocaine snuffing, where smaller amounts are used in intermittent debauches, the chronic effects, the craving and the abstinence symptoms are proportionately less marked. Such patients show characteristic ulceration of the nasal fossæ (Owens; also present in heroine snuffing, Phillips).

Cocaine on Body-weight and Growth.—No effects were produced by doses corresponding to 2½ grains of cocaine per man per day, administered continuously for 8 months to rats, whereas procaine and other synthetics reduced the weight, with doses corresponding to 5 grains per day, after a few weeks (Sollmann, 1924).

The **treatment of cocaine habit** coincides exactly with that of the morphine habit (which see); it is said to be more difficult to cure.

The prescribing of cocaine and tropacocaine comes under the Harrison Anti-narcotic Law. This does not apply to the synthetic substitutes.

ADMINISTRATION OF LOCAL ANESTHETICS

Sensory nerves may be paralyzed at their periphery: *terminal or surface anesthesia*; or in their course: *conduction or injection anesthesia*. This "blocking" of the nerve fibers may be done by infiltrating the field of their peripheral distribution: *infiltration-anesthesia*; or by injection into or around the nerve-trunks: *intraneural or perineural methods*; or at the point of origin in the spinal canal: *spinal or subdural anesthesia*.

Surface Anesthesia.—Anesthesia from intact surfaces requires that the drug must be absorbable. This excludes the intact skin. Cocaine and butyn readily absorbed from *mucous membranes*, and are therefore efficient, but also correspondingly toxic. Procaine and apothesine are relatively inabsorbable and therefore less applicable. Aल्पine and beta-eucaine are intermediate; but the order of absorability varies for different mucosæ.

Ophthalmic Practice.—Cocaine, 4 per cent., or butyn, 2 per cent., are applied to the conjunctiva for deep penetration, as in cataract operations; phenacaine (holocaine), 2 per cent., or butyn, 2 per cent., for surface action (foreign bodies), etc. Aल्पine, eucaine and procaine are considered too feeble. Toxic manifestations are rare and slight since only small quantities are applied. For infiltration, 2 per cent. procaine is advised (Bulson, A.M.A. Committee, 1921, 1925).

A single application of 2 per cent cocaine produces complete anesthesia of the conjunctiva and cornea, starting in 2 minutes, and lasting 7 to 10 minutes. If 5 per cent. cocaine is instilled every 3 minutes for half an hour, the anesthesia generally extends also to the iris. Epinephrine does not enhance the efficiency in the eye (Sollmann, 1918).

Cocaine dilates the pupils, and contracts the vessels; the other anesthetics do not.

Relative Anesthetic Efficiency.—This is shown for the conjunctiva by the chart on page 327. Regnier, 1923, found stovaine requires a concentration about 7 times that of cocaine.

Urethra and Bladder.—The urethra is a good absorbing surface, and has therefore often given rise to poisoning. This danger is practically obviated by using dilute solutions. These are efficient if sufficient time is allowed. Braun, 1903, advocates cocaine, 0.1 to 0.2 per cent. for the bladder, 0.5 per cent. for the urethra, both with epinephrine (about three drops of 1:1000 for the entire injection).

Aल्पine has been rather a favorite, since it is also readily absorbed, and is supposed to be less toxic. However, fatal accidents have occurred from the usual doses. It is used as 0.5 per cent. for the bladder; 5 c.c. of 1 per cent. for the urethra. Braun advocates the addition of epinephrine, as for cocaine.

Absorption of the Hydrochlorides from the Urethra.—Sollmann, 1918, found that aल्पine and tropacocaine were absorbed somewhat better than cocaine; apothesine, beta-eucaine and procaine were absorbed somewhat less efficiently; but the differences were not great.

The rate of absorption increases with the dose and concentration. The absorption is more rapid during the first ten minutes, but continues quite markedly after this time. Alkalinization does not increase the absorption.

Operations in Nose.—Practically all operators prefer local anesthesia as being more convenient than general anesthesia and at least equally safe. The most common method is to swab the mucosa with epinephrine solution, 1:10,000; then to apply a little 10 or 20 per cent. cocaine solution with an applicator; or a trace of powdered cocaine on the point of a moistened probe. The strong cocaine solutions are fairly safe in this case, because only a small surface is covered. For more extensive operations, this is followed by the slow injection of procaine solution ($\frac{1}{4}$ to $2\frac{1}{2}$ per cent.; generally $\frac{1}{2}$ per cent.) in epinephrine 1:50,000 (Mayer et al, 1920).

Operations on Tonsils and Adenoids.—The majority of American operators favor local anesthesia, notwithstanding occasional accidents. The preferred practice consists in swabbing with 5 or 10 per cent. cocaine, followed by the slow injection of a synthetic anesthetic, *f.i.* $\frac{1}{2}$ to 1 per cent. of procaine in 1:50,000 epinephrine. Preliminary morphine is advisable (Mayer et al, 1920).

Operations on Larynx.—These require careful application of fairly strong (10 to 20 per cent.) cocaine solutions (Mayer et al, 1920).

Insoluble Anesthetics for Open Wounds and Ulcers.—The soluble anesthetics are absorbed too rapidly to be of material use in persistent pain. The limited and slow solubility of some of the free synthetic bases renders them more adapted to these conditions. However, their practical usefulness is limited.

They are employed for painful wounds, ulcers, etc., of the skin and accessible mucous membranes; for instance, after dental operations. They have also been used against the pain of gastric ulcer or cancer and other gastralgiæ; but here their efficiency is doubtful.

Anesthesine, cycloform, orthoform-new and propaesine are all about equally effective through intact mucous membranes (Sollmann, 1919). They are practically non-irritant and non-toxic.

They may be diluted with 10 parts of sterilized talcum.

Catarrh, Hay Fever and Asthma.—Cocainization of the nasal mucous membrane may temporarily relieve attacks of hay fever and asthma. The astringent action renders it effective in acute coryza.

One per cent. cocaine ointment has been recommended in *herpes zoster*; it is said not only to relieve the pain, but to put a stop to the disease.

Cocaine locally relieves *hemorrhoids*, producing contraction and diminishing pain. It has been taken by the stomach to prevent *vomiting* and dyspeptic pain.

The *danger of the formation of the habit* interferes with its use in all these conditions; indeed many cases of cocaine habit were started by proprietary catarrh "cures."

Infiltration and Conduction Anesthesia.—None of the local anesthetics penetrate effectively through the intact skin. In most operations they must therefore be injected. Since any excess of the injected anesthetic is not easily removed, the greatest economy must be practiced by employing dilute solutions, placing these only where they are needed, and keeping them there by limiting the circulation by epinephrine or ligature. In view of its relatively low toxicity, procaine (novocaine) is preferred to cocaine. Apothesine, benzyl alcohol, and saligenin are also successful.

It is not necessary to flood the entire field of operation, as in the earliest methods; nor even to infiltrate the whole line of incision, as in the "infiltration anesthesia" of Schleich (1892). It is now aimed to confine the anesthetic mainly to the nerves, by placing it where the nerves chiefly run, or injecting it into the nerves themselves (H. Braun).

For instance, one would start with a small wheal, produced by the intradermal (not hypodermic) infection of a few drops of 0.5 per cent. procaine and 0.0005 per cent epinephrine in normal saline.

Through this anesthetized wheal, the needle is thrust forward into the subcutaneous tissue, and the same solution is injected, so as to outline the operative field. This blocks all the nerves of the area.

When feasible, the injection is made directly into the nerve trunk (*intraneural* method). For unexposed large nerves, this requires 1 to 5 c.c. of 2 to 4 per cent. procaine, for exposed nerves, 0.5 to 1 per cent. suffices (Braun). Epinephrine should be added in the proportion of 1 mg. per Gm. of procaine.

If the injection is made quickly and directly into the nerve tissue, the procedure is quite painful. A few drops should first be injected under the nerve sheath. When these have caused a local anesthesia, the needle should be pushed deeper and more of the solution injected, until the anesthesia is complete. In this way the pain is relatively slight. Anesthesia requires fifteen to twenty minutes, and is not always completely successful.

Anoci-association.—Crile believes that the afferent impulses which reach the brain even in profound general anesthesia are distinctly harmful to the patient; and that therefore these impulses should be suppressed by blocking the nerve-paths from the field of operation by the use of local anesthesia.

It may at times be justifiable to operate without the knowledge of the patient, which is quite feasible by the use of cocaine (Crile).

Morphine in Local Anesthesia.—Nervous, fearful and excitable patients often suffer severely from apprehension that local anesthesia may not allay. This also disposes toward accidents. It may be at least somewhat quieted by morphine (0.015 Gm. hypodermically) half an hour before the operation.

Morphine and atropine, in moderate doses, do not materially alter the toxicity of cocaine or procaine for cats. Large doses of morphine tend to relieve the convulsions, but increase slightly the toxicity of the anesthesia (Hatcher, quoted by Mayer).

Intravenous and Intraarterial Anesthesia.—These were introduced by Bier, 1908, and have a limited field. The limb, for instance, is ligated above and below the field of operation, and the solution is injected into a vein or artery of the ligated area.

Intravenous Injection of Cocaine.—The action of cocaine is sufficiently selective so that a marked, though incomplete general analgesia, without disturbance of consciousness or motor functions, can be produced by intravenous (Ritter, 1909; Harrison, 1911) or intra-arterial (Ransohoff, 1909) injection. However, these methods are both unsatisfactory and dangerous (Bevan, 1915).

Spinal Anesthesia.—The subdural injection of cocaine, or other local anesthetics, anesthetizes the sensory nerve roots at their emergence from the spinal cord. This abolishes sensation in their entire peripheral distribution, beginning in 2 to 10 minutes and lasting for about one and one-half hours (one-half to two hours), without loss of consciousness or motor functions.

The anesthesia extends to the level of the nerve roots reached by the cocaine, the aim being to confine it to the lower half of the body. If it should extend to the fourth ventricle, it would paralyze the respiration. Alarming symptoms and fatalities from this cause are not infrequent (Seifert, *Nebenwirk.*, 1915, p. 105), and the method is more dangerous even than chloroform. The fatality is probably over 1:500 (Bevan). It has also been fatal to the fetus *in utero* (Jung, 1914). Minor accidents are not uncommon. Cord injuries are sometimes produced; severe headache may last for days or weeks. Further, the technic is difficult, disagreeable to the patient, and the anesthesia is often unsuccessful. Spinal anesthesia should therefore not be employed (Hohmeier and Koenig, 1910), unless inhalation anesthesia is directly contraindicated (Anesthesia Commission, *Journ. Amer. Med. Assoc.*, 1908). It is *especially useful* in pulmonary disease, arteriosclerosis, bladder and rectal cases, impending uremia, and diabetics; emergencies after a full meal. It is not justifiable to use it for operations above the costal margin (F. L. Richardson, 1913). Bevan, 1915, can see no justification for spinal anesthesia under any conditions.

Technic of Spinal Anesthesia.—The method was demonstrated by Corning of New York in 1885, and introduced into practice by Bier, 1899, but it was temporarily abandoned, and did not come into vogue until about 1904. The injection is performed by lumbar puncture, withdrawing a little cerebro-spinal fluid, and introducing $\frac{1}{2}$ to 1 c.c. of 2 per cent. cocaine solution; or more commonly, corresponding quantities of its substitutes: Tropocaine, 5 per cent., procaine (not above 0.15 Gm.); stovaine (not above 0.1 Gm.; beginning with one-half or two-thirds of these doses). Epinephrine and strychnine may be added. Glucose, 5 per cent., diminishes the spreading of the solution by increasing its specific gravity. E. Erhardt, 1905 and 1912, proposed with the same object, to increase the viscosity by acacia. Bulk of solution (dilution) favors spreading (Smith and Porter, 1915).

Phenomena of Spinal Anesthesia.—These occur in the following order: Loss of knee-jerk; of plantar and cremasteric reflex; ascending analgesia; later, ascending loss of motor power. The upper limit is usually quite abrupt. Subjectively, there is an ascending feeling of warmth, swelling and heaviness. Occasional *toxic effects* are pallor, nausea, vomiting, sweating, feeble pulse, relaxation of sphincters, dyspnea. The most frequent *after-effects* are headache and insomnia.

Order of disappearance of sensation from the skin: Baglioni and Pilotti, 1910, state this as first, pain; then, after some time, cold; then, soon, heat. Finally, pressure. Recovery occurs in the reverse order.

To paralyze the anterior roots would require a concentration about four times as high as suffices for the posterior roots (Sebastian).

Fall of Blood Pressure.—This is a very common phenomenon of spinal anesthesia. Smith and Porter, 1915, found that it is due to paralysis of the splanchnic fibers in the cord, not in the medulla. Epinephrine with tropococaine or procaine caused even a greater fall. Measures to restore the pressure were only temporarily successful. As the effects of the anesthetic began to wear off, sciatic stimulation produced a fall, instead of the normal rise.

The combined action of *stovaine* and *strychnine* on the cord has been investigated by Aron and Rothman, 1909; and Simon, 1915. The two drugs are not antagonistic; and *strychnine* does not render *stovaine* any safer.

USE OF COCAINE AS CEREBRAL STIMULANT

Cocaine has been employed to combat fatigue, and as a general tonic. It has no advantages and many disadvantages as compared with other stimulants, especially *caffeine*. The danger of habit formation should suffice to condemn it. That the harm has not been greater may be attributed to the unreliability of the coca preparations which are generally employed.

Comparison of Cocaine and its Substitutes.—Cocaine is very satisfactory from the standpoint of efficiency, penetration, and practical absence of tissue-injury. However, its rather high toxicity has led to the use of substitutes wherever practical. Some of these present advantages in special fields, although they lack the general applicability of cocaine. These special fields were pointed out in discussing the applications of local anesthesia.

Structure of Cocaine.—Cocaine is the methyl-benzoyl ester of *ecgonine*, a base closely related to *tropane*, the corresponding base of *atropine*, both being *pyrrolidine* derivatives.

Relation of Structure to Actions.—*Ecgonine* itself produces only the least important of the actions of cocaine, viz., the hepatic degeneration. The other actions are only developed by the entrance of *both* radicals. The methyl may be replaced by any other alkyl radical, without changing the actions of cocaine. The benzoyl radical, however, can not be replaced by other aromatic acids (possible with a few exceptions) nor by fatty acids without great impairment of the local anesthetic action. Indeed, the presence of the benzoyl group gives the anesthetic properties to other alkaloids, and may be considered as the hook by which the molecule attaches itself to the protoplasm of the sensory cell. It is present in most of the cocaine substitutes. The required conditions for the development of a local anesthetic action seem therefore to be: a base with a structure analogous to *ecgonine*, containing a benzoyl and an alkyl radical in certain relations.

Principal Differences between Cocaine and its Substitutes.—These concern especially the following points:

Toxicity.—It is generally believed that cocaine has the highest toxicity. This conclusion was based primarily on animal experiments, which, however, yield equivocal results. Nevertheless, it seems in harmony with clinical experience.

Toxicity-comparisons on Animals.—Extensive series of experiments have been published, for instance by Kochmann, 1914; Closson, 1914; Le Brocq, 1909. These show that cocaine is perhaps three times as toxic to guinea pigs, on hypodermic injection, than are most of the substitutes. This result has very generally been transferred to man, but without real justification. Rodents depart widely from man in their quantitative response to many poisons. The rate of penetration and absorption is a highly important factor in poisoning. Obviously, the hypodermic injection into guinea pigs does not reproduce the absorptive conditions, for instance, of the human urethra.

Intravenous Toxicity for Cats.—This would be a more definite index of absolute toxicity, but its clinical application would also be limited. Eggleston and Hatcher, 1918 and 1919, found the M.F.D. as follows:

Allypine holocaine.....	10 mg.	Tropacocaine.....	20-25 mg
Beta-eucaine.....	12.5	Stovaine.....	25 30
Cocaine.....	15	Nirvanine.....	30 35
Apothesine.....	20	Procaine.....	40 45

Combinations of any two of these local anesthetics produce simple summation of the effects, so that they would not offer any advantages from this standpoint.

The systemic actions of all are similar, death occurring by combined cardiac and respiratory paralysis.

Procaine, apothesine and stovaine and probably also the other synthetic anesthetics are rapidly destroyed in the liver.

The *hypodermic fatal doses* are therefore more than five times greater than the intravenous, except with the relatively indestructible cocaine and phenacaine.

Irritation and Tissue-Injury.—In ordinary concentrations, cocaine, procaine and apothesine are practically non-irritant. Eucaine, alypine, phenacaine (holocaine), and benzyl alcohol produce smarting and some pain, but no permanent injury. Tropacocaine raises wheals on the scarified skin. Stovaine and quinine-urea cause more pain, and lead to induration or gangrene if the ordinary concentrations are exceeded.

The irritative phenomena have been compared for the intracutaneous injection by Braun, 1905. Procaine up to 5 per cent. produced no pain or hyperemia. Stovaine caused strong local irritation, even with dilute solutions; and gangrene with 5 to 10 per cent. Alypine as dilute as 0.1 per cent. gave pain and hyperemia, but less than stovaine; 1 per cent. produced persistent irritation; and 5 per cent., gangrene. Cocaine is practically non-irritant.

The irritative phenomena have also been studied by Le Brocq, 1919; Kochmann, 1914, and Closson, 1914.

Combination with Epinephrine.—The vasoconstrictor effect is produced perfectly in the presence of cocaine, procaine, benzyl alcohol, apothesine and probably alypine. The others interfere more or less; tropacocaine completely.

Penetration of Mucous Membranes.—This probably varies in different situations. Generally cocaine, alypine, benzyl alcohol, eucaine and holocaine are effective; whereas procaine and apothesine are relatively ineffective.

Stability of Solutions.—Cocaine solutions should be freshly made, although their deterioration is not so rapid as was formerly supposed. Alypine solutions also should not be kept longer than a week (Impens, 1905). The others keep for a considerable time. Phenacaine (holocaine) solutions must be slightly acid and are therefore irritant. Procaine solutions become discolored.

Sterilization.—This was formerly considered a material advantage of the substitutes; but it is now conceded that cocaine solutions can be safely brought to boiling.

Habit-formation.—This has not been described for any of the cocaine substitutes.

Incompatibilities.—The substitutes have in general the same incompatibilities as cocaine.

Solubility of the Bases in Oils.—This is in descending order: Alypine (all proportions), eucaine, procaine, cocaine (Gros, 1910).

PREPARATIONS—COCAINE

Cocæ Folia.—The dried leaves of *Erythroxylum Coca* and *E. truxillense*, shrubs indigenous to Peru and Bolivia, and cultivated in tropical countries. Ceylon coca contains mainly cocaine; Java coca contains only other ecgonine derivatives (Jong, 1911).

Cocaina, U.S.P., B.P., $C_{17}H_{21}NO_4$.—Colorless prisms or crystalline powder, of slightly bitter taste followed by anesthesia. Slightly sol. in water (1:600); freely sol. in alc. (1:6.5), chlorof., eth.; sol. in oils (1:12 olive oil). Used especially in ointments. Dose, 15 mg., $\frac{1}{4}$ gr.

* *Cocain. Hydrochl.*, U.S.P.; B.P., $C_{17}H_{21}NO_4.HCl$.—Colorless, transparent prisms; or flaky, lustrous leaflets, or white, crystalline powder. Very sol. in water (1:0.4); freely sol. in alc (1:3.2); sol. in glyc.; practically insol. in oils. *Incompatible* with alkalis,

sodium borate (not boric acid), silver nitrate and calomel. Solutions decompose on keeping (a 15 per cent. solution in Dilute Alcohol is said to be permanent; Wintersteiner, 1906). Contrary to older statements, they are not materially decomposed by boiling. *Dose*, 15 mg., $\frac{1}{4}$ gr., U.S.P.; 6 to 16 mg., $\frac{1}{10}$ to $\frac{1}{4}$ gr., B.P. Maximum dose, 50 mg., $\frac{3}{4}$ gr.

Inject. Cocain. Hyp., B.P.—5 per cent. *Dose*, 0.3 to 0.6 c.c., 5 to 10 minims, B.P.

Lam. Cocain., B.P.—1.3 mg., $\frac{1}{50}$ gr.

Ung. Cocain., B.P.—4 per cent.

Troch. Kramer. et Cocain., B.P.—60 mg. of krameria; 3 mg. of cocaine.

PREPARATIONS—SOLUBLE SYNTHETIC ANESTHETICS

Allocaïne S.—This is a complex benzol derivative. Kubota, 1919, claims that it is somewhat less toxic and more anesthetic than procaine, but rather more irritant. It does not appear to have any real advantage.

Alypine, N.N.R.—Benzoxy-dimethylamino-methyldimethyl-aminobutane hydrochloride.—This is efficient on mucous membranes, and is used especially in the urethra. Its structure resembles stovaine.

It is more irritant than cocaine. Several cases of sudden collapse and asphyxia, after its injection, have been reported (Ritter, 1912; Lichtenstein, 1914; lumbar, Seifert, *Nebenwirk.*, 1915, p. 104). The maximal dose of 0.25 Gm. must not be exceeded.

Alypine solutions should not be kept longer than a week (Impens, 1905). They are not readily precipitated by alkalis and the base is very soluble in oils.

Apothesine.—Diethyl-amino-propyl cinnamate hydrochloride. Properties and uses resemble procaine.

Dosage, for injection anesthesia, 1 to 2 per cent., with epinephrine 1:100,000. On cornea, 2 to 4 per cent. Spinal anesthesia, 2 c.c. of 4 per cent.

Apothesine is relatively safe; but severe collapse has been reported from the injection of 1 and 2 per cent. solutions in throat work (Mayer *et al.*, 1920); and death has occurred from spinal injection (Ireland; Duboff, 1920).

Benzyl Alcohol, N.N.R. (Phenmethylol) $C_6H_5CH_2OH$.—This was introduced by Macht, 1918, as an effective local anesthetic of low toxicity (being largely converted into hippuric acid). Intravenous injection causes vasodilation. The urine-flow may be increased or diminished (Gruber, 1924). The pure substance is irritant and somewhat corrosive; but the watery solutions, which contain up to 4 per cent., are not irritant.

Hirschfelder, 1920, claims that injections of benzyl alcohol solutions in man are unsatisfactory; that the anesthesia is uncertain; and that it is often followed by subcutaneous edema and local pain.

It is somewhat antiseptic (Macht and Nelson, 1918); but ordinary concentrations act too slowly to be efficient in wounds.

It is used for injection anesthesia, generally as 1 to 4 per cent. solution. This is also anesthetic on mucous membrane, but the action is rather brief (Sollmann, 1919).

Benzyl alcohol is effective against the itching of dermatitis; for instance in the milder grades of "mustard gas" poisoning. It is used as a 10 per cent. ointment in lard; or as a mixture of equal volumes of benzyl alcohol, alcohol and water (Hess).

Spinal anesthesia has been produced in dogs by 2 to 4 per cent. solutions in oil or saline (Voegtlin and Livingston, 1919). Benzyl alcohol is soluble in all proportions in oil.

Benzyl Carbinol (Rose-Oil), $C_6H_5C_2H_4OH$.—Hjort and Eagan, 1919, find the anesthetic action more powerful than that of benzyl alcohol. Its toxicity is about the same, but it is more stable and sufficiently soluble for therapeutic use.

Its isomer, phenyl-methyl-carbinol, is even more effective, but also more toxic. It is unstable, and therefore not practical (Hjort and Kaufmann, 1920).

Eucaine Hydrochloridum (Eucain. Hydrochl.), U.S.P. (trimethyl benzoxy-piperidine; beta-eucaine), $C_{15}H_{21}NO_2 \cdot HCl$.—White, crystalline powder; odorless. Sol. in water (1:30) and alc. (1:35). *Dosage*, locally, one to two times that of cocaine. The anesthetic effect is perhaps slightly slower and weaker, and the irritation considerably greater, than with the same concentration of cocaine. The pupils are not dilated; the tissues are rendered hyperemic. The toxicity is four-tenths that of cocaine. Toxic doses cause convulsions, central vagus stimulation, and direct cardiac depression, with fall of blood pressure (Seifert, *Nebenwirk.*, 1915, p. 64; case and bibliography, Orr, 1910).

Benzamin. Lact., B.P. (Beta-eucaine Lactate), $C_{15}H_{21}NO_2 \cdot C_3H_5O_3$.—Freely sol. in water (1:5) and alc. (1:8). *Dose*, 8 to 30 mg., $\frac{1}{4}$ to $\frac{1}{2}$ gr., B.P.

* *Butyn* (sulphate), N.N.R.—A procaine derivative, containing butyl in place of ethyl, and propanol in place of ethanol. Its properties differ practically from procaine, for it

is absorbable from mucous membranes. It is more toxic even than cocaine, and is therefore not advisable for injections; but it is useful in ophthalmic operations (2 per cent.) and in nose and throat work (2 to 5 per cent.). It is easily soluble in water; the solutions may be sterilized by boiling. It is not irritant.

Carbinols.—A series of phenyl-carbinols was investigated by Hirschfelder *et al.*, 1920 (see below, Saligenin). All are anesthetic.

Phenacaine (Holocaine), N.N.R., (phenetidyl-acetphenetidine hydrochloride).—Colorless crystals, soluble in 50 parts water. *Dosage*, for eye, 1 per cent. Anesthetic action about as strong as cocaine, but more rapid (anesthesia in half a minute); more toxic. No effect on vessels has been reported (Gjessing, 1915). It is not mydriatic.

**Procaine Hydrochloridum* (Procain. Hydrochl.), U.S.P.; Procaine, Novocaine (aminobenzoyl-diethyl-amino-ethanol hydrochloride; $\text{NH}_2(\text{C}_6\text{H}_4\text{CO})\text{OC}_2\text{H}_4\text{N}(\text{C}_2\text{H}_5)_2\cdot\text{HCl}$).—Colorless needles, sol. in 0.6 part of water, or 30 parts alcohol. The *nitrate* is compatible with silver salts. *Dosage*, locally, one to three times that of cocaine. Anesthetic and irritant action perhaps slightly less. No effect on pupil.

Procaine is safer than cocaine. Occasionally, however, toxic effects occur even with small doses (0.01 to 0.13 Gm.); while in other cases up to 3 Gm. have been used safely. There is no definite ratio between the toxicity of procaine and cocaine, since this depends enormously on the rate with which they enter the circulation; especially in the case of procaine. This is due to the great rapidity with which procaine leaves the circulation, being fixed and probably destroyed in the liver. Epinephrine diminishes the toxicity, even by intravenous injection, probably by cardiac stimulation (Hatcher and Eggleston, 1916).

Roth, 1917, found that the heart toxicity ratio of (procaine: cocaine) varies for different animals from 1.4: 1.0 for frogs to 1: 10 for rats and guinea pigs. By intradural injection the relative depressant effects on blood pressure and respiration were about equal.

After subdural injection, the excretion reaches its maximum rate in 2 hours, and is completed in 6 hours (Achard, 1919).

The details of the clinical toxic effects are described by Seifert, *Nebenwirk.*, 1915, p. 78; lumbar, p. 107. Renal irritation is not uncommon after local use of 5 to 10 per cent.; but disappears in a few days (Morian, 1915).

Procaine Dermatitis.—Quite frequent in dentists, from leaky syringes. Strictly local. Seems to require usually repeated contact, and hypersensitivity, demonstrable by cutaneous tests (C. J. Lane, 1921; R. C. Morris, 1921). J. Rosenbloom, 1922, reports that the use of a 5 per cent. ointment against rectal pruritus resulted in marked edema, especially of the face, resembling nephritis edema.

Procaine-derivatives.—A series of aromatic analogs have been studied by J. Braun and Kirschbaum, 1919.

Saligenin (Salicyl alcohol, salicain), N.N.R., $\text{C}_6\text{H}_4\cdot\text{OHCH}_2\text{OH}$.—Hirschfelder *et al.*, found this the most effective, and the least toxic and irritant, of the phenyl-carbinols so far studied. Its toxicity is much lower than that of the procaine-apothesine type. In tonsillectomy, 2 per cent. saligenin appeared as effective as procaine.

Stovaine, N.N.R. (benzoyl-ethyl-dimethyl-aminopropanol hydrochloride).—Colorless scales, extremely soluble in water, or in 5 parts alcohol. *Dosage*, locally, as for cocaine. Anesthetic action slightly stronger, irritant action (hyperemia) much greater, toxicity two-thirds that of cocaine. No effect on pupil.

It has been used especially for spinal anesthesia, in combination with strychnine (T. Jonnescu, 1909). The immediate danger may be somewhat less than with cocaine, although it is not negligible. The local injury is much greater. Spiller and Leopold, 1910, and Consoli, 1913, have observed degenerations in the nerve roots and cells, after subdural injection of stovaine. The immediate paralysis is more extensive than with cocaine, involving muscular movements (Santesson, 1906) and spinal reflexes (Adler, 1906). On the circulation, it causes in dogs quickened pulse and fall of blood pressure (Kamenzove, 1911). The kidneys are also rather irritated, especially if albuminuria was previously present (Schwartz, 1907; Chiaie, 1913). The liver is not affected (side actions, Seifert, *Nebenwirk.*, 1915, p. 91; lumbar, p. 109). A comparative study of the local anesthetic actions of stovaine and its homologues has been made by Symes and Veley, 1911.

The literature of accidents is reviewed by M. I. Smith and R. A. Hatcher, 1917, *Jour. Pharm. Exp. Ther.*, 9: 231. Even with intravenous injection or perfusion, it appears to have no direct action on the blood vessels, but toxic doses depress the heart. Death occurs by simultaneous and independent paralysis of the heart and respiration. Stovaine disappears rapidly after injection into the blood stream, and but little is excreted. It is removed and presumably destroyed by the liver. It is more toxic than procaine by corresponding methods of administration.

In over 1,000 cases of stovaine spinal anesthesia, about 30 per cent. showed more or less by- or after-effects. One patient had respiratory failure; 7 patients transient paralysis (Muenchmeyer, 1908).

Tropacocaine Hydrochloride, N.N.R., (benzoyl-pseudo-tropeine); occurs in Javanese coca, but the commercial is synthetic. Colorless needles, readily soluble in water. It destroys the vasoconstrictor action of epinephrine. *Dosage*, locally, one or two times that of cocaine. Anesthetic action about the same; irritation greater; toxicity one-half that of cocaine; less mydriatic; more stable (side actions, Seifert, *Nebenwirk.*, 1915, p. 97; lumbar, p. 112). It is used especially for spinal anesthesia (Stanley, 1916).

Yohimbine, $C_{22}H_{28}N_2O_3 \cdot HCl$.—An alkaloid isolated by Spiegel, 1896, from the bark of Yohimbe tree (Apocynaceæ; West Africa). Fourneau and Page, 1914, consider it identical with quebrachine. Local anesthetic, about same strength but more lasting than cocaine. Less toxic, but much more irritant. Mydriasis, without loss of accommodation. Vessels dilated. Intestines, excised or *in situ*, and bladder stimulated by small, depressed by large, doses (A. Loewy and Rosenberg, 1914). Solutions are unstable.

When it is given by the mouth or hypodermically in moderate doses, it produces a general *vasodilation* in the skin, mucous membranes, and particularly in the *sexual organs*. In consequence of the latter, and perhaps by a direct action on the spinal centers, it produces erection. It does not seem to stimulate the production of spermatozoa or sexual desire. It does not increase the rate of reproduction in mice (Rumry, 1918).

The effect is not produced by therapeutic doses in man (5 mg. or $\frac{1}{12}$ gr.), although it has been promoted as an aphrodisiac. The reports of clinical improvement after several weeks are probably explainable by suggestion. Yohimbine has also been proposed for lowering abnormally high blood pressure; but Lawrence, 1912, found that it may produce a further rise, with dangerous symptoms.

Larger doses produce psychic excitement, cerebral congestion, vertigo, gastric disturbance; and in rabbits, marked injury of the renal epithelium (Huebner, 1912). Toxic doses produce general stimulation and subsequent paralysis of the nervous centers, particularly in the medulla; and complex effects on the cardiac muscle (F. Mueller, 1907; J. Tait, 1910). The coronary vessels are not affected (Rabe, 1912); or they are dilated (F. Meyer, 1912). Death occurs by respiratory paralysis (for literature, see Strubell, 1906).

Difficultly Soluble Local Anesthetics.—These are used locally as dusting powders, as such or diluted with 1 to 20 parts of talc or ointment. The internal dosage and the side effects are stated under each substance.

Aethylis Aminobenzoas (Aethyl. Aminobenz.), U.S.P.; Ethyl Aminobenzoate. Benzo-caine, Anesthesine, $C_6H_4NH_2 \cdot COO(C_2H_5)$ 1:4.—Small white or colorless crystals, or crystalline powder. Odorless. Very slightly sol. in water (1:2,500), freely sol. in alc. (1:5), chloroform (1:2), ether (1:4), almond oil (exp.) or olive oil (1:50:50, at 25°C.). Sol. in dil. acids. *Dose*, 0.3 Gm., 5 grains. U.S.P. Side actions, Seifert, *Nebenwirk.*, 1915, page 44.

Cycloform; Isobutyl para-amino benzoate. *Dose*, 0.1 to 0.2 gram, 1–1.2 to 3 grains. *Orthoform*; Methyl amino oxybenzoate. *Dose*, 0.5 to 1 gram, 8 to 15 grains. Sometimes produces inflammatory reaction (Seifert, *Nebenwirk.*, 1915, page 79; McCleave 1914).

Propæsin; Propyl aminobenzoate. *Dose*, 0.25 to 0.5 gram, 4 to 8 grains.

DRUGS ACTING PERIPHERALLY ON THE AUTONOMIC-SYMPATHETIC SYSTEM

A variety of poisons act peripherally upon the several portions of the involuntary or "vegetative" nervous system, in a more or less specific manner. It appears advisable to premise their individual consideration by a more general exposition, so as to obtain a grasp upon their various relations. Much light has been thrown upon these in recent years, and our conceptions have been largely revolutionized.

Anatomic and Physiologic Relations.—The "autonomic" system (in the wider sense in which the term was introduced by Langley) has certain physiologic and anatomic peculiarities. *Physiologically*, it includes all the

functions which are subject to involuntary nervous control—the smooth and cardiac muscles and the glands. Their relation to the central nervous system is peculiar, in that they are capable of functioning automatically, when all connections with the cerebrospinal axis are severed (hence “Autonomic”). On the other hand, their functions are normally regulated, augmented or inhibited, by central tonic impulses of varying intensity.

The chief *anatomic* peculiarity of these automatic nerves is, that they all pass through relay ganglionic cells, situated outside of the central nervous axis. These cells are partly scattered but mostly collected into the “sympathetic ganglia.” A given nerve fiber has but a single relay cell, although it may pass through a number of ganglia.

Receptor, Connector and Excitor Elements.—These together constitute every reflex path of the voluntary or somatic (Langley) system. The essential anatomic difference between the two systems is that the cells of the effector neurons of the involuntary system have wandered from the central nervous system to the periphery, as ganglion relay cells (Gaskell, 1916).

The *receptor part* comprises the sensory end-organ, the sensory nerve fiber, and the cells in the posterior root ganglion.

The *connector part for voluntary muscle* is entirely within the central nervous system. Its cells lie in the posterior horn, and are connected with the excitor cells of the pyramidal tract.

The *connector part of the involuntary system* also has its cells in the central nervous system (the lateral horn of the cord); but the connector fibers run out by the anterior roots as fine medullated “preganglionic” sympathetic (autonomic) fibers.

The *excitor part of the voluntary system* consists of the motor cells in the anterior horn, and their fibers, constituting the motor trunks.

The *excitor part of the involuntary system* has its cells always outside of the central nervous system, as the “sympathetic ganglia.” Its fibers are non-medullated.

The *sympathetic ganglia* (including not only the spinal ganglionic chain, but also the peripheral ganglionic plexuses—the coeliac, Auerbach’s, etc.) are therefore homologous to the motor cells of the anterior horn; they are simply the cells of the excitor neurons (Gaskell).

The “*autonomic system*” consists purely of connector and excitor neurons. It does not contain any receptor neurons; these all run to the posterior root ganglia.

Connector Elements.—These can not properly be called either sensory or motor (receptor or excitor). They are not confined to one segment of the cord, but may communicate with other segments, near or distant. They need not communicate directly with the excitor neuron, but may connect with other connector neurons, within the central nervous system, thus forming a series of relays between the receptor and excitor elements. However, such relays do not occur outside of the central nervous system. The autonomic nerves therefore do not have relays; and each spinal sympathetic ganglion is therefore strictly segmental. However, the preganglionic fibers form collaterals, through which a connector cell innervates more than one effector neuron, when this is important for securing coördination.

The Differences between the Autonomic and Somatic Systems.—These consist in the central origin, the situation of the cells of the effector neuron, and in the end organ. None of these differences is really fundamental, for they offer many analogies, in the nature of the processes, and in the reactions to drugs. The chief differences arise from the specialization of the striped muscle cells, which results in rapid contraction, loss of automatism, loss of intrinsic tone, and abolition of inhibitory innervation—all these being closely interconnected.

THE PARASYMPATHETIC AND SYMPATHETIC SYSTEMS

Physiologically, and especially pharmacologically, as also in its embryologic development, the autonomic system as a whole has two fairly sharply defined divisions, which correspond, anatomically, on the one hand, to the nerves having their origin in the roots of the midbrain, medulla oblongata, and sacral cord (the *cranio-sacral* or *parasympathetic*

system (Langley, 1905), also often called the autonomic system in the restricted sense); and on the other hand, those arising from the dorsal and down to the fourth or fifth lumbar nerve roots (the *sympathetic system*).

The sympathetic and parasympathetic systems are distinguished by the following features:

By the site of origin in the central nervous system; by the location of the ganglionic cells; by the fact that both systems innervate the same cell, generally in antagonistic directions; and by their characteristic reactions to drugs.

"Outflows" of Autonomic (Connector) Fibers.—These leave the central nervous system mainly in three regions (being interrupted by the outflows of the voluntary motor fibers of the extremities, *i.e.*, of the brachial and of the lumbar-sacral plexus). The three autonomic outflows are the bulbar, the thoraco-lumbar, and the sacral (there are also some fibers from the midbrain (the presomatic system) innervating the ciliary ganglion).

The Sympathetic System Proper.—This corresponds to the dorso-lumbar outflow, the nerves arising from the second dorsal to the third lumbar division. Their excitor cells constitute the entire spinal "ganglion chain," including also the cervical and splanchnic ganglia.

The Parasympathetic System.—This includes the cranio-bulbar and the sacral outflows. The connector fibers of these run directly to the periphery, the excitor or relay ganglion cells being situated in or near the end organs (the vagus and pelvic trunks, therefore, are considered connector fibers).

Distribution and Function.—The two divisions are usually antagonistic, a given organ as a rule receiving its innervation from both divisions, one being augmentor, the other inhibitory.

The *sympathetic division* is generally augmentor to the blood vessels and to the organs derived from the ectoderm; whereas the *parasympathetic system* is augmentor to the organs derived from the endoderm. Gaskell therefore calls the sympathetic the *vasodermal system*, and the bulbo-sacral he calls the *endodermal or enteral system*. The inhibiting innervation is generally just the converse. (Circular and longitudinal coats have the same—not reciprocal—innervation; Gaskell.)

The innervation of the sweat glands occupies a peculiar position; anatomically, it is purely sympathetic, but it reacts pharmacologically as if it were purely parasympathetic. The *uterus* is also exceptional; its sympathetic innervation responding to both classes of poisons. It must be remembered, however, that the anatomic evidence of the origin of the autonomic nerves is in some respects inconclusive.

The following tabulations are adapted mainly from Gaskell:

Augmentory Motor Functions of the Sympathetic (Vasodermal) Division.—These may be grouped as:

Vascular System.—All blood vessels, and including the heart and the spleen. The excitor cells are in the lateral sympathetic chain.

Involuntary Skin Muscles.—Excitor cells also in the lateral sympathetic chain; includes the sweat glands, pilomotor, anus and vaginal orifice, retractor penis, extra-ocular, nictitating membrane, pupillodilator.

Segmental Duct (by hypogastric nerves; excitor cells in organs). Ureter, uterus, fallopian tubes, prostate.

Intestinal Sphincters (excitor cells in mesenteric ganglion).—Ileocolic and internal rectal, perhaps also pyloric sphincter; vesical sphincter, trigone (in some animals spreading over the entire bladder as an additional coat), and urethra.

Augmentory Motor Functions of the Para-sympathetic (Enteral or Endermic) System.—The *vagus* supplies the lungs, gall-bladder, and small intestines; the *pelvic* supplies the cloacal region, *i.e.*, the large intestines, rectum and bladder. The excitor cells are situated at the periphery; those of the pelvic nerves form the pelvic plexus (formerly misnamed hypogastric plexus) on the surface of the bladder and rectum. Gaskell considers the cells of Auerbach's plexus as the motor cells of the *vagus*.

Augmentory Motor Functions of the Presomatic System.—The excitor cells are in the ciliary ganglion, and supply the sphincter of the iris by the short ciliary. This innervation does not properly belong to the sympathetic or parasympathetic. The structure of the sphincter is also unique, being intermediate between the voluntary and involuntary muscles. The dilator of the pupil is strictly sympathetic.

Inhibitory Nerves.—With the voluntary system, inhibition occurs within the central nervous system. With the involuntary system, special inhibitory fibers exist, both connector and excitor. (It is conceivable that, in addition, a single excitor element may transmit both augmentory and inhibitory impulses).

Distribution of Augmentory and Inhibitory Innervations.—The most important are:

Vaso-Dermal System.—Augmentory sympathetic; Inhibitory (so far as they exist), sacral.

Genital System.—(Uterus and Ureter). Augmentory and inhibitory, both sympathetic.

Intestinal Sphincters.—Augmentory, sympathetic; inhibitory, sacral.

Intestinal Muscle.—Augmentory, vago-sacral; inhibitory, sympathetic.

Esophagus and Cardial Sphincters.—Augmentory and inhibitory; both vagal.

Heart and Vessels.—Augmentory, sympathetic; inhibitory, parasympathetic.

Iris Sphincter and Ciliary Muscle.—Augmentory, parasympathetic (tectal division); *Iris radial*, augmentory, sympathetic.

Innervation of Glands.—This corresponds to the same laws as the muscular innervation; the glands derived from the epidermis (sweat) receive their augmentor supply from the sympathetic; whereas the parasympathetic augments the endodermal glands (pancreas, gastric, mucus, etc.). The salivary glands probably have cells derived and innervated from both systems.

PHARMACOLOGIC REACTIONS OF THE AUTONOMIC SYSTEM

The sympathetic and parasympathetic ganglia react alike toward poisons, for instance, nicotine. Beyond the ganglia the reactions to drugs are often more or less strictly confined to one or the other innervation; *i.e.*, peripheral pharmacologic reactions tend to be either “sympathomimetic” (Barger and Dale, 1910), as epinephrine, cocaine and ergotoxine; or “parasympathomimetic” (Langley), as pilocarpine, muscarine, choline physostigmine and atropine. This suggests a fundamental difference in the physico-chemical characteristics of the receptive mechanism of the two systems, but this is not absolute: A number of poisons act only on certain parts of one or both divisions; and even the most specific of the drugs, such as epinephrine or choline, may apparently have their actions transferred to the contrary division under certain conditions.

REACTIONS OF AUTONOMIC GANGLIA

Nicotine.—Pharmacologically, the most prominent characteristic of the whole autonomic system is its reaction to nicotine: this alkaloid paralyzes all the ganglionic synapses of both the parasympathetic and the sympathetic nerves (often after a fleeting primary stimulation). This paralysis is so specific, that it has proved of great value, especially in the hands of Langley, for locating the site of these synapses. Nicotine, whether it is applied locally or systemically, abolishes the response to stimulation of the preganglionic fibers, whereas the post-ganglionic fibers respond normally.

Small doses of Nicotine at first stimulate these preganglionic nerves.

Curare, Strychnine and Brucine.—These also depress or paralyze all preganglionic nerves, analogous to nicotine; and they are antagonized by stimulant doses of nicotine. The susceptibility to paralysis is in the following order: *First*, Cardioinhibitory; *Second*, chorda-secretory, sweat, pilomotor, pupil-dilator and constrictor, probably also bulbar and sacral vasodilators; *Third*, nictitating membrane and cutaneous vasodilators; *Fourth*, epinephrine-secreters and abdominal vasoconstrictors.

PHARMACOLOGY OF THE SYMPATHETIC DIVISION

Epinephrine, the alkaloid of the suprarenal gland, produces a pure peripheral stimulation, restricted exclusively to the sympathetic system, but involving the entire distribution of this system (with the exception of the sweat glands). In other words, the effects of typical doses of epinephrine on a given organ correspond precisely to the stimulation of its sympathetic nerve supply (Lewandowsky, 1899; Langley, 1901; Elliott, 1905). The action of epinephrine is therefore augmentory or inhibitory, according to whether the sympathetic impulses are augmentory or inhibitory, as follows:

Divergences of Epinephrine from Sympathetic Stimulation.—The only structures that are markedly influenced by sympathetic stimulation and not by epinephrine after nerve section are the sweat glands in the cat and some other mammals. There is also an instance of parasympathetic stimulation by epinephrine: The pulmonary arteries of frog and turtle are constricted by epinephrine and by vagus stimulation; antagonized by atropine; and they do not constrict by sympathetic stimulation (Luckhardt and Carlson, 1921).

Quantitative differences are more numerous; and in cases where sympathetic stimulation causes both augmentory and inhibitory effect, the predominance with epinephrine may be the reverse of that with nerve stimulation. This is not surprising in view of the differences in response with weak and strong electric stimulation, etc.

The Principal Sympathetic Reactions (e.g., the Effects of Epinephrine).

—The *augmentory reactions* consist in constriction of most of the arteries and consequent rise of blood pressure; stimulation of the cardiac accelerator; dilation of the pupil; contraction of the plain muscle of the orbit; flow of sympathetic saliva and of tears, not readily abolished by atropine; erection of hair, etc.

Inhibitory reactions concern the tone and rhythm of the contractions of the stomach, intestine, biliary and urinary bladder (cat), and of the virgin uterus of the cat.

Peculiarities of Species.—Certain of the sympathetic reactions vary with the species of animals, being augmentory in some, and inhibitory in others (urinary bladder, anal sphincter). The sympathetic reaction of the uterus varies according to its physiological state; in the cat, the virgin uterus is inhibited, whilst the pregnant uterus is stimulated.

All these peculiarities are reproduced exactly in the reaction to epinephrine, thus furnishing the most striking illustrations of its sympathomimetic action.

Other Drugs with Sympathomimetic Action.—Similar actions are possessed by a large number of primary and secondary amines, the simplest being the primary fatty amines, amylamine, etc.). There are quantitative differences between these. The relative effect on the different sympathetic distributions does not go parallel; nor is there any parallelism between augmentory or inhibitory innervations. The intensity and specificity increase as the amines approach the structure of epinephrine (Barger and Dale, 1910). A compilation of the amines and their relation to pharmacology is also given in the book of Guggenheim.

Cocaine increases the peripheral excitability of the sympathetic system without being directly stimulant.

Peripheral Sympathetic Paralysis: Ergotoxine.—The active alkaloid of ergot (in large doses) destroys the response of the augmentory sympathetic impulses, but does not affect the inhibitory sympathetic impulses (Dale, 1906). It therefore prevents, *f.i.*, the vasoconstrictor action of epinephrine, but does not abolish the inhibitory action of epinephrine on the intestine or uterus.

PHARMACOLOGY OF THE PARASYMPATHETIC (OR CRANIO-SACRAL RESTRICTED) AUTONOMIC DIVISION

The action of drugs on this system is confined mainly to its augmentory functions (with the important exception of the vagus). These, in their entire peripheral distribution, are paralyzed by atropine; and stimulated by pilocarpine, muscarine, choline and anaphylotoxin. Physostigmine heightens their irritability, perhaps without being directly stimulant. (These statements must be restricted to typical doses.)

Atropine is therefore antagonistic to all the other drugs named. If a sacro-cranial function is exposed simultaneously to the depressant action of atropine and to the stimulant action of one of the other drugs, the end result depends on the nature and quantity of the drug, and upon other conditions. Physostigmine, for instance, is a more powerful antagonist of atropine than is pilocarpine; however, larger doses of the stimulants tend to become depressant, so that the atropine action tends to appear predominant.

The centers of the parasympathetic system are stimulated by picrotoxin.

Principal Results of Parasympathetic Stimulation (Pilocarpine, etc.).—These consist in: slowing of the heart; constriction of the pupil; bronchial spasm; contraction of intestine and uterus; increase of practically all centrally innervated secretions (sweat, saliva, mucus, gastric, pancreatic, etc.; not urine, bile, milk, nor the internal secretions). These are the main effects of pilocarpine, muscarine and physostigmine.

Craniosacral depression (atropine) produces precisely the opposite results.

Discrepancies of Parasympathetic Poisons.—One of the most marked is the response of the retractor penis muscle of the dog: stimulation of the nerve gives inhibition, pilocarpine contraction. Differences of degree of effect occur; most striking in small intestines.

Pilocarpine stimulates some sympathetic innervations: sweat glands, uterus, contraction or dilation of arterioles, contraction of spleen. Atropine also paralyzes some sympathetic innervations: submaxillary secretory; sweat glands; skin glands of frog; secretory fibers of the prostate; and antagonizes pilocarpine wherever that acts. Gohara claims that it also abolishes the contractor effect of epinephrine on rabbit's uterus.

AUTONOMIC REACTIONS PROVOKED BY STRIO-MUSCULAR DRUGS

There seems to be a definite relation between the drug-affinities of the autonomic and strio-muscular innervations. Probably all of the drugs that act on the receptive mechanism of the striped muscles act also on the parasympathetic or sympathetic division, and most of the parasympathetic drugs act on striped muscle. The sympathetic division does not seem to affect muscular contraction and tone, but has been credited with influencing muscular metabolism.

The curare and nicotine group acts more especially on the autonomic ganglia, so that their effects on the terminal cells are not easily studied. *Guanidine* is perhaps more strictly terminal. The excised frog-heart (Rosenow, 1921) responds to weak concentrations by increased systole (sympathetic stimulation?); to higher concentrations by diastolic arrest (parasympathetic stimulation?). Bronchial muscle (Macht and Ting, 1922) is relaxed (sympathetic stimulation or parasympathetic depression?).

Contrast of Non-striated and Striated Muscle.—The fibrillary structure of striated muscle favors rapid surface changes, which in turn would favor rapid contraction and relaxation; but with the sacrifice of extent of contraction and of relaxation, and of maintenance of intrinsic tone.

Significance of Motor End-plates.—The longer fibers and the rapid reaction of striped muscle probably require a relatively high potential for efficient stimulation. At the same time the differentiated fibrillary structure is probably less suited than the sarco-

plasm for the transmission of potential-differences from the nerve to the muscle. The condensation of the transmitting sarcoplasm of the nuclei at the "endplates" insures polarity in the muscle fiber, and hence exaggerates the action current which is probably concerned in the stimulation of the muscle fiber.

Strio-muscular Reactions to Parasympathetic Drugs.—The more powerful parasympathetic stimulants, physostigmine and acetyl choline, stimulate the "receptive" mechanism of striped muscle in a manner strictly analogous to the characteristic strio-muscular stimulants, guanidine, nicotine and barium. The phenomena are the same for all, with mere quantitative differences that tend to disappear by varying the dosage: *a*, The lowest effective concentrations produce fibrillary twitchings; with increasing doses these pass to clonic contractions, tonus contractions, and finally into curare-like depression. *b*, With all, the action is strongest at the site of the end-plate. This might mean that the receptive mechanism is concentrated at this place; or merely, that the permeability of the cell-wall at this place is more favorable to the penetration of the drugs or ions. *c*, All continue effective for some time after the division of the nerve endings. Most and probably all become less and less effective when the nerve has completely degenerated, presumably because the receptive mechanism, and eventually the muscle fibers as a whole, deteriorate when they are no longer used. *d*, All are antagonized, though to a varying degree, by curare, atropine and especially 1-scopolamine, and the local anesthetic group. Atropine is more effective against drugs than against nerve-stimulation; a difference that it frequently exhibits in strictly parasympathetic reactions, and which is again merely quantitative, for sufficiently large doses of atropine block the response of striped muscle to nerve stimulation (Haffner, 1918).

The data for these conclusions, but not necessarily the interpretations themselves are chiefly taken from papers of Frank and Katz (1921) (local anesthetics, nicotine, guanidine); E. Frank and Mothmann (1921) (physostigmine and scopolamine, on human); Frank and Stern (1921) (guanidine, degeneration, procaine, atropine, barium); Fuehner (1920) (guanidine); Haffner (1918) (atropine); Langley (1913 and 1914) (curare and nicotine); Magnus (1908) (nicotine, curare, physostigmine); Meighan (1919) (guanidine); Riesser and Neuschloss (1921 and 1922) (acetyl choline, atropine, curare, nicotine, local anesthetics); Schüller (1921) (local anesthetics and caffeine), Schüller and Athmer (1921) (local anesthetics and veratrine).

Sympathetic Innervation of Striped Muscle.—Sympathetic fibers have been traced to the striped muscle fibers; especially by the degeneration method (Dusser de Barenne and co-workers, 1919). It was suggested on speculative grounds that this sympathetic innervation controls the sarcoplasm, and through it the tone of the muscle, in accordance with Bottazzi's sarcoplasmic theory of tone. De Boer (1916) claimed to have demonstrated experimentally a loss of tone on division of the sympathetic supply. Dusser de Barenne (1916) and S. Cobb (1918) showed that this has essentially no effect on the tone. The sympathetic innervation was then credited with the regulation of the metabolism of the muscle, but without direct evidence. Langley points out the difficulty of distinguishing a sympathetic innervation of the muscles from a sympathetic innervation of the blood vessels in the muscles, and does not consider the evidence quite conclusive; but inclines to the positive side; *i.e.*, that sympathetic nerves make direct connections with the muscle cells.

The behavior of striped muscle toward epinephrine supports the view that the sympathetic innervation does not act on muscular contraction or tone; for epinephrine does not affect these in excised muscle (Takayasa, 1916). On the other hand, epinephrine increases the carbon dioxide production, even in excised muscle (Martin and Armitstead, 1922), and also creatine formation (Riesser, 1916). This indicates that the sympathetic innervation may be concerned with possible functions of muscle in general metabolism; perhaps in heat-regulation.

DRUGS WITH PARTIAL AUTONOMIC REACTIONS

The preceding presentation is schematic, and includes only the typical effects, as they are currently conceived. When the doses and other conditions are varied, many of these drugs depart more or less from the schema, as will be discussed later. This indicates that the physiological divisions, which are the basis of the pharmacologic divisions, are not as absolute as the schema would imply. In accordance with this, there are a number of drugs (for instance, apocodeine and pituitary extract; the latter, however, is probably a mixture), which do not fit anywhere in the schema, but whose actions involve isolated functions of one or both divisions.

Significance and Limitations of the Pharmacologic Specificity of the Autonomic Reactions.—The preceding descriptions have emphasized that the striking differences in the origin and distribution of the three great classes of efferent nerve-systems and their end organs—the somatic or voluntary system, the parasympathetic and the sympathetic—are reflected in an almost equally striking manner in their peripheral reactions to certain drugs; so much so that these could be definitely classed as sympathetic (for instance, epinephrine and ergotoxine); parasympathetic (for instance, pilocarpine and atropine); and strio-muscular (for instance, guanidine and curare). The correspondence between the drugs and innervations is so far-reaching that it cannot be accidental. There must be a fundamental, specific relation between the innervation and the drug-reactions; and if so, it might be supposed that all poisons that act in a special manner on the peripheral system should belong, definitely and sharply, to one or the other of these groups; and we should thus be able to arrange all these drugs into a simple orderly, logical and generally satisfying system.

There is, however, another side of the picture: The correspondence is impressive, but not complete. On the one hand, some drugs affect, more or less, several of the systems; and on the other hand, the most typical drugs seem to act on the wrong system in some organs, such as the uterus and the sweat glands. At first these exceptions were naturally set aside as “atypical” until the main scheme could be better digested; but they have continued to accumulate in number and in impressiveness until it seems that they might submerge the whole schema, unless the schema could be sufficiently broadened to cover them. Very evidently, the divisions of the efferent systems are not separated as sharply as the schema would imply: at least, the chasm between them is not impassable. The facts may be reconciled by the assumption that the fundamental distinction goes beyond the nervous systems; that the reactions, whether to drugs or to nervous impulses, depend on the physical or chemical properties of the reacting cell; that these vary with conditions; that a certain complexion of these conditions is ordinarily associated with each of the nervous systems; but that these conditions may be shifted, naturally and artificially; and that then the reactions to nerve impulses and to drugs are also changed, separately or together.

In other words, it would appear that autonomic specificity is not an absolute, separate entity; but that it is conditioned on the ordinary, fundamental properties of muscle, of reactive tissue; in fact, of excitability in general. Conditions which affect these are also capable, potentially, of affecting autonomic specificity. This specificity is relatively fixed, because these properties are relatively fixed in a given type of tissue.

Generalizations of this sort hold out attractive prospects of satisfying the innate longing for unification; but they have little value unless they unify actual phenomena. Perhaps the chief significance of the more recent work on autonomic drugs is therefore the collection of data concerning the conditions that modify response. As yet, these data can furnish only hints, partly because they are incomplete in themselves, and partly because their interpretation must await clearer conceptions of the various properties of excitable tissues than we possess at present. There is reason to hope that each will throw light on the other; and it would not be surprising if the paradoxical effects of autonomic drugs would be important aids in unravelling the complexities of the nature of excitation.

The data for this are however still very incomplete. With some autonomic drugs, as for instance, histamine and nicotine, the non-specificity is very conspicuous. With others, the response is reversed by altering the dosage; for instance, in the action of pilocarpine on the vagus. In such cases, the critical concentration generally varies for different organs; so that a certain dosage may stimulate the innervation of one organ and depress that of another. Modifications in the excitability of an organ, for instance by the presence of other drugs, may alter its response. It is also suggestive that perverted drug-specificity is most prominent in organs in which the innervation is itself unusual or confused. It is especially common when the tissue receives only one innervation; or when one innervation predominates very largely over the other; or where both systems produce the same response. For instance, in the sweat glands, the genito-urinary system; the frog's lungs; the blood vessels; and in the unpublished instance of the frog's small intestine, perverted specificity of drug is generally associated with weak contrast in the specificity of innervation.

LOCATION OF ACTION

Possible points of attack in the peripheral distribution of the autonomic systems: These may be conveniently grouped as (1) The ganglionic elements; (2) The nerve-endings, including the terminal fibrils; (3) The

receptive mechanism or excitability of the terminal cell; (4) The responsive mechanism of the cell, *i.e.*, the contractibility or secretory activity.

Methods of Analysis.—These rest upon the general principle of localizing depression by the application of stimuli, and stimulation by producing depression or paralysis, centrally and peripherally to the suspected site of action. This is simple for the ganglia, when these are situated apart from the other structures; but when they are intermingled, less direct and correspondingly less decisive methods must be employed. The difficulty increases with the more peripheral structures. Stimulation of the nerve-fibrils and endings may be excluded by section and degeneration; but the converse does not hold, *i.e.*, disappearance of response after degeneration does not prove that the stimulation was in the nerves; for section of the nerves also causes degeneration of the muscle fibers, and consequently changes in their excitability. The degeneration method could not, of course, throw any light on the site of a depressant action. This, and still more the distinction between the receptive and the responsive mechanism again rests upon indirect methods. It is tempting to aid the localization by the use of antagonistic drugs; but this is very likely to mislead, since the antagonism of drugs is influenced by factors other than their normal site of action (Magnus, 1908).

Because of these difficulties, the current views as to the localization of autonomic actions are tentative rather than final; they serve to classify the observations, rather than to explain them. Their general tendency is toward simplification: It appears that the nerve-fibrils and endings are not at all concerned in the specific autonomic reactions; that the ganglia play a very minor share, except with the nicotine-group; and that therefore the autonomic poisons act almost exclusively directly on the muscle or gland cell. Even the distinction between actions on the receptive and the responsive mechanism (or between the receptive substance and the contractile substance) tends to become merely quantitative.

The ganglia.—Localization in these structures is illustrated by the effects of nicotine; for instance on the heart. After the injection of the drug stimulation of the vagus trunk fails to slow the heart, but stimulation of the postganglionic fibers, in the sinus, produces the normal slowing. The nicotine must therefore have paralyzed something between these points, *i.e.*, the ganglia. The ganglia of invertebrates (*f.i.*, sipunculus, Magnus, 1903; cardiac ganglia of the king-crab, Carlson, 1906) are susceptible to the whole series of autonomic drugs. With vertebrates, however, wherever the ganglia can be separated with sufficient sharpness, they do not seem to be very susceptible to autonomic poisons other than the nicotine group. It is difficult to confirm this conclusion absolutely in situations where the ganglia are inextricably intermingled with the terminal elements, as in the heart and intestines.

Functions of the Ganglion-Cells.—These are evidently the nutrient centers of the nerve fibers. It is imaginable that they may also alter the nerve impulses, for instance reinforce them or transform them to the optimal rate. Their spontaneous activity probably influences the tone and therefore the excitability of the involuntary muscles; and with invertebrates at least, they may originate rhythmic discharges, and thus set the pace to the rhythm of the muscle, as they do in the limulus heart. In such cases they are usually sensitive to the autonomic poisons. With invertebrates they may also act as reflex centers; but there is no clearly demonstrated instance of this function in vertebrates. As early as 1868, Maurice Schiff (*Leçons sur la Physiologie de la Digestion*, pages 394-396) insisted that the conception of sympathetic ganglia as "peripheral reflex centers" was entirely without experimental foundation.

Cardiac Ganglia.—The analogy of the limulus heart lent color to the suggestion that the ganglion cells might be the seat of the rhythmic activity and of the actions of drugs upon it. The analogy, however, is not binding, and the "neurogenic theory" has almost hopelessly lost ground for the vertebrate heart (Eyster and Meek, 1921). As concerns the autonomic drugs these act on the ganglion-free apex essentially as on the whole heart (S. Loewe, 1918; Sasaki, 1921).

Intestinal Ganglia.—The evidence for the importance of the intestinal ganglion plexus to the autonomic reactions rested essentially on the experiments of Magnus (1904) that seemed to show that the rhythmic contractions of the intestines, and the effect of drugs upon them, depended on the integrity of the Auerbach plexus. Later work, however, showed that the absence of rhythm was due merely to traumatic injury; Gunn and Underhill (1922) showed that plexus-free preparations are rhythmic; and that the rhythm can be evoked for days after the excision, whilst the ganglion cells are assumed to die quite promptly. This has been abundantly confirmed (for instance, Alvarez and Mahoney, 1922); and holds true also for the peristaltic movements of the excised intestine, as shown by the method of Trendelenburg (1917). The results of these indicate that the origin and direction of the peristaltic wave depend on a gradient of tonus and excitability, inherent in the muscle; which in turn depends presumably on adjustment to the optimum ion ration. The effects of drugs in revived intestine also agree essentially with those in intestine in which the ganglia are alive.

Carlson and his co-workers find another argument for the independent activity of the Auerbach ganglia in the capricious response of the cardinal region of the stomach to nerve stimulation: either vagus or sympathetic may produce either contraction or inhibition (Carlson, Boyd and Pearcy, 1922). From this they argue that these nerves do not act directly on the muscle, but that they are largely afferent nerves to peripheral reflex center, *i.e.*, to the ganglion plexus. The deduction does not appear conclusive. It is conceivable that each nerve might carry both augmentor and inhibitory fibers directly to the muscles (as Tashiro (1920) assumes for the intestinal sympathetic), or the end result of the same stimulation on a given muscle fiber may be modified by the state, especially the tone, of that fiber.

On the whole the facts seem in harmony with Gaskell's view that the ganglion cells of the autonomic system are connector elements, analogous to the pyramidal cells of the motor system, but transplanted to the periphery. However, the final conclusion must be left to the future.

Nerve-Fibrils and Endings.—There is no conclusive evidence that any specific autonomic poisons act on the "nerve-endings" that degenerate after section of the nerves; and that the evidence of excised organs is distinctly against this mechanism. Nerve fibers, where they can be reached separately, are practically unaffected by most of the specific autonomic poisons. It is therefore improbable that the finer terminal fibrils, which seem to be mere continuations of the axis-cylinders, should be the site of the specific actions. They differ from the larger fibers in permeability, it is true; but this would cause only quantitative differences, as is shown by the local anesthetics.

Direct evidence against the nerve fibrils is furnished by the persistence of the responses to autonomic drugs, in excised organs after the excitability of the nerve fibers has been lost.

The results after degeneration of the nerve fibrils and endings, following division of the nerve trunk, speak in the same direction. The effects of a number of autonomic drugs, notably epinephrine, can still be evoked, after complete degeneration of the nerve. This localizes their action definitely beyond the termini that are in nutritive connection with the nerve.

The interpretation of the converse phenomenon, disappearance of the drug response as the result of degeneration, is not so decisive. The effects of pilocarpine, for instance, can be evoked like those of epinephrine, after degeneration, *i.e.*, when stimulation of the nerve trunk is ineffective. After a time, however, (6 weeks for sweat, Anderson and Langley, 1904) the response becomes less efficient although the muscle still responds to electric stimulation. This probably means that in the end the muscle cell also deteriorates, "atrophies," when it is not functionally used; and that this deterioration abolishes

its excitability by pilocarpine before it abolishes the contractor response to direct electric stimulation. Further instances will be discussed under the autonomic reactions of the eye.

The Receptive Mechanism.—As was pointed out, degeneration of the nerve endings does not interfere with the typical effects of epinephrine; this must therefore act on the muscle-cells directly. This conclusion, however, is difficult to reconcile with the fact that epinephrine acts in reverse directions on smooth muscle in different situations; producing contraction in one place and relaxation in another. The smooth muscle in both cases appears to be identical, and reacts in a uniform direction to other stimuli, such as electric shocks, or poisons like barium. They differ only in their innervation; and this difference is reproduced very faithfully by epinephrine. Since the degeneration experiments prove clearly that epinephrine does not act upon the nerves themselves it became necessary to assume the existence of some intermediate mechanism, related to the innervation, but not trophically dependent upon it, on which the epinephrine and perhaps the nerve current must act. Epinephrine does not stand alone in this respect; probably all specific autonomic poisons act through the mediation of a recipient mechanism; and even some poisons that were formerly believed to affect the contractile substance directly.

The intermediate mechanism may be conceived in several ways: *a*, as a morphologic structure; *b*, as a chemical receptive substance or side-chain; *c*, as a physical system. The available facts do not permit a decision between these; indeed, the theories themselves lack so much in detail that a decisive attitude toward them would not be justified. Consequently, there is an advantage in employing a non-committal term, such as "*receptive mechanism*" for the entire concept; and to restrict the more specific terms, "*myo-neural junction*" (Brodie), "*receptive substance*" (Langley, 1905), and "*synapse*," to the special theories that they represent.

Critical reviews of these theories may be found in the reviews of Langley, 1921, and of Sollmann, 1922.

The Responsive Mechanism.—The sharp separation of this from the receptive mechanism is of doubtful validity: The functions of excitability and contractility or secretion are so closely related that it is impossible to imagine a muscle that is excitable but does not contract; or one that contracts but is not excitable. The separation can only be made in a restricted sense; *i.e.*, a muscle may be inexcitable for some particular kind of stimulation, but respond to others. In practice, the idea of receptive mechanism has been restricted to the transfer of nervous excitation and to the excitability to specifically autonomic drugs. Drugs like barium, caffeine, the nitrites, the isoquinoline group, etc., seem to have less specific relations.

ANTAGONISTIC AND SYNERGISTIC PHENOMENA

Combinations of Autonomic Drugs.—If an autonomic tissue is exposed simultaneously to several of these drugs, the effects are usually much more complicated than would result from the simple algebraic summation of their actions. The most peripheral actions would naturally tend to predominate over those that were exerted more centrally; and accordingly the ganglionic effects are obscured by any actions on the responsive cells.

Mutual Antagonism.—If two drugs are mutually antagonistic, they must both act on the ganglia, or both on the end cells (for instance, the muscle). Within this cell, drugs with opposite actions on the same receptive mechanism (for instance, the parasympathetic) are generally mutual antagonists; but there may also be mutual antagonism between sympathetic and parasympathetic drugs, and between these and the drugs that act on the responsive mechanism. Mutual antagonism is rarely a simple summation; the presence of one autonomic poison modifies the effects of the others, at least in degree, and sometimes in direction. Accordingly, if concentrations of two drugs, that produced equivalent effects in opposite directions, were mixed, the effect of one would usually predominate very decidedly over that of the other; for instance, a very small dosage of atropine will suffice to remove a very strong pilocarpine stimulation (Magnus). Again, if a combination has been worked out that is essentially neutral, multiples of this combination are generally not neutral; although in some cases they may be so, within certain limits (Cushny, 1915). It may also happen that increased excitability produced by one drug renders effective actions of the second drug that are too weak to influence cells of normal excitability, and in this manner the very site of action of the second drug may appear to be altered and reversed.

Penetration.—It may also happen that the presence of one drug may so alter the penetration or the distribution of the second drug as to modify its effects, without exerting antagonistic actions in the ordinary sense. This has been demonstrated by Ehrlich for certain dyes; and similar conditions have been shown by Straub to prevail for muscarine and atropine; and for morphine and chloroform by Fuehner. Asher and Gannus, 1911, found that the gland cells of the nictitating membrane of frogs take up much more of vital stains when they are stimulated by pilocarpine than when depressed by atropine.

Colloids.—These may modify drug-response materially, presumably by modifying penetration. Van Leeuwen and Gyorgyi, 1922, for instance, report quantitative changes produced by kephalin and lecithin on the response of excised intestines to pilocarpine and histamine.

Examples of Combined Effects of Autonomic Drugs.—The following tabulation gives the usual tendency of the combinations.

A. Drugs acting on the same autonomic division:

I. In the same direction = additive effects; for instance, Physostigmine + Choline; Epinephrine + Tyramine; Barium + Strophanthin.

II. In the opposite direction = neutralization; for instance, Pilocarpine — Atropine; Epinephrine — Ergotoxine; Barium — Magnesium.

B. Drugs acting on different autonomic divisions:

I. In the same *functional* direction = additive effect; for instance, Epinephrine + Atropine, heart = acceleration; Epinephrine + Pilocarpine, certain uteri = relaxation.

II. In opposite functional direction; result in either:

(a) Neutralization; for instance Epinephrine — Choline on heart; Barium — Epinephrine on intestines.

(b) Transposition of action; for instance Epinephrine — Atropine on pregnant uterus = more or less neutralization of the epinephrine contraction.

Relation of Action to Intracellular Penetration, Storage, and Destruction.—According to W. Straub, 1907, the effect of most alkaloids is proportional to their concentration within the cell. With muscarine, however, he found the relation quite different: Here the effect appears to depend upon the concentration *outside* the cell; or rather, on there being a higher concentration outside than inside the cell.

The experiments were made by placing the frog's heart into a muscarine solution. The quantity of poison remaining in solution, and the quantity which could be extracted from the heart were then tested on aplysia-hearts. Hearts laid in a muscarine solution show a primary diastolic standstill, followed by spontaneous recovery in a few hours. The maximal diastolic action occurs when very little muscarine has passed into the muscle; while at the time of "recovery," all the muscarine has passed into the heart. If now the recovered heart is placed into a fresh muscarine solution, it is again arrested, with spontaneous recovery. This may be done repeatedly; but the action becomes shorter and shorter, and finally nil. That is, the heart becomes completely refractory to even the highest concentrations of muscarine. If the muscarine concentration is increased very slowly, the heart does not respond. The presence of atropine appears to delay the penetration somewhat. Any explanation of these phenomena would have to be too hypothetical. (O. Loewi, 1912, considers the resumption of the beat under muscarine as analogous to escape from vagus stimulation, and attributes both to increased excitability of the cardiac muscle.)

Incidentally, this furnishes an interesting example of antagonism. The effects of muscarine are exactly the same in animals which have no vagus mechanism; but atropine is only antagonistic in animals in which a vagus mechanism is developed.

With **Epinephrine**, the action is also proportional to the concentration outside the cells. A still more striking example is described by Trendelenburg, 1912, for *bronchial muscle*. This constricts strongly in solutions of muscarine, pilocarpine or arecoline. Washing away the poisoned solution with pure Ringer's fluid does not remove the constriction; on the contrary, this often causes a further contraction. The same phenomenon was observed by Kuyper and Wijnenbeck, 1913, on excised intestine and uterus. Transferring the poisoned tissues into pure saline again brought on the typical augmentory or inhibitory effect of the poison; while transfer from the old to a fresh solution of the poison produced no result. This is taken to indicate that the effect occurs only during the *passage* of the poison through the cell membrane, into or out of the cell.

Optical Isomers.—Most if not all the autonomic poisons are optically active (or racemic); and the chemic reactions which determine their specificity depend largely on their stereochemic configuration. The stereoisomers have an identical composition and identical radicals; but owing to the presence of one or more asymmetric carbon atoms, these groups are arranged differently in space (Van't Hoff and Le Bel, 1874). This is indicated by the optical activity, so that these isomers are levorotatory, dextrorotatory, or by the combination of the two, racemic. Our knowledge of these phenomena dates from the classic discovery of Pasteur, that racemic tartaric acid is separated into its optical constituents by mold fungi. Since then, very numerous instances have been worked out on higher animals; such as atropine and hyoscyamine; atropine and scopolamine; the epinephrines, muscarines, nicotines, cocaine, cinchona alkaloids, camphors, etc. (Fraenkel, *Arzneimittelsynthese*). Cells and ferments distinguish sharply between these stereoisomers, so that they invariably differ, at least quantitatively, in their pharmacologic effects, the racemic being intermediate between the active forms. This indicates that the reactive substance of the cells must also be optically active; and it is suggestive that the effects of the l-active hyoscyamine and l-epinephrine are antagonistic to those of the d-pilocarpine and ergotoxine (Cushny, 1908). In higher animals, the l-alkaloids usually have more powerful peripheral effects. It is probable that the cells can either attack or destroy the one isomer more readily than the other (Poulsen, 1910). The asymmetric nitrogen atom also modifies the pharmacologic actions, as shown by Hildebrandt, 1905, for coniines; and Laidlaw, 1913, for canadines. The curare action of the ammonium bases (Brown and Fraser, 1869) also depends upon the peculiar orientation of the pentavalent atom of nitrogen or similar elements.

REACTIONS OF THE ORGANS WITH AUTONOMIC INNERVATION

These will be presented in the following order: Iris;—Heart;—Blood-vessels;—Bronchioles;—Genito-urinary tract;—Gastro-Intestinal tract;—Glands;—Miscellaneous.

Autonomic Reactions of the Iris.—The iris is controlled by two reciprocating sets of muscle-fibers, the circular sphincter with oculomotor innervation of parasympathetic type; and the radial dilators, innervated from the superior cervical ganglion (Fig. 6). The dilator-sympathetic set is concerned mainly in the pupillary changes of emotion (Ingalls, 1923) and in asphyxia. The changes of the pupil for vision are effected mainly by the oculomotor-sphincter set which also controls the ciliary muscle. The sphincter is under the influence of continuous tonic constrictor impulses from the pupillary center; the tone of this center again being continuously inhibited, but to a varying degree, by afferent and emotional impulses. The diameter of the pupil is the resultant of these opposing forces.

FIG. 6.—Innervation of iris (adapted from P. Schultz): Solid line = sympathetic (dilator); fine dotted line = oculomotor (constrictor); coarse dotted line = trigeminal.

Peripheral autonomic reactions are produced (*a*) on the ganglia of both systems through nicotine (intermingled constriction and dilation); (*b*) by stimulation of the sympathetic receptive mechanism through epinephrine and cocaine (mydriasis); and (*c*) by the paralysis of the oculomotor receptive mechanism by atropine (mydriasis); and their stimulation by pilocarpine, choline, physostigmine, and the related drugs (miosis).

Localization of the Oculomotor Reactions.—These offer some interesting problems: *Atropine* dilates the pupil. Stimulation of the short ciliary nerve, *i.e.*, of the post-ganglionic fibers of the oculomotor, fails to constrict the pupil. *Atropine* must therefore have paralyzed the sphincter mechanism peripherally to the ganglia. Direct electric stimulation of the sphincter muscle still produces contraction; so that the contractibility of the muscle is not injured. The *atropine* must therefore act on the nerve endings, or on the receptive mechanism. As we are dealing with a paralysis, degeneration of the nerve could not be employed to distinguish between these. Recourse must be had to the indirect method of matching *atropine* against *pilocarpine*.

If the short ciliary nerve is divided and allowed to degenerate until it becomes irresponsive to electric stimulation, *pilocarpine* still produces miosis (Anderson). It must therefore stimulate peripherally to the

degenerable oculomotor endings. Atropine, however, removes the miosis; from this it would follow that the pilocarpine does not directly act on the contractility of the muscle, for this is not affected by atropine, as was shown above. The pilocarpine must therefore stimulate the receptive mechanism. The experiment also shows that the atropine action can not reside in the nerve-endings, for in that case it could not antagonize the effects of pilocarpine peripheral to these endings. This would therefore also localize the atropine action in the receptive mechanism.

If *physostigmine* is chosen as antagonist, the results are more difficult to interpret. Degeneration of the nerve prevents the miotic response to this drug, so that it would appear to act on the degenerated part of the nerve; nevertheless, it overcomes the atropine mydriasis (with undegenerated nerve), even more effectively than pilocarpine. Now, if the atropine paralysis is situated in the receptive mechanism, it should as completely block stimulation of the nerve by *physostigmine*, as it blocks the electric stimulation of the nerve. In other words, the site of the action of the atropine paralysis appears to be in the nerve when it is tested against *physostigmine*, and in the receptive mechanism when tested against pilocarpine. It has been suggested that the antagonist actually shifts the point of attack. It is more probable, however, that the degeneration method has led to an erroneous localization of the *physostigmine* action. There is reason to believe that severance of the nerve supply produces degenerative changes in the receptive mechanism, and the *physostigmine* response may be especially susceptible to these. There is also some evidence that the *physostigmine* action may consist in increased sensitivity without direct stimulation of the receptive mechanism. In that case, it might remove the atropine depression, in the normal eye; but fail to cause miosis in the degenerated eye, because the latter is not reached by any stimuli that the *physostigmine* could reinforce.

Degeneration of the receptive mechanism as a result of nerve section is indicated by the wide but graded differences in the time required for the loss of response to *physostigmine*. The response of the iris is lost within a few days; that of the fibrillary contractions of the striped muscle only between the 18th and 27th day (Magnus, 1908). Such differences would be more natural for the indirect atrophy of the receptive mechanism than for the direct degeneration of the axis cylinders or endings. Evidently the degeneration is not of such a kind as to destroy the response to pilocarpine, or to direct electrical stimulation of the cell.

The evidence in favor of the "sensitizer" theory of *physostigmine* action lies mainly in the observations of Langley and Kato, 1915, that the smaller doses of *physostigmine* only lower the threshold of normal skeletal muscle to nerve stimulation; that somewhat larger doses cause fibrillary twitching only after electric stimulation, and that spontaneous twitchings require a still higher dosage.

Conflict of Sympathetic and Parasympathetic Actions.—Langley and Dickinson, 1890, showed that the effects of *nicotine* on the pupil and nictitating membrane are the resultant of simultaneous stimulation of the sympathetic and cranial innervation. In cats, the sympathetic usually predominates (dilation of pupil and retraction of membrane). Pilocarpine, on the other hand, causes constriction (oculomotor stimulation), which is also unaffected by complete denervation (Anderson). However, it acts also on the sympathetic, for the nictitating membrane retracts. Both drugs therefore act on both systems.

Both drugs act after degeneration of the nerves in the body; but with the excised iris, only the augmentor (oculomotor) response persists. To explain this contradiction, Dale and Laidlaw, 1912, assume that the sympathetic stimulation in denervated animals is brought about by increased secretion of epinephrine, to which the denervated sympathetic endings are especially susceptible.

Excised Iris of Frog and Eels.—These show rather peculiar reactions. In the excised bulbus, atropine (2 per cent.) or cocaine (1:5 per cent.) dilate, but no contraction is produced by pilocarpine, *physostigmine*, *nicotine* or *muscarine*, 1:1000 per cent. (Magnus, 1899).

Mydriatic and Miotic Drugs.—The following table illustrates the mechanism of the more important measures:

Mydriasis may occur by:

Paralysis of the oculomotor receptive mechanism—atropine.

Stimulation of the sympathetic receptive mechanism—epinephrine, cocaine (the latter partly central).

Reinforcement of the sympathetic tone and reciprocal inhibition of the oculomotor tone (central)—excitement, asphyxia.

Miosis may occur by:

Stimulation of the oculomotor receptive mechanism—pilocarpine, physostigmine.

Diminished inhibition of the central oculomotor tone—morphine, sleep, narcosis.

Stimulation of the oculomotor center—picrotoxin.

AUTONOMIC REACTIONS OF THE HEART

The parasympathetic innervation of the heart is inhibitory. It comes by the vagus, and its ganglia are intracardiac. The sympathetic is augmentory, with its ganglia in the sympathetic chain. *Nicotine* at first stimulates and then paralyzes the ganglia of both divisions; the vagus effect predominates ordinarily. *Nicotine* would therefore render the heart irresponsive to stimulation of the vagus trunk; but stimulation of the postganglionic fibers, in the sinus region, would still arrest the heart.

Parasympathetic Drugs.—*Atropine* would destroy the response to postganglionic as well as to preganglionic vagus stimulation. The muscle evidently is not paralyzed, since the heart continues to beat with undiminished vigor; the action of the atropine must therefore be between the ganglia and the contractile mechanism; and by analogy, it may be located in the receptive mechanism. *Parasympathetic stimulants*, acetylcholine, muscarine, pilocarpine, physostigmine, etc., weaken and slow the heart and produce diastolic arrest, and are mutually antagonistic with atropine. The pilocarpine effect is, however, liable to change to vagus-paralysis.

Sympathetic Drugs.—*Epinephrine* increases the rate and amplitude of the contractions; this is prevented by *ergotoxine*.

Ion-ratio.—Increase of the $\frac{\text{Ca}}{\text{K}}$ ratio stimulates sympathetic stimulation, and renders the sympathetic more sensitive and the parasympathetic less sensitive to stimuli (Burridge, 1912). Conversely, increase of the $\frac{\text{K}}{\text{Ca}}$ ratio, favors parasympathetic stimulation. Radioactivity acts like potassium (Zwaardemaker, 1918).

Non-specific Drugs.—Barium, the digitaloid drugs and caffeine stimulate the force of the heart, and quinidine depresses. Their relation to the autonomic system is obscure, but they appear to act more directly on the contractile substance.

Composite Effects.—When the heart is subjected simultaneously to poisons belonging to different groups, they may add their actions in a simple manner; for instance, the acetylcholine inhibition may be removed either by paralyzing the inhibitory mechanism with atropine, or by stimulating the augmentory mechanism with epinephrine (Barlow and Sollmann,

1926). However, discordant effects from such combinations have been reported, especially by Kolm and Pick, 1920; and Amsler, 1920, which these investigators interpret as transfer of the action from one system to the other. They conceive that these drugs, are really "amphotropic," *i.e.*, that epinephrine may stimulate the parasympathetic as well as the sympathetic; but that the normal sympathetic effect so greatly overshadows the parasympathetic, that the latter is only observed when the parasympathetic system is especially sensitive, or when the sympathetic system is especially insensitive.

Seasonal Variations in Vagus Response.—During the summer, frogs show a markedly diminished response to vagus stimulation, electrical or by drugs (Cori, 1921; Langecker, 1924). Cori showed that this is not due to altered K and Ca content, and attributes it to thyroid changes.

Abolition of Ventricular Vagus Response by Excessive Doses of Vagostimulants.—Large doses of apparently all vagus stimulants (aconite, muscarine, physostigmine, digitalis, acetylcholine) render the ventricles irresponsive to vagus stimulation. The sinus and auricles still react by diastolic standstill, so that the interference appears to be with the conduction of the inhibitory impulses (Froehlich and Pick). It is therefore possible that the action does not consist in reversal to the vagus effect, but that it may involve some other mechanism of the heart.

Effect of Epinephrine on Vagus and Accelerator Response.—Vagus stimulation is unable to slow the heart against the maximal stimulation of epinephrine (Langley, 1901; Kuroda and Kuno, 1916); but smaller doses lower the threshold of vagus stimulation for frogs. Stimulation of the accelerator nerve does not add materially to the augmentation produced by epinephrine, so that the response to accelerator stimulation appears diminished or abolished (Barlow and Sollmann, 1926).

Sensitization by Other Conditions.—The presence of *non-electrolytes* (urea, sugar) renders the heart more resistant to calcium deficiency; which Loewi (1921) interprets as sensitization to the smaller quantities of calcium that remain. The non-electrolytes also sensitize to strophanthin; they may therefore be classed with the sensitizers of sympathetic action.

Treatment of the heart with *lecithin* and *soap* renders it more resistant to choline and pilocarpine, *i.e.*, diminishes parasympathetic stimulation and would therefore sensitize to sympathetic stimulation (Loewi, 1921).

Blood serum antagonizes parasympathetic stimulation (muscarine), and increases the parasympathetic depression of atropine. This is due partly to its calcium, partly to the ether-soluble extractives (Kirste, 1921).

Increase of *alkalinity*, within physiological limits (to pH-7.8) increases the tonus (Andrus, 1919); *i.e.*, acts in the sympathetic direction.

AUTONOMIC REACTIONS OF THE BLOOD-VESSELS

Most blood-vessels are innervated only by the sympathetic. This has generally augmentory functions which are under continuous tonic control by the vasomotor center. The caliber of the vessels is adjusted largely by increase or decrease of these central tonic impulses. In a few situations there is a special vasodilator innervation; and in some blood-vessels the nerve supply is parasympathetic. However, even the vessels with purely sympathetic innervation respond more or less to the parasympathetic drugs, the stimulants generally being dilator. It may be assumed that they possess the parasympathetic receptive mechanism, but that this has not made connection with the central nervous system. Dilute epinephrine also often produces dilation.

The arteries and veins show very similar phenomena. The capillaries exhibit some special features.

The *dilator-innervation* is generally if not always parasympathetic; for instance, the chorda tympani and the nervus erigens.

Unusual Innervations.—An entire reversal of the ordinary innervation is seen in *lung vessels of frogs and turtles*. This is entirely parasympathetic, constrictor in the frog,

constrictor and dilator in the turtle. However, it reacts to epinephrine which is antidoted by atropine (Luckhardt and Carlson, 1921).

The *placental vessels* do not receive any nerves, and do not react to epinephrine, although they react to the non-specific stimulants, barium, histamine, etc. (W. Schmitt, 1922).

Dilator Action of Epinephrine.—Under certain conditions, the sympathomimetic constrictor action of epinephrine gives place to non-sympathetic dilator reactions. This is the predominant effect in some vessels (Rothlin, 1921); in others this is seen only with dilute solutions. It may also be evoked by lowering the sensitivity of the sympathetic innervation.

Responses of Different Vascular Areas.—Considerable data for various drugs have been collected by the recent work of Amsler and Pick (1919) (frog-perfusion experiments, splanchnic areas and legs); Adler (1921) (ditto, lung and skin vessels); and Rothlin (1921) (rings of mammalian artery).

Parasympathetic Drugs.—*Acetylcholine* produces marked vasodilation, which is antagonized by *atropine* (Hunt, 1918). The effects of *pilocarpine* are also dilator in most cases; but a few contractor reactions have been described. The data are cited by Langley (p. 37). Brodie and Dixon found that atropine removes the pilocarpine constriction without impairing the response of electric stimulation of the vasoconstrictor nerves. Hildebrandt (1920) also reports that *atropine* antidotes epinephrine and sympathetic nerve stimulation in frog's vessels. It is not antagonistic to barium; but removes veratrine constriction (Kondo, 1919).

Vasomotor Ganglia.—These are first stimulated, then paralyzed by nicotine. They are also paralyzed by curare and large doses of strychnine and brucine (Langley, 1918).

Ion-ratios.—*Calcium excess* acts as a parasympathetic stimulant to the vessels, and as a sympathetic stimulant in the heart. The vessels are dilated, and the constrictor response to sympathetic nerve stimulation and to epinephrine is diminished; they may even respond by dilatation.

Calcium deficiency acts as a sympathetic stimulant on the vessels, and as a parasympathetic stimulant on the heart. The vessels are constricted, and the constrictor response to epinephrine is enhanced.

Potassium excess acts as sympathetic stimulant to the vessels; as a parasympathetic stimulant on the heart. The vessels are constricted. However, the effect on epinephrine is abnormal; the constrictor effect is diminished, or may even be replaced by dilatation.

Potassium deficiency also acts as a sympathetic stimulant, to the vessels, as well as to the heart. The vessels are constricted and react more effectively to the constrictor action of epinephrine.

Alkalinity increase: Moderate increase acts in the direction of sympathetic stimulation for the vessels, as for the heart; *i.e.*, perfused vessels constrict. This is not antagonized by ergotoxine (Heymann, 1921). Moderate alkalinity also promotes the contractions and tone of excised arteries (Opitz, 1920).

Large excess of alkalinity relaxes (Heymann).

Diminished alkalinity and increased acidity: Diminished alkalinity also constricts the perfused vessels (Pearce, 1913). The mechanism is not clear; the constriction is prevented by ergotoxine, so that it might be considered as sympathetic; but the constrictor response to epinephrine and to nerve stimulation is abolished or replaced by a dilator response (Heymann; Schmidt).

A larger excess of acid dilates the vessels; the dilator concentration coinciding with the H-ion concentration that stimulates the respiratory center (Adler, 1921).

Spleen Extract.—This sensitizes to the pressor (sympathetic) response of epinephrine; and antagonizes the depressor (parasympathetic?) response (Collip, 1920).

Autonomic Reactions of the Capillaries.—The lumen of the capillaries is controlled, at least in part, by scattered smooth-muscle cells. These are generally controlled by the sympathetic nerves, but do not respond to epinephrine beyond a certain distance from the arterioles; the distance varying with the organs. They react readily to pituitary extract, which Krogh, 1922, considers a special hormone for the capillaries. They are, however, also influenced by other metabolic products. Wertheimer, 1923, who observed the capillary reactions to a series of autonomic drugs in different organs found these on the whole similar to the arterial reactions. The capillary innervation appears to be seriously disturbed by section of the posterior root fibers (Burn, 1922). Krogh does not believe that the

endothelium itself is capable to active contraction or relaxation; but there is no real evidence on the question.

AUTONOMIC REACTIONS OF BRONCHIAL MUSCLE

These have an important practical bearing on the explanation and treatment of bronchial asthma. Mammalian bronchi are innervated solely by the vagi, which carry mainly constrictor, but also dilator fibers—the latter probably sympathetic. They respond both to parasympathetic and to sympathetic drugs; the parasympathetic stimulants produce constriction and atropine relaxation. Epinephrine results in relaxation, especially if the muscle was contracted; ergotoxine causes constriction. The bronchial muscles contract violently to the non-specialized muscular stimulants, barium, etc.; and especially to histamine, peptone and other anaphylactoid poisons, and to true anaphylaxis. Hypersusceptibilities of this type constitute at least one group of bronchial asthmas. Bronchial spasm may also be produced reflexly, for instance by irritant vapors. The nitrites, caffeine and the methyl-xanthines, and ether or chloroform vapor produce relaxation.

Antagonisms.—The constrictor and dilator agencies tend to neutralize each other, with little reference to their site of action. Accordingly, anaphylactic spasm may be relieved either by atropine (parasympathetic depression), or by epinephrine (sympathetic stimulation); the latter is much more effective, since it is a more active process.

Investigations of Bronchial Reactions.—These were studied in intact animals by Dixon and Brodie, 1903, and by Sanoz, 1914, by recording the excursions of the lungs under uniform artificial respiration. D. E. Jackson, 1913, controlled the reactions with the extra precaution to keeping the blood-pressure level constant. Experiments on excised bronchial muscle were reported by Trendelenburg, 1912; and later by others (for instance Macht and Ting, 1921).

Secondary Dilation.—Nicotine, lobelia, and curare and small doses of pilocarpine produce an initial constriction, followed by dilation. Jackson attributes this secondary dilation to stimulation of the suprarenals.

Iodides.—These have no effect in living animals. Excised bronchial muscle is dilated (Macht and Ting, 1921), but only by concentrations much higher than could be maintained in the blood.

Diseased Bronchi.—The response to parasympathetic and muscular stimulants is weak or absent in bronchial rings excised from bronchitic animals (Macht and Ting, 1921).

Pseudo-spasm of Bronchi.—*Agar solutions* perfused through the lungs of guinea pigs produce prompt and marked distention of the lung and arrest of perfusion flow. The effect is antagonized by papaverine or atropine, and is due to agar emboli in the pulmonary vessels. These arrest the circulation and shut off the bronchi by mechanical compression (Hanzlik and Karsner, 1920).

Lower Vertebrates.—In snakes and turtles, the innervation and the response to drugs is as in mammals: contractor to parasympathetics; relaxor to epinephrine, except that the relaxor effect of epinephrine is quite weak (Carlson and Luckhardt, 1920; Luckhardt and Carlson, 1921). Nicotine, pituitary, lobeline and veratrine produce strong contraction of the turtle lungs, which is not observed in dogs. Codeine and pilocarpine act as in mammals (D. E. Jackson and Pelz, 1918).

In *frogs* and *salamanders*, the musculature of the lung-sacs corresponds to the bronchial muscle of mammals, but it has a different physiology and innervation (frog, Carlson and Luckhardt, 1920; salamanders, Luckhardt and Carlson, 1910). The muscle possesses a strong and continuous inherent tone, which is relaxed by parasympathetic (vagus) stimulation, and is slightly augmented by sympathetic stimulation. The response to epinephrine is transposed; *i.e.*, it produces relaxation. Atropine presents another anomaly, for it does not prevent the inhibiting response to vagus stimulation. Pilocarpine which was tried only on salamanders, acts normally, *i.e.*, relaxes.

AUTONOMIC REACTIONS OF THE MUSCULATURE OF THE UTERUS

Innervation.—The innervation of the uterus is essentially sympathetic, through the hypogastric nerve. There is also a parasympathetic supply

from the pelvic nerve, which appears to act in the same direction (Cushny, 1906, 1910), but so feebly and uncertainly that it is generally considered negligible. The uterus, however, reacts readily to parasympathetic as well as to sympathetic drugs and to non-specialized (muscle) stimulants.

Natural Movements of the Uterus.—The excised uterus when placed in oxidized Ringer's solution executes pendulum and peristaltic movements (Kehrer, 1908; Cushny, 1910; Ogata, 1921) which vary in intensity and in type with the sexual cycle. Analogous movements occur normally in living animals and may be watched by inserting a permanent celluloid window in the abdominal wall. In non-gravid animals the peristaltic movements are relatively slight and alternate with pauses, much as in the intestines. Parturition is accomplished by powerful peristaltic waves, producing the labor-pains (Ludwig and Lenz, 1923). The non-gravid contractions may be intensified or allayed by central impulses; but normal labor may occur after complete severance of the uterus from the central nervous system (Elkin, 1922).

Difference between Uterus in Situ and Excised.—With non-pregnant cats, the uterus *in situ* is inhibited by nicotine, cytisine, hydrastinine, indolethylamine and pilocarpine. Excised uteri, on the other hand, are generally stimulated by these drugs. It seems from this that there is both sympathetic (inhibitory) and parasympathetic (augmentory) stimulation. The sympathetic effect predominates during life, but does not survive excision. Dale and Laidlaw, 1912, believe that the sympathetic stimulation is not direct, but through increased epinephrine secretion.

Sympathetic Stimulation.—The response to stimulation through the hypogastric nerve and through epinephrine are always in the same direction; both are somewhat variable, especially with the species and with the functional state of the uterus. In general, they tend to produce increased movement or tone (in human, monkey, dog, rabbit and hedgehog). This stimulation is more marked in pregnancy. The pregnant cat uterus is also contracted by epinephrine, but the non-pregnant uterus is generally relaxed by it. Guinea pigs and rats usually show relaxation, both when pregnant and non-pregnant (Gunn and Gunn, 1914; Athias, 1921).

The change in the excitability of the uterus appears within a few days after conception (Athias), so that it must be due to a functional sensitization, and not to the development of new muscle-fibers, as was supposed by Quagliariello, 1918. *Castration* diminishes the activity of the uterus, but does not materially modify its reactions to drugs (Athias).

Parasympathetic Drugs.—In animals in which sympathetic stimulation produces contraction, the *parasympathetic stimulants* also produce contraction (Cushny, 1910). When the sympathetic response is inhibitory, the effects of parasympathetic stimulants are inconstant.

Atropine depresses the normal uterus *in situ* (Ludwig and Lenz, 1923).

In non-pregnant cats, in which hypogastric stimulation or epinephrine usually relax or inhibit the contractions, Cushny also noted inhibitory phenomena after pilocarpine injection; but they were much less characteristic than with epinephrine. Dale and Laidlaw did not observe relaxation when the excised non-pregnant uterus was subjected to pilocarpine, although it occurred sometimes during life. This they attributed partly to increased suprarenal output, partly to action on the sympathetic ganglia, and not to a peripheral autonomic affect. Gunn and Gunn (1914), however, did occasionally observe inhibitory effects on the excised uterus of rats and guinea pigs.

Antagonists to the Contractor Effects. Ergotoxine is more effective against epinephrine than against the parasympathetic stimulants; and

atropine is more effective against these than against epinephrine; however, both depressants are sometimes antagonistic against both stimulants (Cushny, 1910; Dale and Laidlaw, 1912; Gohara, 1920). The relaxing action of epinephrine in the guinea pig and mouse may overcome the barium, histamine and choline stimulation (Sugimoto, 1913; Adler, 1918).

Non-specialized Stimulants.—Powerful contractions are produced in non-pregnant as well as pregnant uterus of all animals by *pituitary extract* (Frankl-Hochwart and Froehlich, 1909) and by *histamine* (Barger and Dale, 1910); and by related amines, *peptones*, and *anaphlactoid poisons*, (Hanzlik, 1920). *Quinine* and the other cinchona alkaloids may cause strong contractions (Kurdinowski-Kehrer, 1906; Hale, 1915) but are uncertain (Rucker, 1921; Frank and Katz, 1922). *Hypotonic* solutions also produce contraction (Dale, 1912; Voegtlin and Lake, 1917; Barbour and Rapaport, 1922). Therapeutic doses of *ergotoxine* and of *tyramine* also stimulate contraction (Ludwig and Lenz, 1923) whilst larger doses antagonize sympathetic stimulation.

Reflex Increase of Uterine Movements.—Drastic cathartics and irritant volatile oils produce reflex stimulation of the uterus (Kehrer, 1910). These should therefore be avoided in pregnancy. They are reputed abortifacient, but are highly dangerous. For the excised uterus, moderate concentrations of the *emmenagogue oils* are indifferent, and higher concentrations inhibit (Gunn, 1921).

Miscellaneous Drugs on the Uterus.—Colloid.—Hanzlik, 1920, observed stimulation with peptone and congo-red; most others depressed. Agar was indifferent.

Hydrastine, Hydrastinine and Cotarnine.—These are stimulants.

Ion-ratio.—The effects of variation of K and Ca appear complex (Fate and Clark, 1921; M. Rosenmann, 1923).

Morphine.—Small doses are stimulant, larger doses depressant (Kehrer).

Organ Extracts.—These generally produce stimulation (Fawcett et al., 1915). Extracts of prostate (Macht, 1920), ovary (Itagaki; Athias, 1921) and placenta (Ludwig, 1920) appear especially effective.

Female Remedies.—The effects of a number of these is described by Delzell et al., 1916; Pilcher, 1917.

Scopolamine.—Therapeutic doses have practically no effect (Kehrer).

AUTONOMIC REACTIONS OF THE URETER

Innervation.—Augmentor response occurs to both sympathetic (Splanchnic n.) and parasympathetic (pelvic n.) stimulation. The sympathetic innervation is more active in the upper portion, the parasympathetic in the lower (Satani, 1919). Accordingly, epinephrine and the parasympathetic stimulants all produce augmentation, but are differentiated by the antagonists; ergotoxine being more effective against epinephrine, and atropine against the parasympathetic. Nicotine first stimulates and then arrests the movements of the excised ureter (Satani). The reactions to the non-specialized drugs are of the usual type: *Augmentation* also results from barium, veratrine (Rossi, 1918), morphine, cocaine, procaine, and increased alkalinity. *Depression* is produced by chloroform (Lucas, 1906), by papaverine and the other isoquinoline alkaloids, by chelidonine, benzyl benzoate, hydrastine and emetine (Macht, 1916–1918; Roth, 1917). The effects of obstruction on ureteral peristalsis are described by Wislochi and O'Connor, 1921.

AUTONOMIC REACTIONS OF THE URINARY BLADDER

Innervation of the Bladder.—Micturition requires the coördination of two and perhaps three sets of muscles in the bladder: the active opening of the sphincter by the trigone-muscles (Young); the diminished tone of the sphincter muscle; and adaptation of the tone of the fundus to the diminishing contents. These complex movements are under central control, the voluntary impulse originating in the cerebral cortex. Stimulation of the sympathetic (hypogastric) produces brief contraction of the trigonal region, which probably initiates the opening of the sphincter; and this is followed by

marked relaxation of all the bladder muscles. Stimulation of the parasympathetic (pelvic erigentes) produces constriction, generally confined to the fundus muscles. The extent of the effects, however, vary somewhat with the strength of the stimulation, whether electric or by drugs; and this has caused some confusion (C. C. Stewart, 1899; Elliott, 1907; Langley, 1912; L. R. Mueller, 1919; Edmunds and Roth, 1920; Young and Macht, 1923).

Response to Autonomic Poisons.—The effects of typical doses correspond with the innervation. The *fundus region* is contracted by the parasympathetic stimulants and relaxed by moderate concentrations of epinephrine; too dilute or too concentrated solutions of epinephrine may apparently produce contraction. The parasympathetic contraction can be removed by atropine, and also by epinephrine. Atropine is relatively ineffective against electric stimulation of the nerve (V. E. Henderson, 1922), as in some other situations.

The *trigonal region* is first contracted and then relaxed by epinephrine. It is generally unaffected by parasympathetic stimulants, but may be contracted (Edmunds and Roth, 1920; Ikoma, 1924; Streuli, 1915; Young and Macht, 1923).

The non-specialized stimulants, barium, pituitary, etc. (not histamine, Abelin, 1919), produce contraction in both regions. The barium and pituitary constriction can be overcome by epinephrine, and barium by atropine; at least in frogs (Adler, 1918) whose bladder shows less differentiation and contracts both to sympathetic and parasympathetic stimulants (Langley).

The action of morphine appears to be central (Ikoma).

AUTONOMIC REACTIONS OF THE RETRACTOR PENIS MUSCLE

This furnishes a very striking anomaly. The smooth muscle has a double innervation, the sympathetic being augmentor and the parasympathetic inhibitory (Langley and Anderson). Epinephrine produces contraction and this is antagonized by ergotoxine, as would be expected. The parasympathetic stimulants, however, also produce contraction, that is these act on the sympathetic and not on the parasympathetic. Similarly, atropine, although it antagonizes the parasympathetic stimulants, does not abolish the response to electric stimulation of the parasympathetic (sacral) nerve. It appears therefore that the action of the parasympathetic poisons has been transposed to the sympathetic division. However, ergotoxine does not antagonize the parasympathetic stimulants. Nicotine stimulates, although there are apparently no ganglion cells (Edmunds, 1920; Zilva, 1901; Bottazzi, 1916).

AUTONOMIC REACTIONS OF OTHER GENITO-URINARY ORGANS

The smooth muscle of these does not show important peculiarities.

Prostate Gland.—Waddell, 1916, described the reactions as similar to the uterus. Macht, 1922, confirmed that it responds typically to epinephrine and ergotoxine, barium and papaverine, but claimed that it does not react to the parasympathetic stimulants and to atropine. Its extracts stimulate all genital muscles, and especially the uterus (Macht, 1922).

The reactions of the *seminal vesicles*, *vas deferens*, and "*uterus masculinus*" were studied by Waddell, 1916 and 1917. The *erectile tissue* and *dorsalis penis artery* are contracted by epinephrine, and relaxed by ergotoxine. They do not respond to the parasympathetic poisons.

Vaginal Muscle.—The responses resemble the uterus (Waddell, 1917), but epinephrine produces contraction even in those species whose uterine response is inhibitory (J. A. Gunn and Davies, 1920).

AUTONOMIC REACTIONS OF THE GASTRO-INTESTINAL TRACT

Innervation.—The entire gastro-intestinal canal is innervated from both autonomic systems. The sympathetic supply comes through the splanchnic and mesenteric ganglia. The parasympathetic supply from the esophagus to the ileum is furnished by the vagus; the erigens and pelvis innervate from the colon to the anus. The functions of the two systems are reciprocally antagonistic. Parasympathetic stimulation generally augments the contractions or tone of both coats of the muscular tube; sympathetic stimulation augments the sphincter tone and inhibits the muscular tube. This reversed arrangement of the sympathetic

innervation of the sphincters and the muscular tube naturally simplifies their functional coöperation.

The intrinsic functions of the intestinal musculature, especially its tone, play a very important part in their behavior, and may profoundly modify their reactions to nerve-stimulation, and even to drugs. Consequently there are conspicuous exceptions to the simplified schema in some situations, which vary not only with different species, but even in the same species or individual animal, at different times. The small intestines of mammals, however, respond very generally by augmentation to parasympathetic stimulation and by inhibition to sympathetic stimulation.

Innervation of the Sphincters.—According to Gaskell, the sympathetic appears to augment the tone of most if not all sphincters; in the urinary as well as in the digestive tract. Parasympathetic stimulation inhibits the urinary sphincters and the internal sphincter ani; but the response on other sphincters has not been definitely established. The cardiac sphincter may respond by either augmentation or inhibition, to either vagus or sympathetic stimulation (Carlson, Boyd and Pearce, 1922).

Central Reflexes.—Painful stimuli are apt to arrest the pendulum and especially the peristaltic movements of the stomach and intestines (Literature, Lehmann, 1912). Special reflexes, however, may produce motor stimulation of the stomach, *i.e.*, emesis.

The Significance of the Intestinal Nerve-plexuses.—There is no longer any good reason to assume that the ganglionic nerve-plexuses of Auerbach and Meissner differ in function from the analogous ganglionic plexuses in most autonomic organs, for instance the heart; or to doubt that they are the neuron-cells of the efferent link of the parasympathetic nerves (Gaskell). They have, however, also been interpreted as peculiar peripheral nerve-centers, the "*enteric system*" of Langley (1900, 1913) for the local coördination of peristaltic reflexes. According to this view they might be excited and inhibited by afferent impulses directly from the intestinal mucous membrane and muscle, as well as by efferent impulses from the central nervous system. This explanation was suggested by the impressive appearance of the nerve-plexus and by the apparent complexity of intestinal coördination; it seemed to be supported by the observation of Magnus (1904), that the removal of the nerve-plexus suppressed the rhythm of intestinal strips. It was subsequently shown, however, that the plexus-free strips remain rhythmic if proper precaution was taken to prevent injury of the muscles; and that coördinated peristaltic movements can be evoked in muscle that has been kept on ice five days, when nervous structures would presumably have died (Gunn and Underhill, 1914, 1916; Alvarez and Mahoney, 1922). This leaves no direct evidence for the local coördinating centers. The progression and coördination of peristalsis can be adequately explained by the inherent proportion of smooth muscle, especially the gradient of tone and the stimulant effects of distention. It may be recalled that the uterus executes equally complex movements, without needing an enteric system.

The Intestinal Movements.—The intestines like the uterus, ureter, etc., exhibit two fundamental types of movement: (First), pendulum rhythm; (second), localized contraction rings, stationary, or progressive, *i.e.*, peristaltic. Both types are modified by (third), the prevailing state of tone and excitability, local and general, of the intestinal muscle. For the whole small intestines, there is a strong general gradient of tone, decreasing from the pylorus to the cecum, which determines the descending direction of the peristalsis. In the large intestine, the gradient varies from time to time, and this determines peristalsis and antiperistalsis.

Pendulum Movements.—These consist of continuous rhythmic contractions of the longitudinal muscle of the “resting” intestines, at the rate of about 10 per minute. They are conspicuous through their regularity and from the fact that they are well maintained by the excised intestines immersed in oxygenated Ringer’s solution (Magnus, 1904) and are therefore easily studied. However, they have no material effect on the intestinal lumen, and do not have any apparent direct function; they are perhaps a mere by-play of the healthy excitability of the intestinal muscle. They are diminished or arrested if the general excitability of the intestine is low; and when the contraction of the strong circular muscles interferes with the movements of the weaker longitudinal coat. Pendulum movements of the circular muscles, on the other hand, if they exist, are so much more feeble than those of the longitudinal muscle, that they are not ordinarily observable.

Differences of Rhythm at Various Levels.—In intact animals, the rhythm is faster toward the two ends of the intestine than toward the middle. In excised intestine, the rate decreases with the distance from the pylorus; the rate of the duodenum in rabbits being about 50 per cent. faster than in the lower ileum. The oral end is more irritable and therefore acts as pacemaker. It is also less subject to epinephrine relaxation and its tone is higher. On the other hand, the slower rate of the aboral end is accompanied by greater excursions (Alvarez, 1914, 1915).

The different rates are perhaps based on intrinsic differences in the intensity of metabolism. Cyanide for instance, or shutting off the oxygen supply, interferes more with segments from the higher portions of the intestine (Alvarez, 1918).

Alvarez and Starkweather, 1918, believe that this gradient of excitability is mainly concerned in regulating the physiologic rate of propulsion of the food through the various levels of the intestinal tract.

Drugs on Intestinal Rhythm.—The effects have been studied by Alvarez, 1918. The changes in rhythm are not necessarily parallel to those of the tone and amplitude of the contractions. This has also been found by Pilcher for the uterus.

The Peristaltic Movements.—These consist in rather powerful contractions of the circular coat, which are normally initiated by distention of the intestines, in excised intestines as well as in the living animal (Trendelenburg, 1917). Such distention results first in a gradual increase of tone; and when this reaches a critical point, which varies with conditions, the circular coat suddenly contracts, stretches the longitudinal coat, constricts the lumen and expels the contents. The peristaltic contraction occurs only when the intestine is in good condition and tone, and begins at the region of highest tone, at the oral end of the segment. The contents are propelled in the direction of the lower tone, *i.e.*, to the adjacent lower segment, which is thereby stretched, distended, and thrown into a peristaltic contraction. This accounts for the Bayliss-Starling (1899) “Law of the Intestines” (Alvarez and Starkweather, 1918). The peristaltic wave may travel in this manner, by an automatic, purely muscular mechanism, until so much of the contents has been lost on the way, that the intestine is not sufficiently distended, or until a region of low irritability is reached. When a segment has contracted, it gradually relaxes, so that it again becomes filled with fluid from above, and the process is repeated, at the rate of 2 to 4 contractions per minute. When normal intestines become empty, peristalsis ceases and a period of rest ensues. If the propulsion of the contents is prevented by an obstruction, functional or mechanical, the contractions increase in violence; but they are rather rapidly fatigued by the excessive pressure. The occurrence and extent of the peristaltic contractions depends on the irritability. When this is high, they may occur even in the empty intestines. The

height of irritability is also the chief factor in the extent of spread of the peristaltic wave; exceptionally, a single wave may thus travel rapidly through long distances, the so-called "rolling movement" or "peristaltic rush" (cf. Meltzer and Auer, 1907). In the large intestine, the gradient of irritability and tone changes from time to time, so that peristalsis travels in both directions, at different periods.

Stationary Tonus Rings and Intestinal Spasm.—Contractions of the circular coat may also occur without spreading. The specialized kneading "segmentation movements" of the small intestine of the cat may be classed as rhythmic contractions of alternating segments. More common are strictly localized contraction rings which persist for long periods sometimes quite stationary, sometimes travelling slowly, and sometimes rapidly. The latter constitute a gradual transition to ordinary peristalsis. These rings may be quite narrow or wide bands, or extend over a considerable distance, in which case they merge into intestinal spasm. Whilst they persist, they occlude the lumen and form a strong functional sphincter. They constitute the normal type of contraction in the large intestine (Lenz, 1924; Cannon, 1911). In the small intestine they occur only when the irritability is abnormally heightened, especially by the parasympathetic and "muscular" stimulants. They give rise to temporary obstruction, and provoke the phenomena of "colic."

Paresis of the Intestines.—The general tone and excitability of the intestines is quite sensitive to nervous and chemical conditions, and is easily depressed below the level that is necessary for the contractions, especially of the circular coat. Temporary inhibitions are perhaps a normal provision for resting the intestines; both temporary and more lasting inhibitions occur clinically, in psychic states, in laparotomies, in intestinal obstruction, etc. They also render experimental studies more difficult. *Increased excitability of the muscle* is probably an important factor in the action of many cathartics, especially those that act on the large intestines.

Reactions to Drugs.—These have been studied especially on the small intestines. Epinephrine is inhibitory; the parasympathetic stimulants augmentory; and the non-specialized drugs produce their usual effects. The longitudinal and circular muscles act in the same direction; but when the circular coat is active, its contraction stretches the weaker longitudinal muscle (Inoue, 1923). Magnus' experiments (1904) on plexus-containing and plexus-free preparations appeared to localize the effects of many of the autonomic poisons in the ganglia; but since the removal of the plexus makes the muscle itself abnormal, the localization becomes invalid, and it may be assumed that the actions, as in other situations, are directly on the receptive or responsive mechanism of the muscle. Antagonism appears to occur generally between augmentors and relaxors, no matter on which system they act.

Parasympathetic Drugs.—Physostigmine, pilocarpine, choline, and muscarine all produce increase of tone, of the pendulum movements, and of peristalsis in mammalian intestine. Excessive concentrations produce tonus bands and intestinal spasm. These effects are removed by atropine. It is especially effective against pilocarpine, which is neutralized by doses of atropine very much smaller ($\frac{1}{500}$) than those that affect the unpoisoned intestines or that block stimulation through the vagus nerve or by physostigmine (Magnus, 1904; Bayliss and Starling, 1901).

Pilocarpine.—Neukirch, 1912, found that the action of pilocarpine on the excised intestine is purely stimulant, even with 5,000 times the effective dose. The action can be removed by washing; but during the passage of the pilocarpine out of the cells, there seems to be a supplementary stimulation, the reverse of Straub's muscarine phenomenon.

Pilocarpine-atropine Ratio.—The antagonism of these drugs on the excised intestine is not in simple ratio to their concentration; for while the pilocarpine, physostigmine and muscarine stimulations depend on the concentration of the drug in the fluid, the atropine inhibition depends on the absolute dosage. The antagonism is not materially influenced by temperature or H-ion concentration (van Lidth de Jende, 1918).

Atropine and Choline.—The effect of atropine on the unpoisoned intestine is variable and inconstant, especially in the excised intestine. This has been attributed to variations in the content of choline that is normally present in the intestinal wall, and which acts as a peristaltic stimulus: The greater this stimulation, the more pronounced is the sedative action of atropine; when the parasympathetic stimulation of choline is absent, atropine becomes ineffective except in abnormal concentrations (Le Heux, 1918). The theory, however, requires further confirmation.

Epinephrine.—This inhibits the normal intestinal movements, and antagonizes the stimulant effects of pilocarpine, nicotine, and strophanthin (Magnus); and also those of barium (Roth).

Nicotine.—This paralyzes the ganglia, and therefore renders stimulation of the vagus and of the splanchnic ineffective. At the same time, it produces violent peristalsis and intestinal spasm (Nasse). This stimulation is the most conspicuous effect in excised intestine. It may be preceded by brief inhibition, and with large doses it is followed by paralysis (Trendelenburg, 1917; Magnus, 1904). This paralysis, (which is also produced by conine, curare and gelseminine) is mutually antagonistic with physostigmine stimulation (Ikeda, 1916).

Muscular Stimulants.—These include barium, veratrine, colchicine, strophanthin, pituitary, histamine, peptone and anaphylaxis. They produce violent stimulation, increase of tone, and intestinal spasm. Their antagonisms follow the usual lines: They are effectively relaxed by the muscular depressants, including the nitrites and magnesium. They are also relaxed by sympathetic stimulation through epinephrine; but parasympathetic paralysis, by atropine, has little effect (Magnus, 1904; Roth, 1923; Sollmann and Rademaekers, 1925; Inoue, 1922).

Histamine, Peptone, Pituitary Extracts.—These act less definitely on the intestines than on the uterus. In general, they produce more or less stimulation, which tends to be followed by relaxation. The details vary in different animals, (Olivcrona, 1921), and appear to be somewhat influenced by diet (Degener, 1922). Various *amino-acids* have practically no effect (Hirschfelder and Cantwell, 1918).

Anaphylaxis produces marked stimulation; normal serum also tends to stimulate, but the response is uncertain (Schlecht and Weiland, 1921).

Colloids.—These often enhance the reaction to other stimulants. Van Leeuwen and Gyoergyi, 1922, have studied the influence of kephalin and lecithin on the response to pilocarpine and histamine.

Muscular Depressants.—The intestines are relaxed and inhibited by magnesium, nitrites, chelidonine, papaverine (not narcotine), the benzyl esters, etc. (Trendelenburg, 1917, etc.).

Morphine.—The variable effects are discussed under that drug.

Female Remedies on Excised Intestines.—Delzell, Burman and Pilcher, 1916, found the effects on rabbit's intestine practically the same as on the guinea pig uterus. Caulophyllum, however, leaves the tone almost unchanged, while the amplitude is lowered. Valerian (oil) depresses the contractions. The viburnums are inactive.

Hydrogen Peroxide.—Very weak concentrations (sometimes 1:1,000,00) increase the tone of excised intestine temporarily. Shortly this returns to normal, and further peroxide is then ineffective. Larger doses inhibit the movements (H. J. Hamburger and Brouwer).

Temperature.—Cooling lowers, and warming increases the tone and rate of intestinal contraction (Inoue, 1922; Magnus, 1904).

Reactions of the Large Intestines.—The normal movements are generally more sluggish than those of the small intestines (Alvarez and Starkweather, 1918), and persistent tonus bands are especially important (Cannon, 1911). Their reactions to the autonomic drugs agree generally with those of the small intestines (Lenz). They respond more readily to the emodine irritants (senna, rhubarb, etc.).

Ileo-colic Sphincter.—This is closed by stimulation of the splanchnic nerve; it does not appear to have an inhibitory innervation. It is contracted by epinephrine (Elliott, 1904) and pilocarpine, and the latter is antagonized by atropine (Kuroda, 1916). In this case, as in the uterus, the sympathetic receptive mechanism appears to respond both to parasympathetic and to sympathetic stimulants.

Gastric Movements.—The stomach of mammals, including man, reacts similarly to the intestines. The *parasympathetic stimulants* contract all the regions. They are inhibited by *atropine*, which also relaxes the unpoisoned stomach. *Epinephrine* may provoke different responses: A relaxed cardiac sphincter is contracted by epinephrine, a contracted sphincter is inhibited. It relaxes the fundus in most animals, but contracts it in some, especially in rabbits. It generally contracts the pylorus. *Ergotoxine* relaxes the epinephrine contraction. Pituitary extract produces contraction (M. Smith, 1918 (excised mammalian stomach); Tegner and Turoid, 1921 (surviving human stomach); Carlson, Boyd and Pearcy, 1922 (cardial sphincter); Galan, 1921 (pituitary).)

Gall-bladder.—Lieb and McWhorter, 1915, found that this is augmented by vagus and inhibited by sympathetic stimulation. Epinephrine therefore relaxes, whilst physostigmine and pilocarpine stimulate, and this stimulation is removed by atropine. It is also stimulated by strophanthin and barium; relaxed by bile salts and nitrites.

Morphine and its esters either have no effect on the tonus and contractions, or else tend to stimulate. Papaverine and other isoquinoline alkaloids tend to decrease the tonus and contractions. This inhibitory effect predominates in opium. Atropine in small or therapeutic doses does not relax the gall-bladder (Macht, 1917).

Okada, 1915, states that the normal rhythmic movements are greatly increased during digestion, and by the introduction of acid into the duodenum.

Drugs on Bile Duct.—Vater's papilla is closed by intravenous injection of morphine, epinephrine, histamine, caffeine, large doses of atropine, and especially by pilocarpine. It is relaxed by papaverine, yohimbine and nitrites (Reach, 1914).

Gastro-intestinal Reactions of Cold Blooded Animals.—These do not show pendulum movements; but their tonus waves and rings are similar to those of mammals, although slower. Epinephrine is inhibitory, as in mammals; but parasympathetic stimulants also tend to produce inhibition. This is especially marked in the *small intestine of the frog*, which is relaxed by epinephrine, pilocarpine, physostigmine and nitrites; and each of these is antagonistic to the contractor effect of barium. This is perhaps the most definite instance of inhibitory sympathetic stimulation by the parasympathetic stimulants. It has the further unique peculiarity that it is not antagonized by atropine. The direction of these reactions is not influenced by the ion-ratio or H-ion concentration of the bath (G. B. Roth, 1923).

Small Intestine of Turtle.—Epinephrine is inhibitory and pilocarpine and barium augmentory, as in mammals; but physostigmine tends to inhibit, and tyramine to stimulate. Atropine relaxes and antagonizes barium as well as pilocarpine, although it is less effective against barium (Roth, 1923).

Rectum of Frog.—The innervation is parasympathetic augmentor and sympathetic inhibitory. The excised organ is inhibited by epinephrine and stimulated by the parasympathetic stimulants, and the latter are antagonized by atropine. Muscarine, the methyl-ammoniums and arecoline stimulate strongly, but pilocarpine only slightly, and physostigmine still less; and pilocarpine actually removes the arecoline stimulation (Schueller, 1921). Similar phenomena have been described for the frog stomach.

Frog's Stomach.—This has been an important object for the study of the general properties of smooth muscle. Its contractions were investigated by P. Schultz, 1897, and Boruttau, 1899. Goltz used it in 1872 to demonstrate the reflex tone and inhibition of the alimentary tract; and Patterson, 1920, for the development of peripheral control after nerve section. Bercovitz and Rogers, 1921, investigated the response to nerve stimulation; also in the turtle. The reactions to drugs are described by Fuehner, 1918.

Esophagus of Frog.—This is generally inhibited by epinephrine and stimulated by pilocarpine; but it behaves abnormally to the muscle poisons. Barium is said to have no effect, and histamine and pituitary inhibit (Bercovitz, 1922).

Esophagus of Turtle.—This appears to show a marked difference in response according to the duration of the application. At first, epinephrine is stimulant, pilocarpine depressant; after a time, epinephrine becomes depressant and pilocarpine stimulant. Histamine produces stimulation (Bercovitz, 1922).

Intestine of Fly.—This consists of striped muscle, but performs peristaltic movements similar to those of higher animals. Its behavior toward drugs resembles smooth rather than striped muscle (T. B. Robertson, 1920).

THE RESPONSE OF SECRETIONS TO AUTONOMIC POISONS

Pilocarpine stimulates and atropine arrests the secretions that are controlled by a central parasympathetic innervation. The saliva, buccal and bronchial mucus, gastric and pancreatic juice and sweat, (contrary to the older opinion, the sweat glands appear to have a parasympathetic as well as a sympathetic supply; Dieden, 1915; Muto, 1916). Other parasympathetic stimulants are much less effective than pilocarpine. The salivary and sweat glands can also be caused to secrete by stimulating their sympathetic nerves; but epinephrine does not evoke secretion, perhaps because it produces too much vasoconstriction. It is an effective secretory stimulant for the sympathetically innervated skin-glands of the toad. (Wastl, 1921.)

The pancreatic and gastric secretion may also be stimulated by histamine and peptone, and by specialized "hormones," such as secretin. These are not antagonized by atropine, and presumably act on a "responsive" mechanism of the gland cell. Similar chemical hormones probably affect the regulation of the secretions that are not under nervous control, and that are not responsive to pilocarpine and atropine; *i.e.*, the urine, bile, milk, the secretions of the oviduct (Riddle and King, 1921), the cerebrospinal fluid (Becht and Gunnar, 1921), and the whole series of "internal secretions."

Quantitative Antagonism of Atropine and Pilocarpine on Salivary Secretion.—This has been investigated by Cushny, 1915, on dogs with salivary fistulas. It was found that the antagonistic dose was the same for different dogs. The ratio also remained the same (about 1 part of atropine to 9.5 of pilocarpine) whether the two drugs were injected simultaneously or some time apart; and it remained unaltered whatever total dose was injected.

MISCELLANEOUS OBJECTS

Melanophores.—Barbour and Spaeth, 1917, found that the pigment cells of fish respond to autonomic drugs like smooth muscle. They are generally constricted by sympathetic stimulants (epinephrine). This reaction is "reversed" by ergotoxine. Atropine relaxes; pilocarpine and physostigmine also apparently relax.

Protozoa.—Papaverine produces marked swelling, histamine shrinkage. The effects begin at the vacuoles and extend to the protoplasm. This has been proposed as a model of the effects on muscle (H. S. Hopkins, 1922), but the analogy remains to be established.

Autonomic Poisons on White Cells.—The proportion of these cells is changed, the significance being obscure. Pilocarpine and choline increase, atropine diminishes the eosinophiles and lymphocytes. Epinephrine increases the lymphocytes but diminishes the eosinophiles. Histamine also diminishes the eosinophiles (Port and Brunow, 1914).

Yeast Formation.—This is affected by some of the autonomic drugs, although not in accordance with their autonomic affinities (Somoggi, 1916):

Atropine and quinine: small quantities accelerate; larger inhibit.

Pilocarpine and cocaine: small quantities inhibit; larger accelerate.

Basic dyes (methylene blue): dilute solutions stimulate; moderate concentrations inhibit.

Acid dyes: very little effect.

ATROPINE

Atropine and other closely related alkaloids (hyoscyamine, scopolamine, etc.) produce a variety of peripheral and central effects, namely:

1. Complete paralysis of the peripheral distribution (myoneural junction) of the parasympathetic (cranio-sacral autonomic) nerves (oculomotor, secretory, bronchial musculature, cardiac and intestinal vagus, uterus, etc.).
2. Consequently, antagonism to pilocarpine, muscarine, physostigmine, etc.
3. Slight stimulation and, in large doses, subsequent paralysis of smooth and cardiac muscle and other cells.
4. Slight peripheral sensory paralysis, on local application.
5. Excitation and then paralysis of certain cerebral and medullary centers.

These actions find varied application in therapeutics, and are of great scientific interest.

Specificity of the Autonomic Actions.—The peripheral actions of atropine are confined mainly to the augmentory nerves of the cranio-sacral division of the autonomic system. To this there are a few exceptions; for it affects also inhibitory cranial nerves (cardiac vagus) and a few augmentory and inhibitory sympathetic nerves (uterus and sweat glands) (Cushny, 1910).

Dosage of Atropine Required to Paralyze Para-sympathetic Response.—This varies widely for different organs; for instance, Henderson, 1923, reports the following as necessary to block response to electric stimulation of the nerves (mg. per Kg.): salivary secretion (chorda), 0.025 to 0.15; cardiac vagus, 0.07 to 0.7; pyloric sphincter, small intestines, chorda dilator, to 5 mg.; urinary bladder, more than 20 mg. per Kg. Very much smaller doses prevent stimulation by pilocarpine.

Occurrence.—Atropine occurs in a number of drugs (*Belladonna*, *Stramonium*, *Hyoscyamus*, *Scopola*, *Mandragora*, *Duboisia*, etc.) derived from plants belonging to the order Solanaceæ (the potato family). These also contain varying proportions of other alkaloids (hyoscyamine, scopolamine, etc.) which are closely related to atropine in structure and in action.

The alkaloids, as first isolated, were mixtures; consequently, their properties appeared to vary with the origin, and these mixtures were given specific names (Daturine, Duboisine, etc.). The pretended difference between scopolamine and "hyoscine" is a survival of this tradition.

Historical.—*Belladonna* seems to have been first introduced into practice, as an anodyne, about 1860.

The first indubitable notice of *belladonna* occurs in 1504, but it then came quickly into use for poisoning and cosmetic purposes. The name *Atropos*, which Linné gave to the plant, is from the oldest of the Three Fates, who cuts the thread of life. *Belladonna* comes from the Italian "handsome woman," as it was used to give luster to the eyes. On account of the slow course and the obscure symptoms, *belladonna* was a favorite with professional poisoners in the middle ages, and this abuse in regard to several species of *Datura* (*Stramonium*) has existed in India since remote ages. The name itself is Sanskrit (*Dhatoora*).

Hyoscyamus was mentioned by Dioscorides in the first century, and has been used continuously in domestic medicine. It was introduced into practice by Stoerck in the middle of the eighteenth century. He also introduced *Stramonium*. *Mandragora* (Mandrake) was the subject of some interesting medieval myths. The "herbarium" of Apuleius (eleventh century) quotes its use, externally, for headache and insomnia, and internally for mania.

Chemical Structure and Relations.—These alkaloids are ester-like combinations of certain bases with organic acids of the aromatic series.

Atropine, is the tropeic acid ester of a base, tropine, and is isomeric with *hyoscyamine*; *hyoscyamine* being levorotatory, while *atropine* is racemic. The esters of tropine are called *tropeines*. *Homatropine* is the mandelic ester of tropine; and other tropeins occur naturally or may be prepared synthetically. Tropine itself is closely related to *Ecgonine*, the basic constituent of cocaine. The *osceines* are analogous esters of the base *osceine*. The tropeic acid ester constitutes the important alkaloid *scopolamine* or *hyoscine*, ($C_{17}N_{21}NO_4$). This also occurs in isomeric forms: *atrosceine* (racemic, corresponding to *atropine*); and *scopolamine* proper (levorotatory, corresponding to *hyoscyamine*). *Atropine* and *atrosceine* are the more stable products: alkalies and many other agents convert *hyoscyamine* into *atropine*, *scopolamine* into *atrosceine*.

Chemical Constitution.—Tropine has the formula

Ecgonine (the base of cocaine) is the beta carbo-acid of tropine, one H at (a) being replaced by COOH.

Atropine is the tropeic ester of tropine, the H at (b) being replaced by the radical

The sulphuric ester of *atropine* is nearly devoid of peripheral actions, while the central effects, especially the respiratory stimulation, are preserved. *Scopolamine*-sulphuric ester does not share this respiratory action (Trendelenburg, 1913).

Belladonnine and *Atropamine* are isomeric alkaloids (belladonninic acid tropeines). Their formula differs from *atropine* by the absence of a molecule of H_2O . They are present in the plants in very small amount, and it is possible that they are only formed during the extraction.

Constitution and Action.—The relation between these has been investigated by Cushny, 1919, 1920; using as criterion the antagonism of the pilocarpine salivation. The *atropine* effect is absent from *tropine* itself; but is produced by many of its compounds, especially those with the benzene nucleus. It is greatly intensified by the presence of hydroxyl and of asymmetric carbon in the side-chains. The greatest activity is only reached when these are in the form of an aromatic acid.

The asymmetric carbon is very important. The l-*hyoscyamine* is 40 times more active than the d-*hyoscyamine*; but even this is more active than the nearest homologues that do not contain asymmetric carbon. This is not indispensable, however, for some activity exists in *tropines* without asymmetric carbon and without hydroxyls. These therefore probably do not act as anchoring groups; but more likely by affecting some physical property.

Distribution of Alkaloids.—*Belladonna* and *Stramonium* contain mainly *atropine* and *hyoscyamine*; one or the other alkaloid may predominate. The *hyoscyamine* is the most widely distributed of these alkaloids, and is especially abundant in young parts of the plants, whereas older parts contain more *atropine*. It appears therefore that the *hyoscyamine* is the original alkaloid, and that it is partly transformed into *atropine* in the plant itself, and also during extraction. These plants also contain small traces of *scopolamine* and *atrosceine*, but the latter alkaloids are relatively more abundant in *Hyoscyamus* and *Scopola*, taking the principal part in the actions of these plants. The distribution and variation of the alkaloids in individual plants has been studied by Sievers, 1913 and 1914. This suggests the feasibility of improving the alkaloidal content by selective breeding (Sievers, 1915).

Effects on Psychic Functions.—Therapeutic doses of *atropine* have no perceptible effects on the psychic functions; but overdoses produce symp-

toms (see "Toxicology") superficially resembling alcoholic inebriation. However, the exaltation and stimulation are more prominent, passing from mere restlessness to hallucinations and delirium, and even mania; and the effects are much more lasting. Similar symptoms are seen in animals. With toxic doses the stimulation passes into coma, convulsions, and asphyxia.

Atropine and Scopolamine on the Cerebral Functions of Rats.—Although these animals are very resistant to the toxic actions of atropine, as judged by the minimum fatal dose, their behavior in the circular maze reacts to quite minute quantities of these alkaloids. Atropine, scopolamine, homatropine and their derivatives alike produce stimulation in small doses, and depression with large doses; but differ materially in the absolute dosage. The action is associated with the tropine and oscine (scopoline) nucleus, and appears to be potentiated by the tropic acid, which is itself inactive. The levo-compounds are more active than the racemic (Macht, 1923).

The convulsions are not entirely asphyxial, for they are not abolished by artificial respiration.

The vision is disturbed more than can be explained by loss of accommodation.

The motor areas in dogs are stated by some observers to be more excitable, but others deny this.

In frogs, atropine first increases the reflexes; this is followed by general paralysis, and this again by late tetanus.

Respiration.—Therapeutic doses, in man (1 mg. hypodermically), stimulate respiration, increasing somewhat the rate and minute volume, and sometimes the depth of the respiration. The excitability of the respiratory center is not increased directly, however; for the alveolar CO₂ tension is unchanged, whereas it would be found lower if the threshold of the center were lowered. The stimulation is therefore indirect; being due partly to increased CO₂ production (increased gaseous metabolism); partly to increased "dead space" in the lungs by bronchial dilation (Edsall and Means, 1914; Higgins and Means, 1915). Toxic doses produce a late depression of the center (Binz, 1896), which is the usual cause of death in atropine poisoning.

Respiration in Animal Experiments.—The results have been rather contradictory. Heinz, 1890, found no appreciable change in the respiratory volume of rabbits; Wood and Cerna, 1892, increased rate and minute-volume in dogs. According to most observers atropine counteracts respiratory depression from chloral (Husemann, 1877) or morphine (Henbach, 1878; Binz, 1887; Vollmer, 1892); but others found that it augments the morphine depression (Orlowski, 1891; Unverricht, 1892 and 1896).

Voegtlin and Wiggers, 1918, using an improved method on unanesthetized dogs, find that moderate doses of atropine stimulate slightly after morphine.

Atropine was ineffective against depression of the respiration by cerebral compression (Loevenhart *et al.*, 1918).

Hanzlik, 1923, found that 1 mg. (hypodermically) per Kg. of rabbit (without anesthesia) depressed the respiration. With morphinized rabbits, Meissner, 1923, records increase of depth without change of rate, from the intravenous injection of 1 to 10 mg. of atropine.

With larger doses, the psychic excitement and muscular activity would increase the respiration indirectly. Toxic doses depress respiration, producing slowing, Cheyne-Stokes type, and finally cessation. Artificial respiration may enable an animal to survive six times the fatal dose.

Therapeutic Uses of Respiratory Stimulation.—The mechanism of this respiratory action in man would render its usefulness doubtful. On the basis of the animal experiments (which, however, involve larger doses) it has been used against poisoning by morphine, and as a preliminary to anesthesia, or even as a restorative in anesthetic fatalities (Webster, 1908). It is also often used in whooping cough, but is of doubtful efficiency (child of one year, $\frac{1}{12}$ to $\frac{1}{10}$ gr. of Extr. Belladonna, or 8 to 10 drops of Tr. Bellad. three times daily, doubling the dose in a week if tolerance is acquired (A. Jacobi, 1907).

Bronchial Muscles and Glands.—Atropine paralyzes the innervation of these structures, and therefore dilates and dries the bronchial tubes. The dilation is obtained in excised rings of bronchial musculature (Trendelenburg, 1912), and is therefore peripheral. These effects are especially important for relieving attacks of *bronchial asthma*.

Therapeutic Application to Asthma.—Bronchial asthma is commonly due to spasmodic constriction of the bronchioles, produced in some cases reflexly, in others probably analogous to anaphylactic reaction. The lumen of the bronchi may be further narrowed by catarrhal swelling of their mucosa.

The obstacle to the passage of air is greater in expiration, especially if this is spasmodic, since the sudden expiratory rise of intrathoracic pressure tends to compress and close the obstructed bronchioles, whilst the negative pressure of inspiration tends to open the passage. This valve-like action distends the lungs and produces an acute emphysema, which hinders the respiratory exchange (Cloetta, 1913).

This condition may be promptly relieved by atropine or epinephrine. The atropine acts on both the constriction and the hypersecretion. It is also effective against experimental bronchial constriction (Dixon and Lee, 1912); and with proper dosage against anaphylaxis (Auer, 1912; Karsner and Nutt, 1911). It could not be effective in cardiac, renal, or emphysematous "asthma." Unfortunately, it seems to lose its effects, even in what would appear to be suitable cases. Epinephrine is often much more active.

Administration.—Atropine ($\frac{1}{2}$ to 1 mg., $\frac{1}{120}$ to $\frac{1}{60}$ gr.) or the drugs containing it may be administered by any channel; but inhalation is most effective since it brings the drug directly to the site of its action. This is accomplished by inhaling the smoke of burning stramonium leaves.

Asthma powders consist of atropine containing drugs, mixed with sufficient saltpeter to insure their combustion; e.g., Powdered Stramonium, 3 Gm.; Lobelia, 1; Anise, 2; Potas. Nitrate, 2. This dose is burned on a plate, and the smoke inhaled. Stramonium cigarettes are also used; the smoke of 1 to 1.25 Gm. of stramonium contains 0.3 to 0.5 mg. atropine (Guenther, 1911).

Circulation.—*Single therapeutic doses* of atropine do not usually affect the pulse rate materially; but *ordinary experimental doses* greatly increase the heart rate by paralyzing the vagus endings. All vagus inhibitions are thus abolished. The blood pressure rises moderately, mainly through the quickened rate, but partly through central vasomotor stimulation. If the blood pressure has been abnormally lowered by excessive vagus stimulation, the atropine rise will appear correspondingly greater. The cutaneous vessels are actively dilated by atropine, the skin assuming a more or less scarlet color. *Toxic doses* paralyze the vasomotor center and eventually also the arterial and cardiac muscle, so that the blood pressure falls profoundly.

Action on the Vagus.—Atropine stimulates the vagus center in common with the other medullary centers. It may therefore cause a slight *primary slowing*; this is soon overcome by the peripheral paralysis. This vagus paralysis results in *quickened heart rate* in all animals in which the vagus is tonically active (in man, the cat, dog, etc.). In completely atropinized dogs and cats, the rate is about 140 to 240 per minute. The vagus tone being small in rabbits and in frogs, these animals show little or no quickening; but in these the vagus is also paralyzed, for its stimulation does not slow the heart. In man, the vagus tone is greatest in middle life, between 20 and 30 years, less in old age

(after 50 years), and least in infancy; and the response of the heart rate to atropine varies accordingly.

Both sexes react practically alike, but there are considerable individual variations. These have no constant relation to the rate prior to the injection (J. H. Crawford, 1923).

The inotropic as well as the chronotropic functions of the vagus are paralyzed in frogs (Ransom, 1917).

In the auricles of terrapin, atropine is said to increase the tonus, without affecting the periodic tonus waves (Gruber and Markel, 1918).

The duration of the paralysis varies with the dose, and also with the species. It lasts only a few minutes in rabbits (Rossbach, 1879); longer in goiterous rabbits (Fleischmann, 1911). In dogs and cats, a partial effect persists for hours (Pilcher and Sollmann).

The dosage required to paralyze the vagus has been studied by Pilcher and Sollmann, 1914. It is always small, but varies somewhat in different animals, even of the same species, and even for the two vagi of the same animals; the left vagus being more susceptible. Low blood pressure also increases the susceptibility. In every respect, the susceptibility to atropine is inverse to the natural excitability of the vagi. In the dog, about 0.01 mg. per kilogram lessens the response to vagus stimulation perceptibly; and about two or four times this dose abolishes the response completely. When the paralysis is incomplete, a slight further slowing may be secured by strengthening the stimulus; but with the larger dosage even the strongest stimulus remains ineffective.

The vagus paralysis is *located in the termination of the vagus* (or in the receptive substance); for stimulation of the postganglionic fibers (at the sinus-auricular junction of the frog) fails to slow the heart.

Atropine abolishes cardiac inhibition by all drugs which act through the vagus mechanism, whether they stimulate this reflexly (ammonia or chloroform inhalation); centrally (picrotoxine or veratrum), or peripherally in the ganglia (nicotine), or in the endings (pilocarpine, muscarine, physostigmine).

Results of Vagus Stimulation after Atropine.—In dogs, when the atropine action has gone just so far that stimulation of the divided vagus trunk causes no perceptible slowing, this still produces a slight fall of blood pressure; larger doses abolish this response also, so that the inotropic properties of the vagus terminations seem to be somewhat more resistant than the chronotropic.

When the intact vagus is stimulated in atropinized mammals, the blood pressure may fall or rise by stimulation of the afferent vasodilator or constrictor fibers which run in the vagus.

In atropinized frogs, stimulation of the vagus trunk quickens the heart, since this carries the accelerator fibers, which are not affected by atropine.

Perfusion of Turtle's Medulla.—Atropine, 0.02 per cent., has practically no effect on the heart rate or rhythm (Bush, 1919).

Atropine on Normal Human Heart-rate.—The hypodermic dose of 0.5 mg. produces either no effect or a pure slowing, to about 69. This is attributable to central vagus stimulation. With 1 mg., this slowing is complicated by a tendency to irregularity. With 2 mg., the slowing is very transient, and is followed by quickening. This dosage is the minimum that can be relied upon to depress the vagus (McGuigan; Platz, 1923). Paskind, 1921, records the curious information that the slowing by small doses is practically absent in the negro race (20 cases); but their normal rate averages about 10 beats lower than in the white race; so that the vagus center is probably already in a somewhat higher tone, and therefore less susceptible to further increase. The later accelerator effects are the same in both races.

Atrio-ventricular Rhythm.—This may occur in man from doses of 1 mg. It sets in within 8 to 10 minutes, and soon reaches a maximum, and then disappears. Wilson, 1915, assumes that atropine releases the A-V tissue from vagus control somewhat before it releases the sinus.

Electrocardiogram.—In dogs, small doses of atropine usually produce auriculo-ventricular block. With larger doses, this is followed by increased sinus rate. At the same time, it abolishes any existing blocks, sinus arrhythmias or ectopic beats (as with digitalis). In this last respect, atropine is more efficient than nitrite.

The A-V conduction is usually slowed by small and quickened by large doses. The P wave at first tends to negative, then to more positive (Halsey, 1917).

Response in Cardiac Disease.—In chronic heart disease, in which the sino-auricular node is in control, the response to atropine is diminished; auricular fibrillation shows increased response (J. H. Crawford, 1923).

Removal of nodal rhythm by atropine (milligram doses) has been reported (L. F. Bishop, 1921).

Atropine on Voluntary Tachycardia.—N. B. Taylor, 1922, reports a student who could voluntarily increase his heart rate from 70 to 125 along with other manifestations of sympathetic stimulation (glycosuria, vasoconstriction, mydriasis). After 2 mg. of atropine, which raised the heart rate to 90, the rise by volition was only to 115.

Atropine Response in "Effort Syndrome" with Irritable Heart.—The pulse rate responds with the normal incipient slowing, followed by an increase which is generally greater than normal, i.e., 6 to 30 per minute. The respiratory quotient is slightly lowered. The basal metabolism remains unaffected (Sturgis et al., 1919).

Influence of Heart Rate on the Output of the Heart.—The output of the heart for a given time is the product of the amplitude and rate of its excursions. The removal of the normal vagus inhibition greatly increases the rate; but when the rate exceeds 80 per minute, this tends to lessen the amplitude of the excursions; for a faster rate does not permit time for the complete diastolic filling of the heart. The output is therefore not proportional to the rate, if this exceeds 80 per minute (Y. Henderson, 1909). If the minute-volume with the rate of 90 be taken as 100, it would be about 40 per cent. at the rate of 30; 75 per cent. at 60 beats; 120 to 140 per cent. between 120 to 240 beats; and 100 per cent. at 300 beats. The approximate influence of the atropine quickening on the output, and through it on the blood-pressure, can be easily deduced from these data, but it must not be forgotten that atropine also has other actions on the circulation.

Therapeutic Use of Vagus Action.—The paralysis of the vagus endings indicates atropine (1 to 2 mg., $\frac{1}{60}$ to $\frac{1}{30}$ gr., hypodermically, repeated as needed) in conditions of excessive vagus stimulation, such as cerebral pressure; the reflex vagus inhibition of colic; of angina; of chloroform anesthesia; operations about the vagus trunks, etc. Atropine also abolishes such cardiac irregularities as are due to heightened vagus excitability (pulsus respiratorius), and it may be used to diagnose whether a cardiac slowing is due to vagus stimulation.

In fact, however, response to atropine (or amyl nitrite) merely shows that the heart is still under vagus tone—not that the bradycardia was of vagus origin (Fredericq, 1916).

In partial heart-block, the rate responds to atropine or nitrite (Fredericq, 1916). It has been found clinically effective in sino-atrial block (N. W. Brown, 1919, 0.5 to 1 mg.). It has no effect in complete heart-block (van Egmond, 1913).

Atropine Test for Typhoid Fever; "Vagotonia" and "Sympathicotonia."—In fever, when the vagus control is weak, atropine (2 mg.) does not produce much further quickening. This was suggested as a test for typhoid fever (F. A. Marris, 1916; Friedlander and McCord, 1918), but is of course not specific. It may be absent in this disease, and is often present in other fevers, exophthalmic goiter, etc. (J. H. Crawford, 1923). The sensitiveness to pilocarpine and especially to epinephrine is also often altered in typhoid fever (Matsua and Murakami, 1918), but again is not characteristic. Eppinger and Hess, 1909, suggested that the response to these drugs would reveal disturbances in the equilibrium of the sympathetic and parasympathetic innervation; but the suggestion has not led to any definite results.

Action on Cardiac Muscles.—Atropine has a slight direct effect on the *cardiac muscle*, which can be observed in the isolated heart, and also on the nerve-free heart of the embryonal chick. Small doses stimulate the muscle, causing an increased tonus, greater excursions, and some slowing. An exhausted frog's heart may be made to beat again. Large doses diminish the tonus and may slow or quicken the rate. Finally the heart is paralyzed, but only after the vasomotor center. Indeed, the effects on the heart muscle are not of any importance in the systemic action of the drug, being overshadowed by the other effects.

Atropine after Double Vagotomy.—If both vagi of an animal be divided, there is usually no regeneration apparent, even after long periods; nevertheless, the fast rate gradually returns to normal, but atropine at this stage causes marked quickening (F. T. Rogers, 1920).

In the *excised mammalian heart* (Langendorff method) atropine provokes rhythmic contractions of the apex after the base is clamped. This requires larger doses than are needed for paralyzing the vagus. These large doses may also restore the beat when it has been arrested by muscular poisons (Luchsinger, 1881).

In *intact animals*, atropine increases the auricular, but decreases the ventricular efficiency (Wiggers, 1916).

Vasomotor Center.—Sollmann and Pilcher, 1910, have shown by their perfusion method, that this is moderately stimulated. The stimulation is not sufficiently marked to produce a rise of pressure when ordinary doses are injected after dividing the vagi.

Choline-antagonism.—Large doses of atropine prevent the vasodilator effect of choline. Since atropine does not counteract other vasodilator reactions, this must be a peculiar mechanism, probably peripheral (Hunt, 1918).

Pulmonary Vessels.—Atropine has no effect on the normal vessels, but removes the constriction of pilocarpine or histamine (Berezin, 1914).

Cerebral Vessels.—These are dilated (Berezin, 1916).

Cutaneous Circulation and Skin Eruptions.—Atropine produces intense *scarlet or crimson flushing of the skin*, particularly of the face and chest, occurring as extensive erythematous spots, or as a continuous *erythema* which has sometimes been mistaken for scarlatina. This effect is much greater in some patients than in others; it may occur with therapeutic doses. It is due to dilatation of the cutaneous vessels (vasodilator stimulation), with increased general blood pressure. This hyperemia may be so intense as to lead to desquamation.

Temperature.—Atropine suppresses perspiration, and thus causes a rise of *temperature* with *moderate doses*, notwithstanding the cutaneous vasodilatation. Animals which do not possess sweat glands (dog) do not show this rise. *Larger doses* produce a fall of temperature from lessened heat production, the result of the general depression. The final convulsions may again cause a rise.

Gaseous Metabolism.—This is increased by therapeutic doses (1 mg.) in man (Edsall and Means, 1914; Higgins and Means, 1915).

In dogs, the intravenous administration of atropine diminished the respiratory metabolism and the CO₂ of the blood. This effect is mutually antagonized by pilocarpine (Klemen, 1918).

Actions on the Eye.—Atropine dilates the pupil (mydriasis) and renders it insensitive to light. It also paralyzes accommodation (cycloplegia), the lens being adjusted only for far vision. These actions are entirely peripheral and consist in paralysis of the oculomotor endings. The intraocular tension in glaucoma is increased through the mydriasis.

The atropine effects may be removed by drugs which stimulate the oculomotor endings (pilocarpine, physostigmine, muscarine); and *vice versa*.

The atropine mydriasis and cycloplegia are very persistent; the mydriasis especially may last for several days. The ocular actions are produced to a varying degree by all the atropinoid alkaloids.

Experimental Localization of the Atropine Mydriasis.—Atropine dilates the pupil on local, as well as on systemic application. The mydriasis remains confined to the eye, and even to that side of the eye to which it is applied. The dilation is produced in the excised eye of the frog, and even in the isolated iris.¹ Its action must therefore be peripheral.

The further localization in the receptive mechanism was discussed under the Autonomic Section.

¹ Slight effects may be obtained from atropine and physostigmine for three or four hours after death, in the human eye (Groenow, 1910).

The Behavior of the Sympathetic Mechanism.—There has been considerable discussion as to whether atropine in addition to paralyzing the oculomotor also stimulates the sympathetic mechanism. The question may now be safely answered in the sense that there is no direct sympathetic stimulation by atropine, for stimulation of the sympathetic, electrically or by cocaine, causes a further dilation of the pupil, even after maximal doses of atropine. The atropinized pupil constricts somewhat when the sympathetic is divided; but this is the natural result of cutting off the tonic sympathetic impulses. It has been argued that the atropine dilation can not be a passive process, since it is of sufficient force to tear firm adhesions of the iris. This merely shows that the dilator muscles contract actively; but their contraction is simply the result of the withdrawal of the constrictor tone, and need not involve a direct stimulation of the sympathetic mechanism. It is quite probable, however, that the natural sympathetic tone is heightened when the constrictor tone is withdrawn, for this would harmonize with the general law of reciprocal innervation.

Direct Actions on the Iris Muscle and Ciliary Ganglia.—The statement that the muscular fibers are not affected by atropine must be limited to moderate doses. In greater concentration (according to most observers) it at first stimulates them, producing a temporary narrowing of the pupil; later it paralyzes them.

Direct application of very strong solutions to the ciliary ganglion also depresses this structure.

The *iris of birds* is not dilated by atropine, but by curare, since it consists of striped muscle.

Cycloplegia.—The ciliary muscles are situated at the junction of the choroid and the cornea. They consist of radial and circular fibers, the former predominating. The contraction in both planes narrows the ring of attachment of the suspensory ligament of the lens, thereby relaxing the tension on this ligament, and thus permitting the anterior surface of the lens to become more convex, *i.e.*, to accommodate for near vision. The ciliary muscles are innervated by the oculomotor, and are under more or less tone. Their paralysis by atropine fixes the lens for far vision; and their spasm by pilocarpine or physostigmine for near vision. The derivatives of atropine are all cycloplegics. The sympathetic mydriatics, cocaine and some synthetic bases, have no effect on accommodation.

Changes in Intraocular Tension.—All mydriatics tend to increase intraocular tension in glaucoma, although not in the same degree. Conversely, the tension is lowered by miotics. Neither has much effect on the normal intraocular tension (Wessely, 1905; Bollet and Curtil, 1911; Luebs, 1913; Myashita, 1913).

Mechanism of the Change in Tension.—It is commonly assumed that the rise of pressure in mydriasis is produced mainly by lessened filtration of the aqueous humor into the venous sinuses of the channels of Fontana and canal of Schlemm. These lie in the angle of attachment of the iris, and would be compressed by the contraction of the ciliary muscle, and by the crowding back of the iris. Miosis would have the opposite effect (especially in glaucoma; in the normal eye miotics are said to lower the pressure very little). The intraocular tension is also controlled by the blood pressure, in the vessels of the iris (Leber), and would be lowered whenever these are ischemic either through fall of the general blood pressure (relatively little influence; Kochmann and Roemer, 1914); or through local vasoconstriction. The vasoconstricting cocaine, therefore, generally lowers intraocular tension, although it produces mydriasis; and it is claimed that atropine also tends to lower the pressure in the *normal* eye. Exceptionally, however, glaucoma has been reported after cocaine, holocaine, and even after epinephrine (Gifford, 1916).

Glaucoma.—The phenomena of this very serious eye disease depend mainly upon excessive intraocular tension: due, presumably, to blocked drainage (Schoenberg, 1913). It is therefore treated by miotics (see physostigmine); and it contraindicates the employment of mydriatics.

If their use is indispensable, the choice should fall upon cocaine; and if cycloplegia is necessary, the briefly acting homatropine would be preferred to atropine.

Practical Application of Atropine to the Eye.—The effects of atropine are utilized mainly for paralyzing the ciliary muscle to facilitate ophthalmoscopic examination; and in the treatment of iritis.

For *diagnostic work*, the persistent cycloplegia is often objectionable, but in other cases the enforced rest of the eye may be desirable. The less persistent homatropine may be substituted. This is also much less liable to provoke glaucoma. However, in glaucoma patients, homatropine should also be used as dilute as possible (1 or 2 per cent.), and followed by physostigmine, 0.2 per cent., a drop three times daily until the pupil and accommodation have returned to normal (Gifford, 1916).

In *iritis*, the atropine mydriasis is used to secure rest, to prevent adhesions of the iris to the lens, or break them if already formed; and to effect assumed favorable changes in the circulation of the iris. It is also a weak anesthetic. The more prolonged action of atropine causes it to be preferred for this purpose.

Administration to Eye.—The atropine is always applied locally, by dropping an aqueous solution of the sulphate, or an oily solution of the free alkaloid, on the cornea; or by placing impregnated gelatin discs (*Lamellæ Atropinæ*, B.P., $\frac{1}{5,000}$ gr.) in the conjunctival sac. Watery solutions tend to flow into the lachrymal duct, thereby lessening the local action, and tending to systemic poisoning. To avoid this, but a single drop of 1 per cent. solution should be applied at a time, and the lachrymal sac should be compressed with the finger. For continued use, in iritis, greater dilutions may be employed, down to $\frac{1}{10}$ per cent. (even 1:100,000 is somewhat effective). The effect is increased by the addition of cocaine.

Duration of Action of Atropine.—With a single drop of 1 per cent. solution, the mydriasis reaches its maximum in about twenty-five minutes, the cycloplegia in about two hours. The cycloplegia disappears in two or three days (seven to nine days if the application has been continuous); the mydriasis endures even longer, ten to twelve days.

Side Actions.—Besides the increase of tension, atropine causes photophobia (because of the irresponsive pupil); and micropia, from the loss of accommodation.

In sensitive individuals, atropine produces some conjunctivitis, and rarely edema of the eyelids. If it is used carelessly, it may give rise to systemic poisoning, headache, dryness of the mouth, palpitation, etc. A species of chronic poisoning may occur in this way (Tyrrell, 1906).

If atropine causes local irritation, scopolamine should be substituted, since this may be used in one-fifth the concentration.

Substitutes for Atropine.—These fall into two classes: (1) Those which produce mydriasis without cycloplegia (Euphthalmine, Ephedrine); and (2) those which produce both mydriasis and cycloplegia (Atropine, Hyoscyamine, Scopolamine, Eumydrine, and Homatropine—in the order of the persistence of the cycloplegia). Of these, atropine is the standard, the others being used when it is contraindicated.

The action of hyoscyamine is similar to atropine, but it is effective in about one-half the concentration. Scopolamine is effective in one-fifth the concentration.

Quantitative measurements of the relative efficiency of mydriatics and miotics, alone and combined, are given by Jackson, 1895; by Grube, 1905; by Horovitz, 1912; and by Joachimoglu, 1915.

The following table shows the strength of solutions usually employed for ophthalmoscopic examinations; and the ordinary duration of their actions.

Drug	Percentage used	Action complete, hours	Mydriasis	Paralysis complete, hours	Cycloplegia
			Recovery complete, days		Recovery complete, days
Atropine.....	1	$\frac{1}{2}$	5 to 7	2	3 to 4
Scopolamine.....	$\frac{1}{6}$	$\frac{1}{2}$	5	1	3
Eumydrine.....	1 to 5	$\frac{1}{2}$	2	1	2
Homatropine.....	2	$\frac{1}{2}$	1 to $\frac{1}{2}$	1	1
Euphthalmine.....	5 to 10	1	1		

PREPARATIONS—SYNTHETIC MYDRIATICS

* *Homatropine Hydrobromidum* (Homatrop. Hydrobr.), U.S.P., B.P.; $C_{16}H_{21}O_3 \cdot N \cdot HBr$.—Mandelic ester of tropine. Freely sol. in water (1:6); sol. in alc. (1:40). Instilled as 1 to 2 per cent. solution. *Dose*, 0.5 mg., $\frac{1}{120}$ gr., U.S.P.; 1 to 2 mg., $\frac{1}{64}$ to $\frac{1}{32}$ gr., B.P. Maximum dose, 2 mg., $\frac{1}{30}$ gr.

Lam. Homatrop., B.P.—0.65 mg., $\frac{1}{100}$ gr.

Systemic actions similar to atropine, probably somewhat less toxic. Coma with recovery occurred after the hypodermic injection of 40 mg. Its action on the vagus is purely paralytic, but weaker than atropine (Zulik, 1915).

Mandelic Acid.—Macht, 1922, attributes the actions of homatropine to the mandelic acid part of the ester, rather than to the tropine. Euphthalmine is also a mandelic ester. The structure of this acid is related by benzaldehyde; and sodium mandelate (confirmed by Hirschfelder) relaxes excised smooth muscle (uterus, ureter) similar to homatropine and euphthalmine. Homatropine affects the parasympathetic, for instance the vagus, much less than atropine; or rather, requires 5 to 10 times as high a dosage to paralyze. Homatropine also dilates the conjunctival vessels, and on injection lowers blood pressure.

Eumydrine (Methylatropine Nitrate).—Readily sol. in water. It agrees very closely with atropine in systemic actions, and may be substituted for it, in the same dosage; in eye, $\frac{1}{2}$ per cent. Its toxicity is about one-fiftieth, and its mydriatic strength one-tenth that of atropine. Cushny, 1920, found it $1\frac{1}{2}$ times more active than atropine in the salivary pilocarpine antagonism. Continued use often leads to tolerance (Seifert, *Nebenwirk.*, 1915, p. 66).

Euphthalmine Hydrochloride.—Closely related to beta-eucaine in composition. It is readily soluble in water; 2 to 3 drops of 5 to 10 per cent. solution are instilled. Side actions, Seifert, *Nebenwirk.*, 1915, p. 66.

Paralysis of Secretions.—Atropine and the related alkaloids arrest all secretions which depend upon central innervation: This includes the sweat, saliva, tears, mucus, gastric juice and ordinary pancreatic secretion; but not the urine, milk, bile or secretin pancreatic secretion. The action is localized in the nerve-endings or receptive substance, and is mutually antagonistic with the pilocarpine action.

Suppression of Saliva (Antisialagogue Action).—The submaxillary glands furnish a classical object for localizing the action of Atropine. This suppresses the secretory response to chorda-tympanic stimulation, even when this is applied at the hilus of the gland, *i.e.*, to the postganglionic fibers. The paralysis must therefore be peripheral to these. The cells, however, still respond to sympathetic stimulation, so that the paralysis must be in an intermediary substance, in the nerve-endings.

This argument involves the assumption that the chorda tympani and the sympathetic act upon the same cells in the salivary gland. This is doubted by A. P. Mathews, and by Gaskell, 1916. The evidence is, therefore, not as conclusive as in the case of smooth and cardiac muscle, where the excitability of the contractile substance can be confirmed by direct stimulation; but the analogy is otherwise so complete, that the conclusion is fairly safe.

Large doses of atropine inhibit the response to sympathetic stimulation (Cannon and Cattell, 1916); perhaps by paralyzing the secretory cells directly.

In man, Ewing, 1911, found that 0.5 to 1 mg., by mouth, caused a marked decrease in the volume of saliva secreted. The percentage of organic solids was somewhat diminished; the percentage of inorganic solids showed only a trifling decrease. The percentage of ptyalin fell markedly, but recovered, or was even somewhat increased, long before the volume of solids had returned to normal.

Vasodilator Fibers of the Chorda Tympani Nerve.—These are not affected, so that stimulation of the atropinized nerve still dilates the vessels and produces an increased venous outflow from the gland. (The effects of atropine and pilocarpine on the submaxillary circulation are discussed by Henderson and Loewi, 1905.)

Antagonism.—Atropine completely suppresses the nicotine salivation (since this stimulates the ganglion cells); it is mutually antagonistic with pilocarpine, etc., but the atropine action, as usual, tends to be the stronger.

The quantitative relations have been studied by Cushny, 1915.

Atropine is also said to suppress the mercurial salivation, but not the "paralytic secretion" which sets in when the divided nerve degenerates.

Paradoxic Reflex Secretion in Chronic Poisoning.—Abundant reflex secretion of saliva occurs in cats and dogs after repeated injections of atropine, and continues for months if the injections are continued. The chorda nerve may be excitable or not. The sympathetic is excitable. The action is referred to the salivary center (Arima, 1918).

Practical Significance of the Antisialagogue Action.—This is mainly a rather unpleasant side effect in the therapeutic use of the drug. Small doses (0.5 mg.) may be employed to suppress practically any form of ptyalism. It is not much used, since the benefits scarcely offset the inconveniences attending the use of the drug.

Suppression of Mucous Secretion.—This may be employed in the hypersecretion of coryza, bronchorrhea, ether anesthesia, etc. Minimal doses of atropine are used to abort incipient colds (0.5 mg., $\frac{1}{120}$ gr. or less, in a glass of water, sipped slowly in the course of an hour—Kohnstamm, 1906). The cutaneous vasodilation may play a part in this abortive action.

Suppression of Sweat (Anhydrotic Action).—This is one of the earliest actions, and can be secured with small doses (0.3 to 1 mg., $\frac{1}{200}$ to $\frac{1}{60}$ gr., hypodermically). It is the most effective means of suppressing the night sweats of phthisis, but the relief is only symptomatic, and scarcely justifies the inconveniences.

Other Anhydrotics.—The night sweats may also be suppressed by *scopolamine* or *eumydrine*. *Agaric acid* also arrests sweating by a peripheral action of the sweat glands, but is uncertain. *Camphoric acid* has been employed, but it does not act upon the sweat glands. If it has any effect (which is doubtful), it must be indirect, through improvement of the respiration.

Local measures are often preferred, especially for local hyperhydrosis: Sponging with cold lotions containing alcohol, dilute acids, tannin, salicylic acid, formaldehyde, etc. *Dusting-powders* are likewise useful (talcum with 5 per cent. of salicylic acid or 10 per cent. of boric acid).

Sodium Tellurate appears to act similarly to atropine but is objectionable on account of the persistent garlic odor which it gives to the breath.

Oviduct Secretion of Birds: Atropine has practically no effect on the secretion of albumen or of shell-material (Riddle and Ring, 1921).

Gastric Actions.—The secretion of gastric juice, and especially of hydrochloric acid, is diminished or suppressed, through paralysis of the secretory vagus endings (Chiari, 1915; Crohn, 1918). Atropine has little or no effect on the normal gastric movements, but may relax pyloric spasm (Auer and Meitzer, 1906). Both actions might be useful in hyperchlorhydria, pylorospasm and cardiospasm, in gastric ulcer, tumors, etc. It is usually given in doses of 1 mg. ($\frac{1}{60}$ grain), before meals. The practical results

are inconstant (Bastedo, 1920). Large doses are used against *infantile pylorospasm*, 0.05 to 0.15 mg. three to four times a day (Stolte). This produces flushing, but no dangerous effects; it has been given daily to six-week old infants, for weeks (Ochsenius, 1916). In *cardiospasm* it may cause sudden relaxation, or it may be ineffective (Barclay, 1915; fluoroscope). It is often used in hyperchlorhydria; and especially in acute conditions with severe pain and vomiting (Mathieu and Girard, 1913; A. Schmidt, 1914). It has been used in *seasickness* (atropine, 0.5 mg.; strychnine, 1 mg., hypodermically—Girard, 1906). The sojourn of meat in the stomach is delayed by large doses of atropine (Tysebaert, 1912, 1913).

Excised Stomach.—Atropine counteracts the pilocarpine contraction and produces relaxation (M. Smith, 1918). P. Hecht, 1921, attributes the variable results with excised stomachs to variability of choline extraction.

Influence on Normal Gastric Secretion.—In dogs, intramuscular injection of atropine (0.0125 mg. per Kg.) completely inhibits secretion in response to food. Smaller dosage, 0.003 mg. per Kg., diminishes the volume and the peptic activity. The acid-concentration is not affected until a dosage is reached that diminishes the volume by 50 to 80 per cent. There is a mutual antagonism toward histamine and gastrin, extending to nearly fatal doses of atropine. With large doses, the atropine and gastrin appear to act directly on the gland-cells; smaller doses probably act on some other site (Keeton et al., 1920).

Antagonism to Emetics.—Eggleston, 1916, finds that very small doses of atropine (0.01 mg. per kilogram) prevent the emetic action of pilocarpine and nicotine, but not of apomorphine, morphine, ouabain or emetine. The anti-emetic dose being smaller than is required against peripheral actions of pilocarpine suggests that atropine depresses an emetic center.

Hatcher and Weiss, 1923, attribute the anti-emetic action to paralysis to blocking of certain afferent paths to the emetic centers, whilst other paths remain open.

Pancreatic Juice.—Atropine suppresses the increase of pancreatic secretion which ordinarily follows stimulation of the vagus or the administration of pilocarpine, choline, etc. Large doses, however, provoke a pancreatic flow in the dog (Popielski, 1896; Modrakowski, 1906); the mechanism of this peculiar action is not understood; it may possibly be connected with the actions on the liver.

On the secretin flow, atropine has no direct effect (Chiari, 1915), but since it diminishes the secretion of acid in the stomach, it probably lessens the production of secretin indirectly, and hence interferes with the physiologic pancreatic secretion.

The pancreatic stimulants which are antagonized by atropine yield active juice, whereas those which are not affected by atropine require the addition of erepsin (Camus and Gley, 1905).

Atropine prevents the pancreatic secretory response to vagus-stimulation and to fats in acute experiments; but in permanent fistula experiments Savich, 1919, found it ineffective.

Uric Acid.—Atropine is said to prevent the increase of uric acid that normally follows the ingestion of food; presumably by preventing the secretion of the digestive juices (Mendel and Stehle, 1914). It also prevents the cinchophen increase (Abl, 1913).

Lacteal Secretion.—Ott and Scott, 1912, confirm Roehrig that this is somewhat diminished by atropine.

Glycogenolysis.—The old statement that atropine prevents the transformation of the hepatic glycogen into sugar appears to be erroneous. It originated with Morat, 1883, who concluded that pilocarpine stimulates, and atropine inhibits, the conversion of glycogen into sugar. Cavazzani and Soldaini, 1896, also stated that atropine paralyzes glycoscretory nerves in the liver. The evidence, however, was unsatisfactory and has been disproven by the results of Mosenthal, 1913, and of Macleod, 1908. The latter showed that splanchnic stimulation produces the same hyperglycemia after atropine as normally. McGuigan, 1916, also finds no direct effect of atropine or pilocarpine. Large doses of atropine may increase the blood sugar (also observed by Pitini, 1908). This is due simply to the excitement.

On the other hand, E. L. Ross, 1919 claims that atropine diminishes ether glycosuria materially. The mechanism was not investigated. *Chloroform hyperglycemia*, which is probably asphyxial, is not checked by atropine (Ross, 1920).

Atropine in Diabetes.—It has been asserted that atropine increases the tolerance for carbohydrates (Rudisch, Forchheimer); but the statement needs confirmation (Mosenthal, 1912).

Hepatic Actions and Coagulability of Blood.—The *secretion of bile* is sometimes slightly diminished by atropine (Okada, 1915; Yanagawa, 1916). The lymph-flow may be either increased or unchanged (Yanagawa).

The injection of large doses of atropine into the portal vein lowers the *coagulability of blood*, first that of the hepatic vein. This effect can not be produced by injection into the jugular vein, nor by addition of atropine to shed blood (Doyon and Kareff, 1904 and 1906), and is due to an action on the liver. The anticoagulant substance is also produced by the perfusion of atropinized blood through an excised liver (Doyon, 1910).

The *leucocytes* are not changed by ordinary doses. Toxic doses, especially when often repeated, diminish the eosinophiles. The action is probably indirect (Herrick, 1914; Port and Brunow, 1914). The emigration of leucocytes in exposed mesentery is not inhibited by atropine or scopolamine (Ikeda, 1916).

Yeast Formation.—This is stimulated by small quantities, inhibited by large doses (Somoggi, 1916).

Epinephrine Output.—This is not materially influenced, in cats, by atropine or pilocarpine (Stewart, G. N., and Rogoff, 1920).

Actions on Peristalsis.—These vary according to the dose and conditions. Pilocarpine and other parasympathetic poisons are antagonized by doses that have no effect on the normal intestine (Magnus). Larger doses, from the therapeutic to fatal, tend to relax the normal intestine (Katsch, 1913; Hirz, 1913), and to prevent the response to vagus and eventually also to sympathetic stimulation. The atropine, 1 mg., ($\frac{1}{60}$ gr.) or belladonna extract (15 mg., $\frac{1}{4}$ gr.) or tincture (0.5 c.c., 8 minims) are sometimes administered as sedatives in colics and to diminish the griping of cathartics, but it is often not effective, since the irritation is more generally muscular than parasympathetic.

Excised Intestines.—When fresh, these show essentially the same phenomena (Magnus); but if they have been extensively soaked in saline solution, atropine may produce stimulation, instead of depression. This is attributed to loss of parasympathetic tone by the removal of the choline that is present in the walls of fresh intestine (LeHeux, 1920).

Extreme doses of atropine (so large that they can not be brought into action by systemic application, but only locally and in the excised intestine) paralyze successively the ganglion cells, the endings, and the muscle, thus destroying the response to the muscular poisons such as barium.

The *optical isomers* of atropine act quantitatively alike on excised intestine (Liljestrand, 1919).

Dosage.—In the excised intestine, the relative doses of atropine are as follows: 0.1 per cent. is required to produce depression; 0.025 to produce stimulation; and 0.0005 to antagonize pilocarpine. The quantitative relation between atropine and pilocarpine has been investigated by van Lidth de Jeude, 1918.

Biliary and Renal Colic.—Atropine paralyzes the innervation of the smooth muscle of the bile ducts and ureters, and therefore relaxes the painful and obstructive spasm which results from the passage of calculi through these tubes. The vagus paralysis is also useful in this connection by preventing the dangerous cardiac reflex which sometimes occurs. The atropine, 1 mg., $\frac{1}{60}$ gr., is given hypodermically, usually combined with morphine, 15 mg., $\frac{1}{4}$ gr.

Gall Bladder.—This may be relaxed (Lieb and McWhorter, 1915); but not by ordinary therapeutic doses (Macht, 1917).

Excised Ureter.—Small doses of atropine may stimulate the tone and peristaltic movements. Stronger solutions (1:10,000) inhibit them, as also the stimulant effects of pilocarpine, physostigmine and choline (Macht, 1916).

G. B. Roth, 1917, however, found nicotine, pilocarpine and atropine practically ineffective.

Hyoscyamine Isomers on Ureter.—The levo stimulates the contractions and slightly raises the tonus; very large doses depress. The dextro inhibits from the start, without stimulation (Macht, 1918).

Urinary Bladder and Incontinence of Urine.—Atropine is employed to relieve incontinence of the urine, due to overaction of the bladder muscle; and retention of urine from overactivity of the vesical sphincter. The details of dosage are described by Ruhrah, Am. J. Med. Sc., February, 1912. A. Jacobi advises for children $\frac{1}{2}$ gr. of Belladonna Extract at night, increasing if necessary, to flush the cheeks.

The actions of atropine on the bladder were investigated by Edmunds and Roth, 1920. It produces primary contraction, then relaxation. It antidotes pilocarpine and physostigmine, but not electric stimulation of the erigentes (confirmed by Henderson, 1922).

Urine Flow.—Discordant results have been described by different investigators. They are summarized by Cow, 1912 and 1913. He finds that atropine has no effect if the urine is collected directly from the pelvis of the kidney; but that it merely modifies the flow through the ureter, by lessening its tone.

The suppression of sweat and other secretions might temporarily increase the output of urine.

Uterus.—This is relaxed and its non-gravid peristaltic movements are arrested (Ludwig and Lenz, 1923; Kehrer, 1908). It antagonizes pilocarpine, physostigmine, and also anaphylactic stimulation, but is not as effective against pituitary extract (Stoland and Sherwood, 1923).

Atropine in Dysmenorrhea.—This was introduced by Drenkham, 1910, and is advocated by Novak, 1915; especially in the spasmodic, colic type. The administration is started two days before the expected menses, and continued for two or three days during menstruation; usually in doses of 0.6 mg. ($\frac{1}{100}$ gr.) by mouth, three or more times daily. If dry throat, itching skin or disturbed accommodation develop, the dosage is reduced. These side-actions interfere greatly with its therapeutic availability (Litzenberg, 1919).

Striped Muscle.—Large doses (greater than could be used in living mammals) block the response to nerve-stimulation, similar to curare (Haffner, 1918). Smaller doses suffice to antagonize the physostigmine twitches (E. Frank and Nothmann, 1921) and the acetylcholine contracture (Riesser and Neuschloss, 1921).

Anodyne Action.—The local application of atropine dulls, rather than paralyzes, sensory nerves. It is therefore applied in the form of belladonna liniment or plaster, for the relief of pain, especially neuralgic and rheumatic. Belladonna suppositories (extract, 0.1 Gm., $1\frac{1}{2}$ gr.) are also used in painful hemorrhoids.

Dosimetric Table.—The following (adapted from Schmiedeberg) may be useful in the therapeutic use of atropine.

MG.	GR.	Symptoms
0.5	$\frac{1}{120}$	Slowing of pulse and very slight dryness of throat.
0.5 to 1	$\frac{1}{60}$ to $\frac{1}{30}$	Dryness in mouth, often with thirst. Pupil dilated, not quite immobile. Increase of pulse rate.
3 to 5	$\frac{1}{20}$ to $\frac{1}{12}$	Headache. Dysphagia. Alteration of voice. Muscular weakness. Restlessness.
7	$\frac{1}{10}$	Considerable dilatation of pupils. Disturbance of vision.
8	$\frac{1}{8}$	Excitement and muscular incoördination more marked.
10	$\frac{1}{6}$	Apathy. Hallucinations or delirium. Unconsciousness.

Atropine Poisoning.—Atropine is very readily absorbed, somewhat even from the intact skin, so that toxic symptoms have been observed (though rarely) after the use of belladonna plasters (Doland, 1906). They occur rather commonly in ophthalmic use, through the lachrymal ducts. Where the plant grows wild, the berries are often eaten by children.

Symptoms.—These set in promptly, but usually run a long course; lasting five to fifteen hours, or even several days in fatal cases. The first to be noticed are those arising from *dryness of the mouth and throat*: difficulty of deglutition and articulation, great thirst, a sense of burning and constriction in the throat. On the eyes, the dilatation of the *pupils*, impaired vision, absence of reaction to light will be noticed. There is often *nausea* and sometimes vomiting. *Excitement*, passing into delirium,

is a prominent feature. The delirium may be pleasing, with spectral illusions; or anxious or furious (a graphic description of the psychic experiences is given by L. L. Jepson). The onset of the *paralytic symptoms* is ushered in by giddiness, numbness of the limbs, and staggering gait, and passes into drowsiness and stupor. The *pulse* is quick (to 170) and small. The respiration is stertorous, fast or slowed. The face is flushed scarlet. In *fatal cases* death is preceded by coldness of the extremities, rapid and intermittent pulse, and deep coma. Convulsions are rare. Glycosuria is sometimes seen and may be attributed to the asphyxia. The *postmortem* findings are those of asphyxia.

A fatal ending is, however, quite rare (12 per cent.). The **fatal dose** of atropine is probably 0.1 Gm. or more for adults; 0.01 Gm. for children. Therapeutically, children bear proportionately larger doses than adults, and this holds also for young animals.

Recovery starts within two days, the respiration, pulse and pupils returning gradually to normal. Sometimes violent delirious symptoms may last for days, and it has happened that patients have been consigned to the insane asylum on a mistaken diagnosis.

A psychic "slowness," disturbance of vision, and some other symptoms, may persist for weeks.

Chronic atropine poisoning has been reported, especially from ophthalmic use (Tyrrell, 1906). However, the continued use of small doses establishes partial *tolerance* to the toxic action, but not to the effects on the vagus or oculomotor (Anrep and Rossbach, 1880; Cloetta, 1911).

Treatment of Atropine Poisoning.—This is usually effective since the prolonged course gives ample time for interference. It resolves itself into chemic neutralization, prompt removal, and meeting the symptoms. The delirium is best treated by the ice-cap, the general symptoms by pilocarpine (10 mg., $\frac{1}{6}$ gr. hypodermically, repeated until mouth is moist). Morphine (10 mg.) is also indicated in the early stages, but not after depression has set in. The latter is combated by the usual medullary stimulants (coffee, etc.). Artificial respiration should be kept up persistently, if necessary.

The effects on the eye may be abolished by the local application of physostigmine.

Excretion.—The greater part of the atropine disappears rapidly from the blood (Cloetta, 1908). It is excreted mostly unchanged, entirely by the urine, mainly within thirty-six hours.

The application of a drop of this fluid to the eye of a cat is the most convenient test for poisoning. Mydriasis occurs with a single drop of 1:150,000 solution, equivalent to 0.000245 mg. of atropine. Of scopalamine, the minimal mydriatic dose is 0.0001855 mg. (Joachimoglu, 1915). The human pupil is about equally sensitive (Metzner, 1912). The excretion is not complete, more or less of the atropine being destroyed in the body.

A part is excreted as tropine and as another base (Fickewirth and Heffter, 1912). The variations in this destruction and in the rapidity of excretion explain the racial and individual idiosyncrasies and acquired tolerance.

Atropine resists *putrefaction* for a long time, and may be found in the cadaver even months after burial. Confusion with ptomatropine (a putrefactive alkaloid) must be guarded against.

Racial and Acquired Tolerance.—Rodents and marsupials are very tolerant, as also, to a less extent, the goat, dog, birds, and some other animals. (The dosage for different animals has been determined by Wilberg, 1914.) The immunity is in no case complete. It is perhaps greatest in the case of rabbits, and can be increased by habituation. In rabbits, it is due mainly to destruction of the atropine by the serum and organs.

The liver plays an especially large part in this destruction, and suspensions of liver cells also have this property (Fleischmann, 1910, 1911; Cloetta, 1911; Clark, 1912; Doeblin, Heffter and Fickewirth, 1912; Fleischmann, 1913). The serum of man, dogs and rats generally lacks this quality, and it varies considerably in degree in different rabbits. This is not connected with the thyroid activity (Metzner and Hedinger, 1912) as had been suggested. Rabbit's serum also binds other alkaloids, especially pilocarpine, so that they become undialyzable (Beutner, 1923). Homatropine and scopolamine are also destroyed by serum. Frogs, like rabbits, tolerate large doses of atropine, through rapid destruction in the liver (v. Oettingen, 1918).

Cause of Habituation; Excretion in Animals.—Cloetta, 1911, found that non-habituated rabbits excrete 15 to 20 per cent. of the atropine, the excretion being completed in two to three days. (Fickewirth and Heffter find that the total excretion of all bases is about 50 per cent. of the administered quantity.) After immunization, the excretion is complete in one day; and as little or none can be found in the tissues, it appears that the rapidity of destruction and excretion has been increased.

The destructive power of the serum, however, is not raised (Doeblin and Fleischmann). Normal cats excrete very little of the atropine; but by habituation, the excretion is markedly raised, whilst the capacity for destruction is not increased. With these therefore the tolerance is due mainly to the acquired speed of excretion. Dogs excrete about one-third of the atropine within two days (Wiechowski, 1900).

Heckel, 1875, found that rabbits and guinea pigs did not only thrive for weeks on an exclusive diet of atropine-containing plants (Schroff, 1852), but that this exclusive diet could be continued for several generations. A further degree of immunity was thus acquired, so that the mydriatic effect was smaller and the fatal dose (hypodermically) higher. The flesh of these animals contained relatively little atropine, although the meat of ordinary rabbits poisoned with atropine is toxic to other animals and man (Koppe, 1866; Lewin, 1894.)

HYOSCYAMINE

Actions and Uses.—This is the levo-isomer of the racemic atropine. Cushny, 1903, compared these two alkaloids and the dextro-isomer. He finds that the peripheral actions on the iris, cardiac vagus and glands are 12 to 18 times as strong with the l.-isomer (ordinary hyoscyamine) than with the d.-; and about twice as strong as with atropine. Hyoscyamine, therefore, has some advantage when the peripheral effects are desired, especially in ophthalmic work. Internally, it has no advantage. All the isomers act practically alike on the central nervous system of mammals. The d.- has a greater stimulant effect on the spinal cord of frogs.

On the intestine, the isomers act quantitatively alike (Lilgestrand, 1919).

PROTocatechyl Tropeine

This has been investigated by Marshall, 1910. It paralyzes the vagus endings, but is less powerful than atropine or even homatropine. It produces a curare effect on striped muscle and a temporary central paralysis of respiration. There is also an independent gradual fall of blood pressure.

PREPARATIONS—ATROPINE GROUP

Atropina, U.S.P., B.P.; $C_{17}H_{23}NO_3$.—The alkaloid obtained from *Belladonna* and other plants of the *Solanaceæ* family. Slightly sol. in water (1:455); freely sol. in alc. (1:2); sol. in fat solvents and oils. Dose, 0.6 mg., $\frac{1}{100}$ gr., U.S.P.; 0.3 to 0.6 mg., $\frac{1}{200}$ to $\frac{1}{100}$ gr., B.P.

* *Atropinæ Sulphas* (Atrop. Sulph.), U.S.P., B.P. ($C_{17}H_{23}NO_3$) $_2$ ·H₂SO₄·H₂O.—White crystalline powder; odorless. Very sol. in water (1:0.4); freely sol. in alc. (1:5) or glyc. (1:2.5). Incompatible with alkalis, tannin and mercuric salts. Atropine solutions deteriorate rather rapidly; a 1:1,000 solution losing considerably in activity within three days (I. Simon, 1915). Sterilized solutions in ampules, however, preserve their full activity at least four weeks (Joachimoglu, 1915). Dose, 0.5 mg., $\frac{1}{120}$ gr., U.S.P.; 0.3 to 0.6 mg., $\frac{1}{200}$ to $\frac{1}{100}$ gr., B.P. Maximum dose, 1 mg., $\frac{1}{60}$ gr.

Commercial atropine is usually contaminated with varying quantities of hyoscyamine (Liljestrand, 1919).

Lam. Atrop., B.P.—0.013 mg., $\frac{1}{5,000}$ gr., B.P.

Liq. Atrop. Sulph., B.P.—1 per cent. Dose, 0.03 to 0.06 c.c., $\frac{1}{2}$ to 1 minim, B.P.

Ung. Atrop., B.P.—2 per cent.

Belladonnæ Folia, U.S.P., B.P.; *Belladonna Leaves* (Deadly Nightshade).—The dried leaves and tops of *Atropa Belladonna*, yielding not less than 0.3 per cent. of alkaloids. Dose, 0.06 Gm., 1 gr., U.S.P. Maximum dose, 0.2 Gm., 3 gr.

Belladonnæ Radix, U.S.P., B.P.; *Belladonna Root*.—The dried root of *Atropa Belladonna*, yielding not less than 0.45 per cent. of alkaloids. Dose, 0.045 Gm., $\frac{3}{4}$ gr., U.S.P.

Emp. Bellad., U.S.P.; *Belladonna Plaster*.—About 0.25 per cent. of alkaloids of belladonna leaves.

Emp. Bellad., B.P.—Prepared from *Liq. Ext. Bellad. Root*. 0.25 per cent. of alkaloids.

* *Ext. Bellad.*, U.S.P.; *Ext. Bellad. Sicc.*, B.P.—The U.S.P. extract occurs in powdered and pillular form; the B.P. is powdered. The U.S.P. contains 1.25 per cent., the B.P. 1 per cent. of the alkaloids of belladonna leaves. Dose, 15 mg., $\frac{1}{4}$ gr., U.S.P.; 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P. Ordinary maximum, 50 mg.

Fldext. Bellad. Fol., U.S.P.—0.3 per cent. of alkaloids. Dose, 0.06 c.c., 1 minim, U.S.P.

Fldext. Bellad. Rad., U.S.P.—0.45 per cent. of alkaloids. Dose, 0.05 c.c., $\frac{3}{4}$ minim, U.S.P.

Ext. Bellad. Liq., B.P.—0.75 per cent. of alkaloids of the root.

Lin. Bellad., B.P.—50 per cent. of *Liq. Ext. Bellad. (root)*; 1 per cent. of Camphor.

Tr. Bellad., U.S.P., B.P.—10 per cent. of leaves, 0.03 per cent. of alkaloids, U.S.P.; 0.035 per cent., B.P. Dose, 0.6 c.c., 10 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P. Ordinary maximum, 1 c.c., 15 minims.

Supp. Bellad., B.P.—1 mg. of the alkaloids of the root.

Ung. Bellad., U.S.P.—10 per cent. of extract of belladonna leaves, 0.125 per cent. of the alkaloids.

Ung. Bellad., B.P.—0.6 per cent. of the alkaloids of the root.

Daturæ Folia, B.P.—The dried leaves of *Datura fastuosa* and *Metel*.

Datur. Sem., B.P.—The seeds of *Datura fastuosa*.

Tr. Datur. Sem., B.P.—25 per cent. Dose, 0.3 to 1 c.c., 5 to 15 minims, B.P.

Hyoscyamin. Hydrobr., U.S.P.; $C_{17}H_{23}NO_3$ ·HBr.—Strongly levorotatory. Very sol. in water; freely sol. in alc. (1:2.5). Dose, 0.6 mg., $\frac{1}{100}$ gr.

Commercial hyoscyamine is usually contaminated with varying quantities of atropine (Liljestrand, 1919).

Hyoscyamin. Sulph., B.P.; ($C_{17}H_{23}NO_3$) $_2$ ·H₂SO₄ + 2H₂O.—Very sol. in water (1:0.5). Dose, 0.3 to 0.6 mg., $\frac{1}{200}$ to $\frac{1}{100}$ gr., B.P.

Hyoscyamus, U.S.P.; *Hyoscy. Fol.*, B.P.—The dried leaves and tops of *Hyoscyamus niger*, yielding not less than 0.065 per cent. of alkaloids, chiefly hyoscyamine, with some atropine and scopolamine. Dose, 0.2 Gm., 3 gr., U.S.P. Maximum dose, 0.4 Gm., 6 gr.

Ext. Hyosc., U.S.P.; *Ext. Hyoscy.*, B.P.—0.25 per cent. of alkaloids, U.S.P.; 0.3 per cent., B.P. Dose, 0.005 Gm., $\frac{5}{6}$ gr., U.S.P.; 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Ext. Hyosc., U.S.P.—A pillular extract, 1 Gm. representing 4 Gm. of drug, 0.25 per cent. of alkaloids. Dose, 0.05 Gm., $\frac{5}{6}$ gr., U.S.P. Maximum dose, 0.2 Gm., 3 gr.

Ext. Hyoscy., B.P.—A dry extract, with 0.3 per cent. of alkaloids. Dose, 0.12 to 0.5 Gm., 2 to 8 gr.

Fldext. Hyosc., U.S.P.—0.065 per cent. of alkaloids. Dose, 0.2 c.c., 3 minims, U.S.P.

Tinctura Hyoscyami (Tr. Hyosc.), U.S.P., B.P.—10 per cent. Miscible with water or alc. Dose, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P. Maximum dose, 4 c.c., 1 drachm.

* *Stramonium*, U.S.P.; *Stramon. Fol.*, B.P.; *Stramonium* (Jamestown Weed, Jimson Weed).—The dried leaves of *Datura Stramonium*. Contains not less than 0.25 per cent. of alkaloids, chiefly hyoscyamine, with some atropine and scopolamine. *Dose*, 0.075 Gm., 1¼ gr., U.S.P. Maximum dose, 0.3 Gm., 5 gr. Against asthma, 10 to 20 grains of the dried leaf, smoked in a pipe; hemorrhoids, fissures and painful ulcers, 10 per cent. ointment.

Ext. Stramon., U.S.P.—A pilular or powdered extract, 1 Gm. representing 4 Gm. of drug, 1 per cent. of alkaloids. *Dose*, 0.02 Gm., ½ gr., U.S.P.

Tr. Stramon., U.S.P.—10 per cent. *Dose*, 0.75 c.c., 12 minims, U.S.P.

Tr. Stramon., B.P.—20 per cent. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

AGARIC ACID

Acidum Agaricum, and the impure mixture *Agaricinum*, is derived from a fungus of the larch tree. It is a white, odorless and tasteless crystalline powder, but slightly soluble in cold water and alcohol.

The anhydrotic action of the fungus was probably known for some centuries. Agaricin was introduced against the night-sweats of phthisis by Young, 1882. The effect appears only after some hours (if at all) and then lasts for about 24 hours. It is a local irritant, and therefore can not be given hypodermically. Large doses produce vomiting, diarrhea, and death through central paralysis (Hofmeister, 1888). The maximum single *dose* should not exceed 0.03 Gm., (½ gr.); and the daily dose should be below 0.1 Gm. (1½ gr.). As habituation occurs, it is better to start with 0.5 mg. (⅓₂₀ gr.). Clinical opinions differ as to its value.

The mechanism of its action has not been satisfactorily explained. Hofmeister claimed that it prevents the sweating-response of the cat's paw to sciatic stimulation or heat, indicating that its action is peripheral and similar to atropine. However, it does not arrest the saliva or tears. McCartney, 1917, finds that it has a digitalis action, and that it stimulates smooth muscle. He therefore suggests (but without direct evidence) that it arrests perspiration by a special action on the muscular tissue of the sweat glands.

SCOPOLAMINE OR HYOSCINE

The commercial samples of scopolamine (also called hyoscyne) are usually indefinite, and often rather impure mixtures of two isomeric alkaloids (tropeic esters of oscine: scopolamine proper (levorotatory, 25.75°), and atropine (optically inactive). They occur in the various atropine-containing plants, but are now prepared mainly from *Scopola*. The U.S.P. now specifies the optically active alkaloid, *f.e.*, scopolamine proper.

The *peripheral actions* of scopolamine agree qualitatively with those of atropine; but there are quantitative differences; for instance, the actions on the oculomotor and secretions are stronger, while the vagus action is relatively weak.

The *central actions* differ almost qualitatively; scopolamine being mainly sedative, in all doses; while moderate doses of atropine are excitant. However, there are great individual variations in the response to scopolamine, and, therefore, in its toxicity. The variable toxicity is due mainly to idiosyncrasy, for it occurs with the purest samples; although the uncertain composition of the commercial samples probably plays a part.

Chemical Differences in Scopolamine.—It was formerly stated that there are specific differences in the effects according to the origin of the alkaloids; and that "hyoscyne" derived from *hyoscyamus* is therapeutically superior to the "scopolamine" of *scopola*. No such difference can exist if the pure alkaloids are employed; for these are identical, whatever their source (E. Schmidt, 1892 and 1894).

Apoatropine (C₁₇H₂₁NO₂, also called belladonnine or atropamine) was demonstrated in a commercial sample by Kobert, 1905, and has been held responsible for the occasional toxic effects. This is improbable. It is a rare impurity (Kionka, 1908) and its presence

is easily shown, by reduction (brown color), on adding a few drops of permanganate solution (Kessel, 1906). It exists preformed in the plants and may be derived chemically from atropine by the abstraction of one molecule of water. It causes, in rabbits, a rise of blood pressure, paralysis of cardiac vagus endings, central excitation, and death with relatively small doses, by paralysis of respiration. The oculomotor and secretory endings are not paralyzed (Marcacci, 1885; Kobert, 1905).

Deterioration of Solutions.—This has been suggested as a cause for idiosyncrasy (*f.i.*, by Gauss, 1907; Langer, 1912; and Sachs, 1912); but according to the seemingly more reliable experiments of Kionka, 1908; Willstatter and Hug, 1912; and Beck, 1914; the solutions keep unchanged indefinitely, at least in sealed ampuls.

H. Bolten, 1917, however, again describes abnormal effects in six patients from a solution that had been kept for several months in a "sterile" bottle (not ampule).

Pharmacologic Differences between Scopolamine and Atroscine.—These play an important part in the peripheral actions, but not in the more important central effects. Cushny and Peebles, 1905, found that the l- and i-alkaloids act alike on the central nervous system in mammals, and on the motor endings; but that the levo-alkaloid (scopolamine) is twice as active on the salivary and vagus endings as the racemic atroscine.

This has been confirmed, also for the pupil, by Hug, 1912. Königsdörfer, 1896, claims that there is no difference in the pupil action. Cloetta, 1913, contends that the racemic is less toxic than the l- in man, but without good evidence (Cushny, 1912). Smith, 1915, found the fatal dose the same for mice.

According to Cushny, 1921, there are 11 hyoscine isomers possible, since both tropeinic acid and oscine are asymmetric. He quotes instances showing that the optical rotation may be involved in some of the actions, and not in others of the same substance.

Psychic Actions.—In man, doses of 1 to 3 mg. ($\frac{1}{60}$ to $\frac{1}{20}$ gr.) generally produce, within ten or fifteen minutes, fatigue, drowsiness, and a natural, dreamless sleep, lasting several hours. The response, however, is variable. In some the sleep is preceded by hallucinations, which may be rather pleasant with small doses, but which become violent if the dosage is increased. Animals are also affected differently by scopolamine (Kochmann, 1913).

Dogs react similarly to man: very small doses produce sleep and hallucinations; larger doses cause more marked hallucinations and restlessness, ataxia, and often emesis. The excitability of the motor areas is said to be lowered (Sohrt, 1886; Ramm, 1893).

Rats, whose behavior was tested by the circular maze, are stimulated by very small, but depressed by somewhat larger doses (Macht, 1923). *Rabbits* react by a mixture of depression and stimulation (Liljestrand *et al.*, 1910). *Frogs* show a central abolition of reflexes (Wood, 1883), preceded by more extensive spreading of the reflexes (Kochmann)

Therapeutic Use of Sedative and Hypnotic Action.—Scopolamine is employed especially in acute maniacal excitement, delirium tremens and tetanus. It has *advantages* over morphine, by quieting the reflexes and by avoiding habit formation; and over chloral, in that it does not usually depress the medulla. On the other hand, it produces the unpleasant *side effects* of mydriasis, cycloplegia, and excessive dryness; sometimes muscular tremors; and occasionally serious delirium (the latter is said to be promptly controlled by small doses of morphine). The therapeutic dose lies much below the ordinary fatal dose; but small doses (0.2 to 0.75 mg.; $\frac{1}{300}$ to $\frac{1}{75}$ gr.) have produced serious poisoning, with cardiac and respiratory collapse. On the other hand, $\frac{1}{10}$ and even $\frac{1}{5}$ gr. (0.5 and 50 mg.) have been taken without ill effects. Insane patients generally seem to be tolerant, so that the effective doses (1 to 3 mg.; $\frac{1}{60}$ to $\frac{1}{20}$ gr.) may be given; with ordinary individuals it is not safe to exceed 0.5 mg. ($\frac{1}{120}$ gr.), repeating this smaller dose every six to eight hours, if necessary; and it would be safer to use this dosage also for the insane. Smaller doses (0.2

mg.; $\frac{1}{300}$ gr.) may be used to enhance the hypnotic effect of morphine. The use in *drug addictions* has been described under "Morphine."

Respiration and Circulation.—Therapeutic doses ordinarily do not produce any important effects (Kochmann, 1903). The respiration is practically unchanged. The pulse may be unchanged or considerably slowed (central vagus stimulation). The blood pressure shows no change, or with somewhat larger doses a moderate rise (stimulation of vasomotor center). Toxic doses depress the respiration, the heart, and the blood pressure. With fatal doses, the respiration stops before the heart.

The Eye.—The effects of scopolamine correspond qualitatively with those of atropine. They are produced more quickly and by doses only one-fifth or one-tenth as large (Joachimoglu, 1915), but are not quite as lasting. The intraocular pressure is less affected (Bollet and Curtil, 1911). It is less irritant than atropine and patients who have an idiosyncrasy against atropine can often tolerate scopolamine. It is used like atropine (iritis, etc., 0.1 per cent.; cycloplegia, 0.2 per cent.).

The secretion of saliva sweat, mucus, etc., is paralyzed by therapeutic doses of scopolamine, more actively than by atropine.

The effects on the intestine correspond to those of atropine. The excised uterus is stimulated (Kehrer, 1907; Barbour and Copenhaver, 1915).

Isomers on Excised Ureters.—The *levo*- stimulates the contractions and slightly raises the tone. Very large doses depress. The *dextro*- inhibits without stimulation. The racemic is also inhibitory (Macht, 1918).

Scopolamine Poisoning.—The symptoms resemble those of atropine poisoning, except for the early tendency to sleep, coma, collapse, and the lesser effect on the pulse rate (Details, Seifert, *Nebenwirk.*, 1915, p. 87). The treatment would be as for atropine. The *excretion* occurs by the urine.

Scopolamine-morphine Narcosis.—The combination of the two alkaloids results in a deep narcosis that may permit of major surgical operations (Scheiderlin, 1900; Korff, 1901 to 1902; Blos, 1902). Smaller doses produce a partial anesthesia ("Seminarcosis," "*twilight sleep*" or "*Dämmer-schlaf*," Gauss, 1906 and 1907) which has been used in obstetrics. Still smaller doses quiet the patient, and may be employed to facilitate the administration of the ordinary inhalation anesthetics.

Scopolamine alone is not narcotic (for rabbits or mice), even in large doses; nor does it diminish the concentration of ether or chloroform required for light anesthesia; but it does permit a deep anesthesia with relatively lower concentrations. It also deepens the morphine narcosis. The two alkaloids used together produce a deeper anesthesia with a given concentration of inhalation anesthetic (Ludewig, 1913).

The earlier investigators believed that the mixed alkaloids produce a deeper narcosis than would correspond to the simple addition of their individual actions; *i.e.*, a "potentiated synergism" (Madelung, 1900; Buergi, 1910; Kochmann, 1913). The later work of M. I. Smith, 1915; and van Leeuwen *et al.*, 1919, fails to confirm this, and indicates a simple summation of the effects.

Buergi claimed that a dosage of scopolamine that has no effect when given alone (0.1 to 1 mg. per Kg., by mouth or hypodermically) produces narcosis when used with $\frac{2}{3}$ of the dose of morphine that is required to produce narcosis when given alone. Similar "potentiation" was described for a mixture of $\frac{1}{80}$ of the minimal effective dose of morphine with $\frac{1}{2}$ of the minimal effective dose of urethane, or $\frac{2}{5}$ morphine with $\frac{1}{25}$ urethane.

The advantages of exclusive scopolamine-morphine anesthesia, as compared with ether or gas, are rather minor, while the disadvantages are very serious (see Hatcher, *J.A.M.A.*, 1910, 54:446; H. C. Wood, Jr.,

J.A.M.A., 1906, 48:454; Bevan, *ib.*, 1915, 65: 1418; M. Kochmann, 1903; A. Mayor, 1908). The combination increases not only the narcotic action, but also the depression of respiration and circulation; and this in a very irregular degree. The susceptibility varies so much that the surgical anesthesia is often incomplete and must be supplemented by ether; and on the other hand, serious accidents and fatalities are alarmingly frequent. The anesthesia can not be modified to suit the needs of the moment. Delirium, sometimes serious, is not uncommon. The obstetric anesthesia is especially dangerous to the child, owing to the great susceptibility to morphine. In non-fatal cases, the child may show somnolence and deficient respiration for days after delivery (Jung, 1914). The use of scopolamine-morphine anesthesia is justified (if at all) only in specially equipped institutions, and not in private practice, or even in ordinary hospitals.

The smaller doses used preliminary to anesthesia would alone appear justifiable; and even these may cause marked fall of blood pressure (A. Mayor, 1908). Chloroform is especially dangerous (W. Straub, 1913). Bevan, 1915, believes that the use of the alkaloids in ordinary doses (morphine, $\frac{1}{4}$ gr.; scopolamine, $\frac{1}{50}$ gr.) adds distinctly to the risks of chloroform, ether or gas or local or spinal anesthesia, more than morphine alone; and that it has been responsible for many deaths, especially by masking the danger signals. It also increases the percentage of vomiting and of bladder paresis, and reduces immunity,

Dosage for Surgical Anesthesia.—As a preliminary to inhalation anesthesia, Korff injects hypodermically a mixture of 0.4 mg., $\frac{1}{160}$ gr., of scopolamine hydrobromide, and 10 mg., $\frac{1}{6}$ gr., of morphine hydrochloride, one and one-half hours before the operation, and repeats the same quantity an hour later. If the scopolamine-morphine is to be the chief anesthetic, to be merely supplemented by ether if necessary, he precedes these injections by another, of the same size, two and one-half hours before the operation. The total dosage would therefore be 1.2 mg., $\frac{1}{50}$ gr., scopolamine and 30 mg., $\frac{1}{2}$ gr., morphine.

Results of Scopolamine-morphine Seminarcois in Obstetrics.—The introduction of the "twilight sleep," intended to deprive labor of its terrors, has led to much discussion and diversity of opinion. Its advocates do not claim that it abolishes pain, but they assert that it successfully removes the memory of the experience, in the majority of cases, and with practically no danger to mother or child; provided it is used by experienced operators, under exactly prescribed conditions, and with proper dosage. The experience of independent observers has been contradictory, but by no means as favorable. The early failures may be attributable to excessive doses of morphine or other faults of technic; but this criticism can not apply to the later compilations. The serious objections are: prolonged labor (averaging three to four hours); frequently delayed respiration of child, sometimes requiring vigorous measures; larger number of fetal asphyxias; excessive thirst and intense headaches; difficult control of patients with chance of infection; more frequent postpartum hemorrhage; blurred vision; ghastly deliriums persisting for long time; difficult recognition of onset of second stage; masking of early symptoms of accidents; failure of narcosis in one-seventh to one-third of the cases and uncertainty of the whole treatment (Baer, 1915; Libby, 1915).

Effects on Uterus.—Morphine and scopolamine slightly increase the tone of the excised uterus, without synergism or antagonism (Barbour and Copenhaver, 1915). In anesthetized animals, there is little effect of any kind (Barbour, 1915). The clinical delay of labor is therefore probably cerebral (narcotic).

Dosage for Twilight Sleep.—The minutely defined technic can not be described here with sufficient detail to be useful. The reader is referred to the original articles, or text-books of obstetrics. It involves painstaking exclusion of noise, light and all excitant factors—apparently the coöperation of suggestion is essential. The drugs are not started until the regular pains occur, perhaps every four to five minutes and lasting half a minute. The first injection is of 0.008 to 0.015 Gm. of morphine and 0.45 mg. of scopolamine hydrobromide. The Freiburg school prefers narcophine, 30 mg., to the morphine, but this is immaterial. The morphine or narcophine must not be repeated. The scopolamine, however, is repeated; first in three-quarters of an hour with

0.45 mg., then every one and one-half hours with 0.3 mg., until amnesia (loss of memory) is sufficiently advanced. This is tested every half hour. When successful, the pains are fully felt, but promptly forgotten. The patient is rather drowsy; the heart slightly quickened (the simplified technic is described by Siegel, 1914).

PREPARATIONS

* *Scopolamine Hydrobromidum* (Scopolamin. Hydrobrom.), U.S.P.; *Hyosine Hydrobrom.*, B.P.; $C_{17}H_{21}NO_4 \cdot HBr \cdot 3H_2O$.—An alkaloid obtained from various plants of the Solanaceæ. The U.S.P. specifies the levorotatory isomer (specific rotation, 22° to 27.5°). Colorless crystals. Freely sol. in water (1:15); sol. in alc. (1:20). *Dose*, 0.5 mg. $\frac{1}{120}$ gr., U.S.P.; 0.3 to 0.6 mg., $\frac{1}{200}$ to $\frac{1}{100}$ gr., B.P. Ordinary maximum, 0.6 mg., $\frac{1}{100}$ gr.

PILOCARPINE

Pilocarpine, the principal alkaloid of jaborandi leaves (*Pilocarpus*), stimulates those peripheral structures which are paralyzed by atropine. It therefore increases the secretions, augments the gastro-intestinal movements, constricts the pupils, etc. The stimulation of these functions persists even with large doses. The vagus, however, is first stimulated, then depressed. All these autonomic actions are purely peripheral (on the myoneural junction). The central effects of pilocarpine are unimportant.

Pilocarpine is used as a miotic, but especially as a diaphoretic; in this respect it surpasses all other drugs. Pulmonary disease enjoins caution in its use, to guard against fatal pulmonary edema.

The stimulant effects of pilocarpine are easily inhibited by atropine. Conversely, pilocarpine removes the depressant effects of small doses of atropine, but is ineffective against large doses.

Other Jaborandi Alkaloids.—*Pilocarpus* contains two other alkaloids: viz., isopilocarpine and pilocarpidine. These differ merely in the strength of their action, pilocarpine being by far the strongest, and pilocarpidine the weakest. It was formerly believed that *pilocarpus* contained another alkaloid, jaborine, with atropine actions. This view has been shown to be erroneous (Jowett, 1900 and 1903; Marshall, 1904).

Arecoline, the alkaloid of *Areca* or Betel nut, is closely related to pilocarpine in its actions (Marmé, 1889; Leepin, 1891). It stimulates peristalsis (Paetz, 1910) and produces marked bronchial constriction by peripheral action, but is overcome by atropine or epinephrine (D. E. Jackson, 1914).

Glands.—Pilocarpine increases the secretion of saliva, sweat, tears, mucus, and of the gastric, pancreatic, and possibly of the intestinal juice and of the milk, not of the urine or bile. A gallon of water may be removed by these secretions, after a single injection.

Pilocarpine causes sweating after degeneration of the nerves; though less than on the sound side (Langley and Anderson, 1904). It is completely antagonized by atropine, and diminished by epinephrine—the latter perhaps through vasoconstriction.

Acceleration of the blood current through the glands occurs as a secondary effect of their increased action. A common effect of pilocarpine, a *hyperemia of the skin* (resulting in an increase of its temperature), may possibly be due to the increased activity of the sweat glands.

The increased circulation of the skin is said to increase the growth of hair, and to darken its color. The statement may be doubted.

Gastric Secretion.—The quantity and the ferment content of the gastric juice are increased (Chiari, 1913).

Production of Gastric Ulcers.—G. A. Friedman, 1918, claims that repeated hypodermic injections of pilocarpine into rabbits results in acute gastric ulcers; and that

alternate injections of pilocarpine and epinephrine produce also erosions in the duodenum. Confirmation is desirable.

Pancreatic Secretion.—Lannoy, 1905, claimed that this is not increased if the pylorus is ligated. He therefore believed that the ordinary increase is indirect, due to the increased secretion of acid in the stomach, and therefore increased production of secretin. Camas and Gley, 1913, find, however, that it is effective even when the small intestine has been removed, so that it must act directly on the pancreas.

Milk Secretion.—The earlier investigators claimed some increase (Roehrig; Ott and Scott, 1912; O. H. Henderson, 1915; McCandish, 1918); but Hays and Thomas, 1920, found the response inconstant and within the range of accidental variation. Other reputed lactagogues were also ineffective.

Urine.—Ordinarily, pilocarpine has no direct action on the urine (MacCallum, 1905); but the great loss of fluid by other channels usually diminishes the water and chloride output by the kidneys (Asher, 1905; Cow, 1912). Repeated injections of large doses produces glycosuria and diuresis, which Waterman, 1911, attributes to increased renal permeability.

Glycogenolysis.—This is not directly affected (McGuigan, 1916).

Bile and Lymph Flow.—Janagaw, 1916, claims that these are increased.

Cerebro-spinal Fluid.—This is increased by the respiratory embarrassment (Dixon and Halliburton, 1913).

Oviduct Secretions.—Pilocarpine has practically no effect on the albumen or shell production in birds (Riddle and King, 1921).

Sialagogue Action in Man.—Five to 10 mg. of pilocarpine, by mouth, increases the volume of saliva considerably. The percentage of inorganic solids is unchanged; that of organic solids shows an insignificant increase. The proportion of ptyalin is markedly diminished, but its total quantity is considerably increased (Ewing, 1911). The composition of pilocarpine saliva is not changed by the injection of sodium phosphates, sulphate or carbonate, or of glucose, unless toxic doses are given (Asher, 1908). The submaxillary gland, when perfused with Locke's solution, can be provoked to secretion by pilocarpine, but not by chorda stimulation (Demoor, 1912).

Therapeutic Use.—The *sialagogue* action is employed (10 mg., $\frac{1}{16}$ gr., by mouth, three or four times a day) against poisons which suppress this secretion (atropine, meat-poisons, etc.). The increased secretion of *mucus* may be used in a dry cough. This also results in loosening croupous membranes. The increase in biliary mucus is said to facilitate the passage of *gall-stones*. Its utility is doubtful.

Diaphoretic Action.—To produce this effect, pilocarpine should be injected hypodermically (5 mg., $\frac{1}{12}$ gr.), the patient being kept warm. This dose may be repeated in half an hour if necessary. Several liters of alkaline sweat may be excreted.

This dosage usually produces salivation, sweating, and nausea, often vomiting and singultus; exceptionally slowing of the pulse; sometimes considerable general depression, and with larger doses even serious collapse, especially in children. As has been said, pilocarpine should be avoided in pulmonary disease, since the increase of mucus and the action on the circulation may result in dangerous *pulmonary edema*.¹

The diaphoretic action is used especially in *nephritis*, to relieve the kidneys and to remove the toxic metabolites.

In paralyses of the cortical psychomotor region, the corresponding parts of the skin are said to perspire especially strongly in response to pilocarpine (Bikeles and Gerstmann, 1915).

Other Diaphoretics (Sudorifics or Hydrotics).—The secretion of sweat may be increased (1) by stimulating the secretory structures, (*a*) peripherally (pilocarpine) or (*b*) the sweating center (camphor, ammonium acetate); or (2) by increasing the cutaneous circulation, (*a*) locally (mustard);

¹ The edema produced by the drugs of this series consists rather in the aspiration of the bronchial effusion, than in a true serous effusion. Injury to the walls of the capillaries is a necessary actor for the latter.

external heat) or (b) through the vasomotor center (internal heat; alcohol, salicylates, acetanilide, nauseants, etc.).

Children sweat more, old people less easily, than adults. Among animals, horses sweat most profusely; pigs and beef, not very readily; dogs, rabbits, and sheep not at all; cats only on the paws.

Indications for Diaphoretics.—The various sudorific measures specially adapted to the different indications are as follows:

For the Absorption of Edemas and Exudates.—A powerful action is needed: pilocarpine combined with external heat (hot baths or packs).

To Relieve Inflamed and Overtaxed Kidneys.—The large amount of fluid and excrementitious material removed by a thorough sweating secures functional rest to the kidneys and lowers blood pressure. Here, also, pilocarpine and hot baths are preferred.

Ordinary sweat (Hoelscher, 1904) contains 0.22 to 0.81 per cent. of ash, and 0.043 to 0.084 per cent. of nitrogen, mainly in the form of urea, (0.285 per cent. of NaCl and 0.21 per cent. of urea; Kovesi). The daily cutaneous excretion of nitrogen is from 0.3 to 1.8 Gm. (Benedict, 1905; Schwenkenbacher and Spitta, 1907). Even during rest, the sweat averages 0.07 Gm. of nitrogen per day. This is considerably increased in proportion to muscular labor, to 0.22 Gm. of nitrogen per hour (F. C. Benedict, 1905).

The sweat excreted under the influence of pilocarpine contains in normal individuals 0.051 to 0.085 per cent. of nitrogen, and 0.26 to 0.31 per cent. of ash. Three liters of sweat—a not unusual quantity after pilocarpine—would therefore remove about 2.5 Gm. of nitrogen. In nephritis, the nitrogen content may be much higher, to 0.288 per cent.; so that the 3 liters could remove 8 Gm. of nitrogen. This indicates how efficiently the kidneys may be relieved by diaphoresis. This is also shown by the examination of the blood; the abnormally great depression of the freezing point of the blood of uremic patients may be reduced to normal by diaphoresis (Bendix, 1904). The freezing point of the blood of normal animals is not affected. Alimentary glycosuria could also be prevented by free diaphoresis, the excess of sugar being excreted by the skin. However, Austin and Miller, 1914, could find no evidence that sweat baths materially diminish the nitrogen retention in nephritis.

To reestablish disturbed circulation in the skin, and thereby to influence the circulation of internal organs: this determines their use in colds, rheumatism, etc.; in cold skin from whatever cause; in inflammations of the lungs, pleura, etc. Relatively mild diaphoretics suffice for this purpose: External heat; hot drinks (teas, lemonade or alcohol); Sweet Spirits of Nitre; Dover's powder; salicylate, etc.

The increased vascularity of the skin is also used to hasten the outbreak of *febrile exanthemata*, to promote the absorption of *salves*, etc. Further, in certain diseases of the skin where its nutrition is defective.

For the removal of poisons, especially in chronic intoxication by the metals. The efficiency is doubtful. Hot baths and drinks would be used.

In *ophthalmology*, diaphoresis has been found useful in congestive and exudative lesions of the uveal tract, in retinal detachment and in toxic blindness; it is useless in atrophic and cicatricial lesions.

Pilocarpine on Unstripped Muscle.—The stimulation of the myoneural junction of the cranio-sacral autonomic nerves results in contraction of most unstripped muscles (not of the blood vessels). The intestines are especially stimulated, with diarrhea and colic. The stimulation extends also to the muscles of the bronchi, uterus, ureter, bladder, spleen, stomach, etc.

The pharmacologic details are discussed under the general description of the autonomic system.

The *nausea and emetic action* are essentially central (Eggleston and Hatcher, 1915). They are antagonized by atropine (Eggleston, 1916).

Leucocytosis results from the contraction of the spleen and lymph glands (Harvey, 1906). The gall-bladder is stimulated (Lieb and McWhorter, 1915).

Development of Ova.—Sollmann, 1904, described the phenomena of antagonism with atropine.

Yeast Formation.—Somogyi, 1916, claimed that this is inhibited by small concentrations, but stimulated by larger doses.

Eye-effects.—The application of pilocarpine produces miosis and spasm of accommodation, by peripheral stimulation of the oculomotor. The intraocular tension is affected as with physostigmine, first raised, followed by more persistent fall. Pilocarpine nitrate in $\frac{1}{2}$ to 4 per cent. solution is applied as a milder substitute for physostigmine in glaucoma, corneal ulcer, etc.

The miosis begins in fifteen minutes (independently of the concentration); reaches its maximum in thirty to fifty minutes, and disappears in twenty to twenty-four hours. The spasm of accommodation also begins in fifteen minutes, and lasts about two and one-half hours.

Suprarenal Stimulation.—Dale and Laidlaw, 1912, describe evidences of oculomotor stimulation even if the cervical ganglia have been excised but not if the suprarenal has been removed. They ascribe this to stimulation of the suprarenals *i.e.* increased production of epinephrine. There is a similar condition as regards the uterus. Jackson, 1913, accepts the same explanation for a dilator effect on bronchial muscle. Stewart and Rogoff, however, have shown that pilocarpine does not increase the output of epinephrine.

Circulation.—Pilocarpine first stimulates, and then paralyzes the vagi peripherally, and therefore produces slowing (in frogs, diastolic standstill, Harnack and H. Meyer, 1880), followed by quickening of the heart rate. In mammals, the stage of stimulation and slowing is very short; it may be entirely absent in dogs, and often in man. In these the blood pressure rises, partly from the faster heart, and perhaps partly through stimulation of the vasomotor center.

Nelson and Keiper, 1923, observed, with small doses, that the organ volume may increase after the fall of blood pressure, from which they conclude on a vasomotor factor. Such deductions, however, are insecure.

Perfused blood vessels are dilated (frogs, Froelich and Pick, 1913; lung, Baehr and Pick, 1913). Berezin, 1914, claims constriction of the lung vessels.

Frog's Heart.—The slowing occurs after nicotine (Gaisboeck, 1911) and is therefore probably postganglionic. The vagus excitability is increased. Combinations with muscarine give additive effects; physostigmine does not (Loewi, 1912). In the secondary vagus depression, stimulation of the sinus produces but little slowing, showing that this action is also largely postganglionic. High concentrations paralyze the cardiac muscle. Small doses of chloral, by depressing the cardiac muscle, delay the escape from vagus inhibition, whether by pilocarpine, muscarine, or electric stimulation (Loewi, 1912).

Chronotropic and Inotropic Antagonisms.—Perfusion of the excised frog heart with 0.001 to 0.02 per cent. pilocarpine produces both slowing and weakening. These are due to distinct functions of vagus stimulation. Both are antagonized by atropine which paralyzes both the chronotropic and inotropic functions; and by epinephrine and caffeine, which stimulate the heart muscle. The digitaloids antagonize the weakening, but not the slowing (F. Ransom, 1917).

Terrapin's Heart.—Pilocarpine arrests the contractions, but does not affect the auricular tonus waves (Gruber and Markel, 1918; Gruber, 1920).

Excised Mammalian Heart (Hedbom-Langendorff).—The effects are similar to the frog heart, but the stage of vagus stimulation is short: the rate is suddenly slowed; this lasts but a short time, then there is marked quickening with increased tonus (peripheral paralysis of vagus). If the auriculo-ventricular bundle is divided, pilocarpine or muscarine does not produce inhibition (Cullis and Tribe, 1913); nor do they inhibit isolated ventricular strips (Leatham, 1913). Their action must therefore be on the auricular vagus terminations. Large doses paralyze the muscle.

Increased Blood Concentration.—Bornstein and Vogel, 1921, find in dogs and rabbits that pilocarpine (1–2 mg. per Kg.) concentrates the blood (increase of corpuscles, hemoglobin and protein); the chloride concentration is not changed; the glucose is increased by more than the amount due to loss of fluid. All these changes are antagonized by atropine.

Central Nervous System.—The action is weak and appears late, so that it is entirely overshadowed by the peripheral actions. The effects are mainly *depressing*. *Vasomotor paralysis* is a rather early and prominent symptom; it leads to *dyspnea*. Later, the *respiratory center* is also depressed. The *motor centers*, especially those of the cord, show some stimulation (increased reflexes, tremors, convulsions) and later paralysis. The emetic center is stimulated.

Metabolism.—Pilocarpine somewhat increases CO₂ production and tends to raise the temperature, even in curarized animals, *i.e.*, by direct stimulation of the glands and unstriated muscle. The increase is antagonized by atropine (Keleman, 1918).

Mendel and Stehle, 1915, claim that pilocarpine and other stimulants of digestive glands increase the excretion of uric acid.

Fate and Excretion.—A large part is excreted unchanged, but in combination, by the urine (Curci).

Disintoxication of Pilocarpine by Tissues.—The activity of pilocarpine is destroyed by digestion with liver-emulsions or serums; but active pilocarpine can be extracted from such mixtures by acidified alcohol. The inactivation is therefore probably an adsorption phenomenon.

The “bound” alkaloid does not dialyze (Beutner, 1923) and is not precipitated by iodine (Jendrassik, 1923). The inactivating substance is not cholesterol or lecithin. Its quantity varies for the serum of different animals, the disintoxication occurring most readily in the serum of rabbits and least readily in dogs; with cat or ox serum intermediate (van Leeuwen, 1918).

Similar combinations appear to occur between rabbits’ serum and other alkaloids; for instance atropine, strychnine, procaine and cocaine (Beutner, 1923).

Symptoms of Poisoning.—The toxicology of pilocarpine is not very important. The symptoms, which apply also to muscarine, begin with greatly increased secretion of saliva, sweat, and tears; then nausea, profuse vomiting, and painful diarrhea; pupillary contraction and spasm of accommodation; pulse variable in rate, tense, and arrhythmic; palpitation; dyspnea with râles; sometimes confusion of ideas, vertigo, tremors, and feeble convulsions. Death occurs either by paralysis of the heart or edema of the lungs.

Untoward effects from the alimentary canal are seen most frequently if the drug is given by mouth, but occur also on hypodermic administration. They consist in very prolonged and depressing nausea and vomiting, sometimes leading to collapse. The disturbance of accommodation causes misty vision. A burning sensation in the urethra, with sudden and irresistible desire to urinate, is often noticed.

Treatment.—Atropine is a physiologic antidote. Otherwise, the general treatment of alkaloidal poisoning would be employed.

PREPARATIONS

Pilocarpin. Hydrochl., U.S.P.—Very sol. in water (1:03). *Dose*, same as the Nitrate. The hydrochloride is highly deliquescent and therefore undesirable (A.M.A. Laboratory Report, 1920, 12:96).

* **Pilocarpinæ Nitras** (Pilocarpin. Nit.), U.S.P., B.P.; C₁₁H₁₆N₂O₂.HNO₃.—Colorless, faintly bitter crystals. Freely sol. in water (1:4). *Dose*, 5 mg., 1/4 gr., U.S.P.; 3 to 12 mg., 1/20 to 1/5 gr., B.P. Maximum dose, 30 mg., 1/2 gr.

PHYSOSTIGMINE

Physostigmine (also called *eserine*), the alkaloid of physostigma or “calabar bean,” stimulates the peripheral structures which are paralyzed by atropine. Its most important actions consist in powerful contraction of the smooth muscle of the eye (miosis) and intestine. It is employed in eye diseases (glaucoma, etc.) and in intestinal paresis. The glandular stimulation is less marked than with pilocarpine. It also causes fascicular twitching of striped muscle and is mutually antagonistic with curare

and substances having a curare action. On the central nervous system, the effects are mainly paralyzing. They have a toxicologic importance and limit its internal use.

Actions on the Eye.—Physostigmine causes constriction of the pupils (discovered by Fraser of Edinburgh, 1863); spasm of accommodation (near vision); twitching of the eyelid and lowering of the intraocular pressure. These actions are due mainly to increased excitability of the oculomotor receptive mechanism. The effects of physostigmine can be removed by the application of atropine, and *vice versa*; but this requires much larger doses than does a normal eye. The localization was discussed in the general description of autonomic reactions.

The action on the pupil appears somewhat earlier and lasts somewhat longer, than that on accommodation; on local application of a 1 per cent. solution, the *miosis* begins often within ten minutes, reaches its maximum in thirty to fifty minutes, stays maximal for three or four hours, and then disappears gradually in three or four days. The physostigmine contraction is greater than can be produced by the strongest light, although the physostigmine pupil contracts further even to weak light. With the maximal contraction, the pupil is generally irregular in shape. Physostigmine is much more effective in counteracting the mydriasis of cocaine than that of atropine.

The *spasm of accommodation* begins in about twenty minutes, and passes off in about two and one-half hours, leaving the excitability somewhat increased. Through the contraction of the ciliary muscle, the lense becomes more spherical, and objects appear enlarged and more distant.

Excised Iris Sphincter of Mammals.—This is constricted by dilutions down to 1:30,000, the intensity varying with the concentration. With 1:50,000, it dilates (D. R. Joseph, 1917).

Intraocular Tension.—In the normal eye, physostigmine produces a slight fall (3 to 8 mm.) lasting some twelve hours (Luebs, 1913; Myashita, 1913). The fall is more marked in glaucoma (Bollet and Curtil, 1911).

Trypan Red.—After intravenous injection, this dye appears in the aqueous humor much more abundantly when the eye is inflamed, or when physostigmine is applied. It is not influenced by atropine (P. A. Lewis, 1916).

Therapeutic Use of Oculomotor Actions.—Physostigmine may be used to counteract the effects of atropine; to break up adhesions of the iris and lens (in alternation with atropine); in the treatment of peripheral corneal ulcer and to lower the intraocular pressure in *glaucoma*. The continued use of physostigmine or pilocarpine produces distinct amelioration of the glaucoma symptoms, often more than iridectomy; but they are, of course, not curative (Posey, 1914). Witmer, 1921, states that strong solution (2 drops of 1 per cent.) may provoke an acute attack of glaucoma in patients subject to the disease; whilst $\frac{1}{50}$ per cent. solution tends to relieve attacks. Even this concentration may produce conjunctivitis if its use is long continued. The mechanism of its action in *ulcer* is not understood; it is perhaps explained by contraction of the iris vessels.

Application.—Physostigmine is always used locally, in $\frac{1}{10}$ to 1 per cent. solution of the sulphate or salicylate (in glaucoma 0.1 to 0.4 per cent., two to six times a day). Solutions of 0.5 per cent. and higher sometimes cause considerable irritation and pain. This is lessened by employing an oily solution of the free alkaloid. Casey Wood advises the addition of $\frac{1}{5}$ per cent. of cocaine to $\frac{1}{10}$ per cent. of physostigmine; or pilocarpine or arecoline may be substituted.

Intestines.—Therapeutic doses of physostigmine increase gastric and intestinal peristalsis. Toxic doses produce tetanic contraction of the gut. The action is utilized in intestinal paresis (postoperative ileus, etc.), 2 mg. ($\frac{1}{30}$ gr.) hypodermically (larger doses would be dangerous). Cannon

and Murphy, 1907, have shown that it has a marked effect, lasting, however, only a few hours.

Other unstriated muscles contracted by physostigmine are those of the bladder, spleen, ureter, uterus, arterioles, and bronchial muscles.

Synergism of Smooth Muscle—Fuehner, 1918, found on the ganglion-free smooth muscle of the leech-body a most remarkable potentiation by physostigmine of the stimulant action of acetyl choline (over 1,000,000 times); and to somewhat less degree of barium, whilst choline and pilocarpine, etc., are not potentiated at all by physostigmine.

Guanidine acts like physostigmine, but somewhat weaker.

Rings from frog stomach may show the potentiation or not, inverse to the original tone. The irregularity is perhaps attributable to the nerve-centers.

Mammalian organs do not show any potentiation.

Earthworms.—Physostigmine produces peculiar contortions (Sollmann, 1918).

Glandular Secretions.—Physostigmine stimulates the same glands as pilocarpine (except milk; Ott and Scott, 1912); but the increase of secretion is much less marked, being counteracted by the vasoconstriction. Like other intestinal stimulants, physostigmine increases the elimination of *uric acid* (Abl, 1913).

Sweat.—Physostigmine provokes sweating of cat's paw. This is decreased or arrested by section of the nerves, so that the action is perhaps partly central (Langley and Kato, 1915).

Epinephrine Output.—This is increased by physostigmine, in contrast to pilocarpine. The stimulation is central, *i.e.*, does not occur after section of the nerves (Stewart and Rogoff, 1920).

Striped Muscle.—Small doses of physostigmine lower the threshold to stimulation; and somewhat larger doses produce fibrillary twitchings. These may be noted locally in the clinical application, for instance in the eyelids (compare also the effect on "idiomuscular contraction," E. Frank and Nothmann, 1921). Similar twitchings are produced by guanidine, barium and nicotine, and by nerve tetanization in certain stages of fatigue (Langley, 1916; Langley and Kato, 1920). The physostigmine twitchings persist after section of the motor nerve (sciatic). They are therefore peripheral (Harnack and Witkowski, 1876). They are suppressed by curare, which paralyzes the endings; on the other hand, physostigmine removes the curare paralysis (Pal and Rothberger). Atropine and scopolamine also arrest the twitching. A similar antagonism exists between physostigmine and magnesium salts (Meltzer and Auer, 1906; Joseph, 1908; Joseph and Meltzer, 1909).

Magnus, 1908, and Langley and Kato, 1915, found that the physostigmine fibrillations cannot be produced when the motor nerve has been cut and allowed to degenerate completely (but while the muscle fibers still respond to direct stimulation). Apparently, therefore, the receptive mechanism for physostigmine degenerates more rapidly than that for nerve-stimulation. In fowls, physostigmine produces a tonus, which is not prevented by nerve degeneration, nor antagonized by atropine (Edmunds and Roth, 1908).

Aside from the fascicular contractions, physostigmine also provokes coarser contractions of the muscles; nystagmus, and rhythmic movements of the nictitating membrane of cats. These are of central origin and are abolished by atropine.

Circulation.—In mammals, ordinary doses slow the heart by vagus stimulation, and raise the blood pressure by vasoconstriction. Large doses produce further slowing and fall of pressure. In man, however, serious dizziness and faintness occur before the heart rate is affected (Robinson, 1915). In frogs, the heart muscle is stimulated directly so that it contracts more strongly, and can not be stopped by vagus stimulation. The action of cardiac depressants is antagonized. (This stimulant action is not noted in mammals.)

The slowing in mammals is due to peripheral vagus stimulation, sufficiently powerful to counteract even atropine (Winterberg, 1907).

The rise of pressure must be vascular, since the cardiac output is not increased. It occurs after destruction of the spinal cord and must therefore be peripheral. It is due partly to the contraction of the intestines, and partly to direct stimulation of the arterial nerve-endings. It does not occur after apocodeine (Dixon, 1903). **The fall of pressure** is due to central vasomotor paralysis and to cardiac depression.

Sensitization of Cardiac Responses by Physostigmine.—Froehlich and Pick, 1920, found that preliminary treatment of the frog's heart (Straub method) with physostigmine rendered it more sensitive to ammonium, Ca and Ba, and especially to the diastolic action of strophanthin; so that even maximal doses of the latter did not produce contraction, but only diastolic arrest. This was not affected by atropine, but could be prevented by changes in the ion-ratio of the Ringer's solution.

Blood.—Physostigmine produces an acute increase of the red cells and also of the total volume of the circulating blood, (maximum in an hour, return to normal in 2 or 3 hours) (Nelson and Edmunds, 1923). This is perhaps an indirect result of the stimulation of smooth muscle, which might express the blood from stagnant areas.

Central Effects.—The action on the central nervous system is first tetanizing (Heubner, 1905); then rapidly paralyzing, *beginning*, at least in man, in the *lower portions*, so that *consciousness is preserved* to the end. The *respiration* is at first increased; this is due largely to stimulation of the afferent endings of the vagi; for the quickening is much less after the vagi have been cut.

There are also other evidences of stimulation—excitement, etc.—but these have been considered *secondary to respiratory paralysis*, the central actions of the alkaloid being mainly depressing. Dyspnea is a marked symptom, due to paralysis of the respiratory center and spasm of the bronchial muscles. Asphyxia forms the *cause of death* (Harnack and Witkowski, 1876).

The depressant action of physostigmine has led to its therapeutic trial in epilepsy, chorea, tetanus, etc., without much success.

Physostigmine Poisoning.—The *symptoms* consist in restlessness, weakness, nausea, vomiting, sometimes purging; epigastric pain; rarely miosis; salivation, lachrymation and sweating; palpitation with slowed pulse; dyspnea; muscular twitchings; convulsions. Death occurs by paralysis of respiration, under general collapse, with the reflexes preserved to the end. The fatal dose is not known.

The location of the *emetic action* has not been definitely determined, because of the difficulty of fixing the emetic dose (Eggleston and Hatcher, 1915).

Treatment of Physostigmine Poisoning.—This consists in evacuation, stimulants and atropine ($\frac{1}{2}$ to 1 mg.).

Frazer found that small doses of atropine saved animals from three times the fatal dose of physostigmine, but that larger doses are synergistic; Curare and Magnesium are effective in the laboratory, but are dangerous for man.

Fate.—Physostigmine is not destroyed by frog's liver (Clark, 1912).

PREPARATIONS

* *Physostigminæ Salicylas* (Physostig. Salicyl.), U.S.P. (Eserine Salicylate); $C_{16}H_{21}N_3O_2 \cdot C_7H_5O_3$.—Colorless or faintly yellow crystals; of slightly bitter taste. Soluble in water (1:75) and in alc. *Dose*, 2 mg., $\frac{1}{30}$ gr., U.S.P.

Watery solutions of Physostigmine salts (not the dry salts) oxidize under the influence of light, air, and the alkali of glass vessels, acquiring a pink color (due to "rubreserin," Woelfflin, 1913). Such colored solutions should not be employed; Hallauer, 1899, states that they are more irritant, although the miotic action is not impaired. The decomposition is retarded by the addition of a little boric acid.

Physostig. Sulph., B.P.—More freely soluble, but less stable. *Dose*, 1 to 2 mg., $\frac{1}{64}$ to $\frac{1}{32}$ gr., B.P.

Lam. Physostig., B.P.—0.065 mg., $\frac{1}{1,000}$ gr.

MUSCARINE

Muscarine, an organic ammonium base, found in a mushroom, and a similar base, prepared synthetically from choline, produce typical peripheral stimulation of the parasympathetic system, *i.e.*, all the effects of pilocarpine; and also a nicotine and curare action.

The most characteristic action of muscarine is a vagus standstill of the frog's heart. Its interest is mainly scientific, and to some extent toxicologic, since it occurs in the most poisonous fly-mushroom.

Constitution.—Muscarine, as isolated by Schmiedeberg and Koppe, 1869, from the fly agaric (0.016 per cent. in the fresh fungus; Harmsen, 1903), is a substituted ammonium base. It is closely related to choline (trimethyl-oxyethyl-ammonium hydroxide):

Synthetic Muscarine.—"Synthetic Muscarine" is prepared artificially by the oxidation of choline ("choline-muscarine") and was supposed to have the same composition: later investigations, however, showed that it is the nitrous ester of choline (Dale and Ewins, 1914). Its actions agree qualitatively with those of the natural, but exhibit quantitative differences; the natural being ten times stronger on the heart, while the synthetic produces more pronounced nicotine and curare actions (Schmiedeberg and Harnack, 1876; Boehm, 1885; H. Meyer, 1893; Honda, 1911). The antagonism to atropine is also less complete with the synthetic base.

Weinhagen, 1920, finds that the composition of synthetic muscarine differs with slight and accidental variations in the method of its preparation.

Muscarine Action on Frog's Heart.—Muscarine causes slowing, with lessened systolic and increased diastolic excursions, and finally *stoppage in diastole*. These effects resemble those of electric vagus stimulation (also the electrocardiogram; Samojloff, 1913); and the results of submaximal vagus stimulation and muscarine are strictly additive, in frogs (Honda; O. Loewi), in turtles (Fleischhauer, 1912), and in mammals (Schott, 1911). Muscarine also produces additive results with pilocarpine. Large doses of both paralyze the vagus (Loewi) and the ganglia (Schott). The muscarine effect is more persistent than electric vagus stimulation, and occurs even in calcium-poor hearts, in which ordinary vagus stimulation is ineffective (Loewi, 1912).

The refractory period of the heart to artificial stimulation is shortened by weak muscarine, as by vagus stimulation (Raaflaub, 1914). The effects of muscarine on the electric response of the heart was investigated by Mines, 1914.

Perfusion of the excised frog heart with very dilute muscarine in Ringer's solution produces simultaneous weakening and slowing. If it is perfused in blood, it may also slow without weakening; while perfusion of muscarine blood through the isolated ventricle may give weakening without slowing (Raaflaub, 1914).

Turtle Heart.—Muscarine increases the auricular tonus waves (Fano and Sciolla; Gruber and Markel, 1918).

Location of Action.—In mammalian hearts, muscarine causes no inhibition if the auriculo-ventricular bundle is cut (Cullis and Tribe, 1913), or in ventricular strips (Leetham, 1913); but in frogs, the muscarine standstill occurs also in the isolated apex, showing that the stimulation is peripheral to the ganglia; and since it can be abolished by atropine (Schmiedeberg and Koppe), the action can not be on the muscle. It is therefore assumed that it stimulates those endings which atropine paralyzes. If muscarine and atropine are exhibited at the same time or successively, their respective quantities will determine which predominates, but atropine is much the stronger. Drugs which act upon the ganglia—e.g., nicotine—will be ineffectual; but the standstill may be raised by substances effecting a direct stimulation of the muscle fibers—e.g., physostigmine, veratrine, digitaline, aniline, camphor, guanidine. It should be added, however, that the type of contractions under muscarine differs in some respects from those of vagus stimulation (Rhodius and Straub, 1905).

It is interesting that muscarine causes an acceleration of the crab's heart, although a well-defined inhibitory mechanism exists in these animals.

In guinea pigs, it may cause bronchial spasm, similar to that of anaphylactic shock (Modrakowski, 1912). It has no effect on *lacteal secretion* (Ott and Scott, 1912).

Excretion.—In toads, this occurs quantitatively by the urine (Fuehner, 1908 and 1909).

MUSHROOM POISONING

Active Constituents.—Many fungi contain poisonous constituents, varying in the different species. Ford, 1911, 1913, has studied a large number of species, and finds that the principles toxic to man belong mainly to three classes: (1) muscarine, which is confined practically to the "fly-mushroom," *Amanita muscaria*;¹ (2) substances producing degenerative changes in internal organs (especially *Amanita phalloides*); (3) substances producing gastroenteritis.

Glucosidal hemolysins are also present in *Amanita phalloides* and several related varieties, especially in *Helvella esculenta* (Ford, 1913). They are easily decomposed by heat and digestion, and are therefore not concerned in poisonous effects. *Agglu-*

¹ *Agaricus remousus* also owes its effect to muscarine (Muto, 1918).

tinins, perhaps glucosidal, are also widely distributed; some of these are not destroyed by boiling, but they are probably not pathogenic (Ford and Rockwood, 1913). Practically all species of *Amanita* slow or stop the frog heart on direct application. In the case of *A. phalloides*, this is not due to muscarine, but to inorganic salts (Ford and Brush, 1914).

From *Amanita phalloides*, two interesting principles were isolated in pure form, one a hemolysin, the other a toxin. Both are antigens, a high-valence serum being obtainable against the hemolysin, a much weaker one against the toxin. Nevertheless, the hemolysin is a typical glucoside (Abel and Ford, 1907), identical with the "phalline" of Kobert, which was formerly considered a toxalbumin. It is readily destroyed by cooking. The toxin (which was considered an alkaloid by Kobert) is alone responsible for the symptoms of poisoning (widespread fatty degenerations of important organs; Ford, 1906 and 1909; Abel and Ford, 1908). Rabe, 1911, claims to have also isolated an alkaloid of muscarine action.

Symptoms of Mushroom Poisoning.—These vary with the species. More or less common features are: Abdominal pain, nausea, vomiting, violent diarrhea; variable pulse; labored respiration; consciousness unaffected, or delirium; coma or convulsions. Some cause fatty degeneration of the liver and kidneys. Many mushrooms produce abdominal symptoms simply by being indigestible.

The **treatment** would be by evacuation, and symptomatic. The chance of poisoning may be somewhat diminished by prolonged boiling, as some of these substances are decomposed in this manner, but reliance on this would be dangerous. Drying does not diminish the toxicity. Verrill, 1914, reports symptoms of inebriation (not dangerous) from eating *Panaeolus papilionaceus* (Maine).

Symptoms of Amanita Phalloides Poisoning.—These set in after a latent period of six to fifteen hours; sudden abdominal pain, with vomiting and diarrhea, stool containing blood and mucus; rapid loss of strength; cyanosis; death in two or three days. Histologic examination shows extensive necrosis and fatty degeneration of visceral organs (Ford, 1913). Uremia, from greatly impaired kidney function, may be responsible for part of the symptoms (Clark, Marshall and Rowntree, 1915).

Edible Mushrooms.—The food value of mushrooms is popularly supposed to lie in a large percentage of assimilable nitrogen. This is not borne out by analyses; they contain 0.1 per cent. in the fresh condition, or 0.3 to 1.5 when dried; *i.e.*, no more than potatoes, and only one-tenth as much as wheat bread, or one-thirtieth of that in lean meat. As the fiber of mushrooms is also quite indigestible, their dietary value is as a relish rather than as food.

CHOLINE

Choline (trimethyl-oxyethyl-ammonium hydroxide),

occurs as a constituent of lecithin probably in all animal and vegetable tissues, although often merely in traces. It is doubtful whether it exists free in the living tissues, in detectable quantity, but it may be liberated by putrefaction or autolysis, not by pepsin or trypsin (Coriat, 1904). It therefore occurs in organ extracts, in many vegetables (Schulze and Trier, 1912) and in certain drugs (especially ergot). It may be formed in intestinal putrefaction and thus contribute to the systemic phenomena of constipation; but it is readily destroyed by the intestinal bacteria and is less toxic than the analogous neurine and various amines which are also found in putrefaction. Choline is also but slightly toxic on hypodermic injection.

The peripheral actions comprise two independent elements: a muscarine effect (stimulation of parasympathetic endings, similar to physostigmine); and a nicotine effect (stimulation and paralysis of autonomic ganglia; curare action on muscle). These two sets of actions are produced, in varying degree, by all quaternary ammonium bases (Dale, 1914).

The most marked effects of choline are on the blood pressure, which it usually lowers, often with a secondary rise. After atropine, it produces a rise instead of fall. The fall is due mainly to a powerful vasodilator action, exerted directly on the vessels, but not fully understood.

Acetyl-choline and other choline esters produce similar effects, and are much more active.

Action on Blood Pressure.—Choline generally produces a marked fall of blood pressure (Mott and Halliburton, 1897); but sometimes there is instead a rise of pressure. In cats, the rise generally follows the fall (Pal, 1911). The variable response does not depend upon impurities (Renshaw, Underhill and Mendel, 1912). The result is influenced by the dose, anesthetic, and other conditions (Abderhalden and Mueller, 1911). The fall predominates if the blood pressure has been high (Benelli, 1914); in protracted ether narcosis, and after some sorts of curare. It counteracts the epinephrine rise (Gautrelet, 1909). The *pressor effect* is more prominent in light anesthesia, or after section of the medulla (Pal, 1911).

After large doses of *atropine*, choline gives only a rise; and it also constricts the vessels of excised and perfused organs, after atropine (Mueller, 1910). Nicotine does not act like atropine (Hunt and Taveau, 1911).

Mechanism of the Circulatory Action.—This involves to a varying degree the vasomotor center, the vessels themselves, and the heart.

The work of Hunt, 1918, indicates that the peripheral vasodilation is the most important. With acetyl-choline, there is an intense dilation of the vessels of most organs, including the skin; relatively feeble in the splanchnic area in comparison with the nitrite fall; doubtful in the kidneys; absent in the lungs. Larger doses are constrictor.

This dilator effect is more powerful than that produced by any other method. It is diminished or prevented by atropine, but synergized by physostigmine. It does not involve any of the known vasodilator paths, sympathetic or parasympathetic, or the posterior roots. Apparently it is not connected with the nerves, and is different both from epinephrine and nitrite dilation, which are not antagonized by atropine.

Peripheral vascular dilation by choline was previously described by Handovsky and Pick, 1913; Hunt, 1915; and Dale and Richards, 1918. Mueller attributed the fall of pressure partly to cardiac stasis, but also to vasodilation in the extremities, intestines, kidneys and brain; he attributed the atropine reversal to paralysis of the dilator elements.

Vasomotor Center.—Pilcher and Sollmann, 1915, showed that choline produces a marked direct depression of the vasomotor center, which seems to play an important part in the fall of blood pressure, and which is abolished by atropine. However, other causes contribute to the fall; and when these predominate they may overcome the vasomotor depression, and may even stimulate the center by anemia.

Heart.—Choline weakens and slows the heart by vagus stimulation, central and peripheral (Hunt, 1915; Patta and Varisco, 1915; and Pal, 1911). This vagus effect is mutually antagonized by atropine and by epinephrine, in the perfused frog heart (Barlow and Sollmann, 1926). The turtle heart is said to be slowed but strengthened (Lausana, 1913).

Organ Extracts.—The fall of blood pressure produced by the extracts of many organs and of nerve tissue may be due partly to their choline content; but some characteristic differences have been described (Osborne and Vincent, 1900; Busquet and Pachon, 1910).

Choline Derivatives.—Hunt and Taveau, 1906, 1909, 1911; Hunt, 1915; Ewins, 1914; and Dale, 1914, have investigated the relative toxicity and circulatory effects of a large series of *choline derivatives*, with very interesting results. For instance, the substitution of OH in choline, in almost any manner, generally increases its activity, often very greatly (Dale). The introduction of the acetyl radical increases the depressor effect 100,000 times, the toxicity only three times (Hunt). Ewins, 1914, has found acetyl-choline in ergot, and considers it responsible for the cardiac inhibition.

Peristalsis.—Choline stimulates gastric and intestinal peristalsis like the other parasympathetic stimulants, but is milder and less toxic. X-ray observations on cats after slow intravenous injection of 5 to 10 mg. per Kg. show that the increased peristalsis is of the normal type and not spasmodic. The stimulation persists for hours. The large intestines are relatively little affected (Le Heux, 1921). Such injections also remove the gastro-intestinal paresis produced by prolonged chloroform anesthesia (V. Kuchlewein, 1921), or by peritonitis through laparotomy and handling, or through the intraperitoneal injection of iodine (Arai, 1922). Adequate observations on animals other

than cats are lacking. In rabbits, however, the beneficial effects of choline are not very marked.

Weiland, 1912, showed that saline solutions in which intestines have been immersed extract a stimulant substance from the serous coat. Le Heux, 1918, identified this as choline, and showed that its removal from the intestines decreased their excitability, and their response to atropine. He therefore assumed, perhaps without sufficient justification, that choline serves as a normal "peristaltic hormone;" and also, that the cathartic action of the salts of organic acids is due to the synthesis of powerful choline esters (1921).

Toxic Dosage.—With ordinary slow venous injection, cats show no toxic effects after 15 mg. per Kg.; 30 mg. produce reversible arrest of respiration; 35 mg. per Kg. are fatal. As the choline is rapidly destroyed, 0.8 to 0.9 mg. per Kg. per minute (as 0.2 to 0.4 per cent.) may be injected practically indefinitely (Arai, 1922). Magnus, 1925, proposed for *clinical use*, the intravenous injection of 0.6 mg. per Kg. per minute, for 17 minutes. However, the formation of decomposition products may greatly increase the toxicity, so that caution would be necessary. Properly prepared ampules do not deteriorate.

Striped Muscle.—Acetyl choline produces a contracture, which is antagonized by atropine, not by curare (Riesser and Neuschloss, 1921).

Sterility.—Werner and Lichtenberg, 1906, claim that choline injections, in rabbits, produce sterility or lessened fertility, analogous to the effects of X-rays or thorium X. Werner and Asher, 1912, find similar blood and skin changes.

Distribution.—Normal serum contains about 1 part of choline in 400,000; about the same concentration exists in amniotic fluid; somewhat more in the urine, and in cardiac and skeletal muscle; much less in cerebro-spinal fluid and saliva. The proportion in the blood or cerebro-spinal fluid has not been found increased in any pathologic conditions examined in man. It has been reported increased by removal of the suprarenals, but the evidence is not decisive and does not prove any causative connection (Hunt, 1915).

Fate.—Choline is largely destroyed in the body (v. Hoesslin, 1906); a part of the methyl being probably oxidized to formic acid, the remainder to CO₂ and water. After oral administration, only 3 per cent. of the choline can be recovered from the tissues; with intravenous, about 50 per cent., the greater proportion from the skin (Ellinger, 1914). It disappears rapidly from the blood stream (Hunt, 1915).

Practically none is excreted by the urine after hypodermic injection of large doses; and very little after intravenous injection (Guggenheim and Loeffler, 1916).

Neurine.—Trimethyl-vinyl ammonium hydroxide; $(\text{CH}_3)_3\text{N} \begin{cases} \text{CH:CH}_2 \\ \text{OH} \end{cases}$ may be

formed from choline by bacteria. Its actions are similar to choline, but much stronger (Pal, 1911); and it is far more toxic (Lohmann, 1911).

Betaine.— $(\text{CH}_3)_3\text{N} \begin{cases} \text{CH}_2\text{COOH} \\ \text{OH} \end{cases}$ is nearly inactive by mouth; hypodermically,

it acts similarly to choline. It is quite non-toxic (Velich, 1914); even 2.4 Gm. per kilogram by vein, in the rat, are harmless. It is excreted unchanged, and is therefore not a food (Andrlick, Velich and Stanek, 1902). The preparation and properties of its salts are described by Stolzenberg, 1914.

R. R. Williams, 1917, considers the betaine ring as probably essential to antineuritic *vitamine*. Betaine itself is somewhat protective, although not very efficient.

Betaine hydrochloride dissociates in solution, and has been utilized as a means of administering loosely bound hydrochloric acid. The dose, 0.5 Gm., 8 gr., corresponds to about 1.1 c.c. of Acid Hydrochloric Dilute.

QUATERNARY AMMONIUM BASES

The organic derivatives of ammonium are strikingly similar in their action. They produce a curare effect, *i.e.*, paralysis of the nerve endings of striped muscle (Brown and Fraser, 1869); some also muscular tremors in frogs; and those possessing three or four methyl groups cause a muscarine effect, *i.e.*, peripheral stimulation of the cardiac vagus; and a nicotine action, *i.e.*, paralysis of sympathetic ganglia. The curare effect evidently depends on 5-valent nitrogen; or rather, on the stereochemic configuration; for the same characteristic is shown by the corresponding phosphorus, arsenic and antimony com-

pounds. The various actions differ in degree with the various derivatives—*i.e.*, the methyl and ethyl ammoniums—in ways which are not easily explainable by their constitution (Burn and Dale, 1915).

Tetra-methyl Ammonium Chloride.—This produces a typical curare effect in mammals and frogs. Ammonium convulsions occur in mammals, but not in frogs, being prevented in the latter by the more powerful curare paralysis. The *circulation* shows a fall of blood pressure, generally with slowing of the heart, by peripheral vagus stimulation and peripheral vasomotor depression. The *respiration* is temporarily paralyzed by intravenous injection; in decerebrated animals, this is preceded by respiratory stimulation. The paralysis is due to a curare effect on the phrenic nerves (Marshall, 1913). Loevenhart, 1914, however, believes that the respiratory action is entirely central; *i.e.*, primary stimulation and later depression of the medullary centers.

Tetra-methyl Ammonium Chloride.—In frogs, this produces irregular muscular contractions and tremors; first fibrillary, then tonic. With larger doses, these are succeeded by paralysis. Both actions are seated in the muscle-nerve endings. Mammals also show increased excitability and depression of the endings. Rabbits exhibit dyspnea, tremors, convulsions, and arrest of respiration. In distinction to tetra-methyl ammonium, there is no direct action on the circulation; the respiratory effects are also smaller (Marshall, 1914). Burn and Dale, 1915, found no curare or muscarine action, but a good nicotine effect.

Methyl-ethyl Ammonium Compounds.—The actions of these are, on the whole, intermediate; but without definite ratio to the alkyl radicals (Marshall, 1915; Burn and Dale, 1915).

NICOTINE

Nicotine, the chief alkaloid of *tobacco*, has no therapeutic importance, but considerable scientific and toxicologic interest. Both the central and peripheral actions are important; both consist in short stimulation, followed by depression or paralysis. Centrally, small doses cause chiefly a respiratory stimulation; larger doses produce convulsions of the medullary type. The action is enormously rapid, approaching hydrocyanic acid. Peripherally, nicotine paralyzes all autonomic ganglia, parasympathetic as well as sympathetic. The paralysis may be preceded by stimulation. The most important effects are on the circulatory and gastro-intestinal systems. It has also a curare action on muscle-nerve endings.

The effects of tobacco are due practically solely to its nicotine. Limited tolerance to the acute toxic effects is soon acquired, after which it acts chiefly as a central sedative. Overindulgence produces chronic nicotine poisoning, with digestive disturbances, functional arhythmias, optic changes, etc. The differences in the various forms of tobacco habit are probably explainable by differences in absorption.

Related Drugs.—Very similar in their actions to nicotine are *piturine*, the alkaloid of *Duboisia Hopwoodii*, which is chewed by the natives of Australia as a substitute for tobacco; and *cytisine* (Dale and Laidlaw, 1912), the alkaloid of the ornamental Laburnum tree (*Cytisus Laburnum*). *Caulophyllum* also contains methyl-cytisine, with similar actions; besides volatile oil, a saponin (Lloyd's Leontin), and caulophyllosaponin (Power and Salway, 1913). *Lobelia* is less perfectly related.

Central Actions of Nicotine.—These consist in stimulation, followed by depression, of the whole cerebro-spinal axis, from above downward. The symptoms from large doses resemble those of asphyxia or hydrocyanic acid.

The stimulation may be entirely absent, especially in large doses, so that the animal may drop dead almost instantaneously, without any other symptom. But this is not common.

The effects of small doses, such as are noticed in the first attempt at smoking, will be discussed later.

In mammals, moderate doses act mainly on the *hemispheres*, producing transitory excitement, followed by lasting depression, with violent headache. (In frogs, the action on the cerebral centers seems to be very small, for the effects are the same, whether the hemispheres are intact or removed.)

Medullary Centers.—The action on these is marked and violent. *Respiration* is at first increased, and then markedly depressed; paralysis of the respiratory center being the *cause of death*. The vagus and vaso-motor centers are also first stimulated, and then paralyzed. The salivation and vomiting, which are so prominent with moderate nicotine intoxication are probably also due to medullary stimulation (Eggleston and Hatcher, 1915). The emetic action is antagonized by atropine (Eggleston, 1916).

Nicotine Apnea.—In anesthetized dogs, nicotine intravenously may produce prolonged arrest of respiration (de Almeida, 1920).

Bronchial Muscle.—This is constricted in the surviving lungs (Baehr and Pick, 1913).

Spinal Cord.—The motor cells are strongly stimulated, resulting in *convulsions*, passage of feces and urine, etc. If the nicotine is applied to one part of the cord, the convulsions remain confined to the muscles innervated from this area (difference from strychnine, which acts on the sensory cells). The stimulation is followed by paralysis. The nicotine convulsions are not seated exclusively in the spinal cord, but involve the hind-brain and medulla as well. They are much weakened by anesthesia.

The *cutaneous reflexes* of frogs are depressed. Partial tolerance to this action is acquired by repeated administration (Howat, 1916).

The *spinal ganglia* (posterior roots) are not affected, even when a 1 per cent. solution of nicotine is applied directly to them.

Location of Peripheral Actions.—The typical paralytic effects of nicotine are exerted on the ganglia; for electric stimulation of the post-ganglionic fibers remains effective (Langley, 1890). The stimulant effects in many situations are also ganglionic, for they disappear after division of the post-ganglionic fibers, but persist after degeneration of the preganglionic fibers. The nicotine must therefore act on the "receptive mechanism" of the ganglion cells. These ganglionic effects are overcome by the drugs that act directly upon the receptive or contractile mechanism of the muscle. However, nicotine may also act in part directly on the muscle.

Circulation.—The effects are explained in Fig. 7. They are complex, involving stimulation and paralysis of the heart-muscle, vagus and vessels, centrally and peripherally. The total effects are fairly constant and characteristic.

Initial Effects.—The heart is first greatly *slowed*, from central and ganglionic vagus stimulation. At the same time the blood pressure begins to rise, from strong stimulation of the vasomotor center (Pilcher and Sollmann, 1915), and ganglia (Hoskins and Ransom, 1915); the central and peripheral stimulation playing about an equal rôle.

The blood pressure may be raised by nicotine (and anagrine) even in the absence of the vasomotor center, but not if the suprarenals are also excised (Gley, 1914). A part of the blood-pressure rise seems therefore attributable to increased output of epinephrine.

Smoking of tobacco increases the coronary pressure (Bond, 1911). In novices, there is generally a rise, then fall of systemic blood pressure (Lee, 1908). John, 1913, found in typical cases, after smoking eight to ten cigarettes or two medium cigars, that the diastolic pressure rises, and often remains high for two hours. The effect is proportionate to the nicotine content, and is perhaps due to the nausea. The effects on the pulse rate were variable.

W. G. Thompson and Sheldon, 1917, investigated the acute effects of smoking in patients with high blood pressure. The response differed greatly: The maximum effects ranged from a rise in systolic pressure of 25 mm. and in pulse pressure of 22 mm., to a fall in systolic pressure of 30 mm. and in pulse pressure of 34 mm. Rise, fall, and no effect were about equally numerous, and varied even in the same patient. There was no difference between cigars and cigarettes.

J. Parkinson, 1917, studied the immediate circulatory response to the smoke of 4 or 5 cigarettes in normal subjects and "soldier's heart." All the subjects who "inhaled" the smoke showed effects, which were generally greater in the patients with circulatory instability. The response consisted in increased pulse rate, averaging 9 beats in the patients, and slight rise of blood pressure, 5-10 mm. systolic, 5 mm. diastolic. Respiration was unaffected; but exertion easily rendered the subjects "breathless."

Nicotine is the Essential Agent in the Cardiac Effect of Tobacco Smoke.—This has been shown by Clerc and Pezzi, 1914. Ringer's solution through which tobacco smoke had been passed produced the typical nicotine effects on perfusion through excised rabbits heart, *i.e.*, temporary vagus standstill. Prolonged perfusion, however, leads to permanent arrest which is not due to the nicotine, but to collidine and other bases that occur in the smoke of tobacco or other leaves, for instance, oak.

Carotid Reflex.—The reflex fall of pressure which ordinarily results from traction of the cephalic end of the carotid artery is abolished by nicotine (Sollmann and Brown, 1912).

Arrhythmia.—With larger experimental doses, the slow heart beat is replaced quite suddenly by great *quickenings* through paralysis of the vagus ganglia. The nicotinized

FIG. 7.—Diagram of the actions of nicotine.

heart may therefore be slowed by muscarine, or stimulation of the sinus, but not by stimulation of the vagus trunk. According to Kose, 1905, the secondary acceleration also involves a ganglionic accelerator stimulation, which passes finally into paralysis. *Electrocardiograms* (dog) often show a nodal rhythm (synchronous action of auricles and ventricles), interrupted by extrasystoles; and other irregularities identical with those of stimulation of the vagi and accelerators, separately or together (Pozzi and Clerc, 1913; Bull, Clerc and Pezzi, 1914; Clerc and Pezzi, 1920).

Blood Pressure in Toxic Stage.—This may be very high and the central vasomotor stimulation may persist into death (Pilcher and Sollmann, 1915) but as the peripheral vaso-motor mechanism becomes more and more depressed, the vessels become dilated and the *pressure falls*. The dilation can be plainly seen in the intestinal vessels or the rabbit's ear. The vasomotor paralysis is rarely complete, so that direct or reflex stimulation, or a second injection of nicotine, again causes a short constriction.

When the paralysis of the vasomotor ganglia is complete, it is impossible to restore the blood pressure permanently (Langley, 1918). The heart-muscle eventually wears out, mainly because of the lowered coronary pressure.

Coronary Circulation.—This is slowed by the constriction of the coronary vessels, notwithstanding the raised blood pressure (Morawitz and Zahn, 1914).

Pulmonary and Hepatic Vessels.—These are constricted (Berezin, 1914).

Renal Vessels.—When one kidney is denervated in a normal animal, the urine on that side is more abundant and richer in chloride and urea. This is attributed to the vasodilation. When nicotine is injected (0.7 to 1.5 mg. per Kg.), the difference disappears, since the vessels on the sound side are also paralyzed by the alkaloid. Ergotoxine, atropine, and ether have a similar effect (A. C. Kolls and Marshall, 1917).

Reaction in Shock.—The blood pressure of animals in peptone or anaphylactic shock reacts but little to epinephrine, but rises sharply under nicotine ($\frac{1}{4}$ mg. per Kg.).

This rise, however, is attributed essentially to the increased respiration (J. P. Simonds, 1916).

Peripheral Actions on Frog's Vessels.—By perfusion through decerebrated frogs, nicotine produces immediate vasoconstriction and muscular fibrillation. These effects disappear in a few minutes, during the perfusion, and can not be restored by further nicotine. Epinephrine is still effective. Tyramine suppresses the nicotine constriction almost completely (Handovsky and Pick, 1913).

Excised Mammalian Heart.—When perfused with nicotine, this shows typical vagus effects; first, diastolic standstill; then gradually resumption and finally acceleration above normal, with increased amplitude. The primary standstill is abolished by atropine. The secondary acceleration is probably due to accelerator stimulation (Clerc and Pezzi, 1912).

Frog Heart.—The application of nicotine produces a brief diastolic standstill (stimulation of vagus ganglia). The heart then resumes its beat, and stimulation of the vagus trunk becomes ineffective, whereas sinus-stimulation or muscarine slows or arrests the heart. The nicotine has therefore paralyzed the vagus ganglia.

The cardiac effects were studied in 1868 by Truhart on intact frogs. Observations of Helt, 1920 on the excised heart by Straub's method show that the effects of increasing doses are (1) Vagus stimulation (diastolic tendency and slowing), spontaneously reversible; arrested by atropine. (2) Disturbance of conduction (partial heart block). (3) Diminished electric irritability. The nicotine is rapidly fixed in the heart, so the action becomes irreversible.

Electrocardiographic Studies on Perfused Hearts of Frogs and Turtles.—Barry (1921) found that the effects vary with conditions: strengthening or weakening; quickening or slowing; dissociation of the chambers; partial or complete arrest; or reversal of the beat (starting in ventricle).

Heat and Nicotine on Frog Heart.—The typical effects of heat are opposite to those of nicotine; their combination increases their toxicity, by summation of their injurious action (Zanda, 1915).

Turtle's Auricle.—Nicotine, 0.03 to 0.05 per cent., increases the height of the contractions, without changing the tone or the tonus waves. Concentrations of 0.1 to 1 per cent. increase the tone and the tonus waves; the contraction height may be increased or diminished (Gruber, 1921).

Digestive Tract.—Nicotine produces nausea, emesis, and violent diarrhea. The emetic action is mainly central, the intestinal mainly peripheral.

Nicotine Emesis.—This may be evoked by the direct application of a minute trace to the medullary emetic center (Hatcher and Weiss, 1923).

Excised Stomach.—This is contracted in most mammals, but relaxed in a few forms (M. Smith, 1918).

Mammalian Intestine.—The effects are peripheral, *i.e.*, essentially alike in intact animals and in excised intestine. Small doses stimulate the muscle and slightly increase its tone. Larger doses produce violent stimulation, culminating in intense contracture (Nasse); but this is soon followed by inhibition of the movements and relaxation of the tone (Pohl; Ikeda, 1916). Dogs show relatively more stimulation and less depression.

The contracture is abolished by atropine. The ganglia are also paralyzed, so that the response to stimulation of the vagus or splanchnic are abolished (Nasse). Large doses paralyze peristalsis, but not the segmental movements (Magnus, 1904).

Urinary Bladder.—In cats, nicotine produces contraction followed by relaxation. The responses are not affected by section of the nerves, nor by atropine (Edmunds and Roth, 1920), and therefore would appear to consist in sympathetic stimulation peripheral to the ganglia.

Excised Ureter.—G. B. Roth, 1917, found practically no effect. Macht, 1916, describes primary stimulation and secondary depression.

Retractor Penis Muscle.—This is stimulated by nicotine (Edmunds, 1920). As it does not contain any ganglion cells (Fisher) the action is presumably on the receptive mechanism.

The effects on the uterus and on the bronchial muscle are described in the general discussion of autonomic poisons.

Pupils.—These show both contraction and dilatation at different times, nicotine acting upon the ganglia of both the oculomotor and sympathetic fibers. There may even be a direct action upon the iris muscle. The effect is different in different animals; The dog and cat usually show dilatation; the rabbit first constriction and then dilatation.

Effects on Glands.—Secretion is generally stimulated through the ganglia. This is particularly prominent with the *saliva*. Small doses, however, change the response to stimulation of the chorda nerve, so that this diminishes secretion (Dale and Laidlaw, 1911). *Lactal* secretion is not increased (Ott and Scott, 1912).

Glycosuria.—Nicotine prevents the glycosuria which ordinarily follows the injection of caffeine and epinephrine; or on piqûre (Macleod and Dolley, 1905). This could be due to paralysis of the ganglia, or to the lowered blood pressure.

Epinephrine Output.—This shows a brief increase, followed by marked and enduring decrease, presumably by stimulation and paralysis of ganglia. The epinephrine store of the gland is apparently unchanged (Stewart and Rogoff, 1919).

Cerebro-spinal Fluid.—The pressure simply follows the circulatory changes (Dixon and Halliburton, 1914).

Oviductal secretions of birds: Nicotine has no effect on the output of shell-material (Riddle and King, 1921).

Skeletal Muscle.—The injection of nicotine into frogs produces fibrillary twitching merging into tonic contracture (O. Kushima 1919). The minor grades may cease temporarily on section of the nerve, but they return, especially on stimulation. They occur also in excised muscle, and after degeneration of the nerve-endings, so that they are intramuscular. Microscopical examination shows that the contracture may be confined to the region of the endplates, and that smaller concentrations of the poison ($\frac{1}{500}$) are effective at this region (Langley, 1913, 1914). This holds true also for other muscle poisons, for instance caffeine, and probably means that the sarcolemma is more permeable at this place; it has, however, been interpreted as evidence that the nicotine acts on a receptive substance that is assumed to be localized especially about the intramuscular "end-plate." The nicotine stimulation is mutually antagonistic with curare, atropine, cocaine and procaine (Frank and Katz, 1921; Schueller and Athmer, 1921). A number of other poisons produce essentially identical effects; namely physostigmine, guanidine (Fuehner, 1920; Frank and Stern, 1921), acetyl-choline (Riesser and Neuschloss, 1922), barium, and probably veratrine. They also show essentially the same antagonisms. Physostigmine, guanidine and barium become ineffective rather early after nerve-degeneration, which evidently induces intra-muscular degenerations that interfere more with the response to these drugs than with those to nicotine and acetyl-choline. As the stimulation by all these drugs is mutually antagonistic with curare, which does not paralyze the muscle to direct nerve stimulation, it may be assumed that they and curare act on a "receptive mechanism" in the striped muscle.

The muscle of fowls is especially susceptible to the tonus (Langley 1906; Edmunds and Roth, 1908).

Mammals.—These also show fibrillar contractions, but of central origin. Excessive doses of nicotine do not produce these central convulsions; although they do not prevent strychnine convulsions (Langley, 1918). This indicates that the nicotine convulsions start from a different center than those of strychnine.

Tobacco Smoking on Ergographic Response.—This produces a periodicity in the contractions, apparently due to central fatigue and depression (Raphael, 1920).

Curare Action.—Nicotine also has a curare-like effect, which becomes prominent later. In the milder stages this is shown by an equally strong, or stronger, current being required to obtain contraction when the stimulus is applied to the nerve than when it is placed on the muscle. In the normal preparation the opposite is the case. The excitability and irritability of the muscle cells is also diminished by nicotine on direct application. The curare action may lead to paralysis of respiration in mammals (Thomas).

Invertebrates.—In the *squid* (*Loligo*) nicotine acts on the cerebral, and not on the stellar ganglion (A. R. Moore, 1919). In *star-fish* (*Asterias*) it produces ventral flexure, whereas strychnine produces dorsal flexure. When both drugs are used, the strychnine effect predominates (Moore, 1920).

Insecticide.—Nicotine is one of the most efficient insecticides (McClintock, Hamilton and Lowe, 1911). However it is applied, it kills the insects by paralysis, ascending along the ventral nerve cord, from the abdomen to the brain. It produces structural changes in the nerve cells, analogous to those of oxygen deprivation (McIndoo, 1916).

Antiseptic Action.—Tobacco juice and smoke are distinctly antiseptic, and Fullerton, 1912, claims that they tend to preserve the teeth. Common experience shows that they are not effective.

Local Actions.—Free nicotine is caustic by its alkalinity. Strong solutions paralyze the nerve fibers.

Fate.—Nicotine is absorbed extremely rapidly from mucous membranes, and especially from the lungs; more slowly from hypodermic injections and from the intact skin. It is excreted only in small part, mainly by the kidneys, but also by the lungs and sweat.

Dixon and Lee, 1912, confirm the older statement that it is partly destroyed in the liver, and claim that this destruction is increased by habituation; but Clark, 1912, found no destruction by frog's liver.

Acute Nicotine or Tobacco Poisoning; Etiology.—Serious poisoning is usually the result of attempts, especially by the laity, to use tobacco as a medicine; and of the swallowing of the concentrated nicotine solutions used as plant-sprays (Feil, 1916; McNally, 1920).

The application of tobacco to wounds or bruises is not without danger. E. G. Garvin, 1913, has reported the death of a girl of six and one-half years, forty-five minutes after the administration of less than 1.5 Gm. of tobacco by enema, against pinworms. In other cases, the *time of death* has varied from three minutes to seven hours. Prompt death has also occurred from swallowing nicotine plant spray (Feil, 1916).

Toxicity.—Nicotine is one of the most fatal and rapid of poisons; the vapor arising from a glass rod moistened with it and brought near the beak of a small bird causes it to drop dead at once, and 2 drops placed on the gums of a dog may give a similar result. The fatal dose for a man is about 60 mg.; of tobacco, about 2 Gm. It acts with a swiftness equaled only by hydrocyanic acid. In view of the high nicotine content of tobacco (one cigar contains a quantity of nicotine which would prove fatal to two persons, if directly injected into the circulation), also because of its popular distribution, it appears astonishing that fatal nicotine poisoning is not more common; but just this wide distribution and knowledge of the drug form the safeguard, as also the marked taste.

Symptoms.—In lighter cases, such as commonly occur in *smoking*, the peripheral and nauseant actions predominate. There is first an increased flow of saliva, partly reflexly through the mechanical irritation of smoke, but mainly by direct stimulation of the ganglia through the nicotine. Nausea, vomiting, and diarrhea soon appear. There is a sensation of oncoming sweat, which does not actually break out. A feeling of exhaustion appears very early—partly as the result of nausea, partly as the first indication of central collapse action. Palpitation is also noted.

Severe cases show immediate faintness, prostration and muscular weakness; severe nausea, vomiting and diarrhea; followed quickly by convulsions and collapse (Garvin).

The effects of poisoning with pure nicotine, which have been very carefully studied experimentally on *man*, bear the greatest resemblance to the above. After 1 to 4 mg. there were burning in the mouth, a scratching sensation in the pharynx, increased salivation, a sensation of heat spreading from the region of the stomach over the whole body; excitement with headache now appeared, then vertigo, confusion, disturbed vision and hearing, photophobia, dryness in mouth, cold extremities, nausea, vomiting, and diarrhea. Respiration quickened, but difficult. Pulse at first increased, then irregular. After forty-five minutes there was syncope, with clonic spasms. Recovery occurred, but general depression persisted for three days.

The **treatment**, aside from the chemic, consists of coffee and other stimulants and in meeting the symptoms. Emetics will usually not be necessary.

The **postmortem appearances** are not characteristic although large doses cause, in animals, anemia of the meninges and peculiar anatomic changes in the cortical nerve-cells. When taken by the mouth, there may be gastric and intestinal hyperemia, since nicotine is sufficiently alkaline to be somewhat caustic. The odor may furnish a valuable indication.

The *proof* of the poison after its separation may be had by its odor and by obtaining its physiologic actions on frogs. The muscular tremors and the position which a frog assumes after nicotine (Van Praag, 1885) are highly characteristic (Fig. 8). A control animal should, of course, be used.

The chemic tests are of no practical importance, since very similar reactions are given by coniine and by a ptomaine.

Nicotine is very *resistant to putrefaction* and has been isolated from the decomposed bodies of animals three months after death.

FIG. 8.—Nicotine. Successive positions of frog poisoned with 25 mg. nicotine.

HABITUAL USE OF TOBACCO

Composition of Tobacco Smoke.—The effects of the smoke are due practically entirely to the nicotine contained in it. There are other toxic constituents, but their quantity is too small to be practically important. This has been proved both by chemical considerations and by animal experiments (Lee, 1908; K. B. Lehmann; van Leeuwen, 1918).

Nicotine exists in tobacco mainly in the form of salts of organic acids (Garner, 1908). By the heat of smoking, these are largely dissociated, a part of the nicotine being burned, and a part passing into the smoke as free nicotine (Lehmann, 1909). The drier the tobacco and the greater the heat, the less nicotine will escape destruction. Moist tobacco, especially cigars, therefore, produce severer effects. This is more important than the nicotine content of the original tobacco (Lee, 1908). In experiments, between 15 and 90 per cent. of the nicotine present in the tobacco are recovered from the smoke; but a greater part of this is exhaled or expectorated; in natural (intermittent) smoking, the aspirated smoke contains only a sixth of the nicotine. About 1 to 1.4 mg. of nicotine would actually be absorbed from a cigar (Lehmann, 1907). In *cigarette smoking*, where inhalation is commonly practised, the percentage absorbed would be relatively high, thus accounting for its reputed deleterious effects. The average nicotine content of cigarettes (1.69 per cent.) is rather lower than that of other forms of tobacco (leaf, 3.04, cigars, 1.52; chewing, 1.14); nor is there anything in the popular notion that cigarettes contain opium or other added narcotics (Thurston, 1915).

The smoke of a cigarette, with intermittent smoking, contains 6 to 8 mg. of nicotine (Asherson, 1919); but only a fraction of this would be absorbed.

All the preceding data are based on chemical methods, which do not actually identify the nicotine. This may be done quantitatively by the blood-pressure rise produced by solution of the smoke. By this means, and with intermittent smoking, cigar smoke contains 160 to 425 mg. of nicotine per 100 grams of cigar consumed. "Light" and "heavy" cigars do not show constant differences. So-called "nicotine-free" cigars yield just as much nicotine in the smoke as ordinary tobacco (van Leeuwen, 1918).

Other Toxic Constituents.—These are formed by combustion, and vary greatly according to conditions. As an illustration, Lee found in the smoke of 100 Gm. of tobacco, besides 1.165 Gm. of nicotine, the following: Pyridine bases, 0.146 Gm., chiefly pyridine and collidine; hydrocyanic acid, 0.08 Gm.; ammonia, 0.36 Gm.; CO, 410 c.c. The *pyridine bases* act somewhat similarly to nicotine, but with important differences (Lee). *Pyridine* is a strong local irritant with low toxicity; a 10 per cent. solution has been used by atomizer in asthma and fetid bronchitis. It produces first dyspneic then shallow respiration. Brunton and Tunncliffe (J. Physiol, 17:292) refer the effects mainly to sensory paralysis. Large doses arrest the heart. Smaller amounts stimulate the bone-marrow to increased production of blood-platelets (R. L. Lee and Minot, 1917).

The *hydrocyanic acid* in the smoke of a cigar amounts only to 0.002 to 0.5 mg., and would have no significance (Lehmann and Gundermann, 1912). It has been suggested that the *carbon monoxide* of the air might rise to a deleterious degree, when many persons smoke in a confined atmosphere, but according to experiments of the U. S. Bureau of Mines, smoking under most intensive conditions does not increase the CO concentration of the air of the room to more than $\frac{1}{100}$ per cent.; and the maximum blood-saturation of the subjects was 5 per cent.—quantities that are considered negligible.

The *aromatic oils*, which constitute the aroma of the tobacco, are practically inactive.

Arsenic is sometimes present in harmful quantities when Paris green has been used on the plant as an insecticide.

Tolerance and Habituation.—The quantitative effects of nicotine vary considerably in different persons. Similar variations are observable in animals. *Young* individuals are more susceptible than adults. Considerable tolerance is acquired by continued use, so that moderate doses lose all the usual unpleasant acute effects. The rapidity and completeness of the habituation also varies with individuals; dependent partly on individual susceptibility; partly on the manner in which the drug is used, whether the smoke is inhaled, the saliva expectorated, etc. The tolerance is never absolute; it seems to be higher against sublethal than against lethal doses.

Wahl, 1920, found that non-habituated men are nauseated by 1 or 2 mg. of nicotine, by mouth; whilst tobacco users required more than 8 mg.

Habituation in Animals.—These acquire only a limited tolerance (Hatcher, 1904; Edmunds, 1909; Adler and Hensel, 1905, could not produce any tolerance). Hatcher showed that the serum of habituated animals does not protect others against intoxication. Dixon and Lee, 1912, claim that the liver of habituated animals destroys nicotine somewhat more rapidly. Edmunds, 1916, failed to confirm this. At best, since the destruction is slow, it would protect only when small doses are introduced gradually.

Effects of Moderate Use of Tobacco.—When the tolerance has been acquired, the continued use of tobacco within a certain individual limit produces no unpleasant symptoms; but if the limit be at any time sufficiently exceeded, the symptoms of chronic poisoning, presently to be discussed, arise. After a long time, some twenty years, these symptoms may also, but rarely, occur in those who have always kept within bounds.

Psychic Effects and Efficiency.—The habitual users of tobacco experience a certain pleasure, which appears to resolve itself into a reposeful, calmative and stabilizing effect on the nervous equilibrium; provided that the quantity of the tobacco is not excessive, in which case it may increase nervous excitability. This stabilizing action has been demonstrated by the threshold to painful electric stimuli: Smoking leaves the normal threshold unaffected but both excessive and defective irritability are brought toward normal, the effect being similar to that of rest, (Mendenhall, 1921 and 1925). In the same sense, smoking tends to nullify the sensory depression by analgesics and hypnotics (Hale and Grabfield, 1923).

The resultant of such an effect on efficiency would depend so much upon individual conditions, on temperament, fatigue, difficulty of the tasks, suggestion, etc., that it is not surprising that direct tests of efficiency have given discordant results. For instance, the speed and accuracy of arithmetic addition has been reported as increased (Berry, 1917), and as unaltered (Wahl, 1920). The sensation of fatigue and discomfort (including hunger) can doubtless be temporarily obscured, and a temporary extra spurt of effort secured; but whether the total performance is increased is an open question. Deprivation of tobacco induces in habitual users, a condition of nervousness analogous to the craving of the more serious drug habits, that interferes conspicuously with work, especially with mental effort and concentration.

Attempts have been made to evaluate the effects of tobacco by comparing the efficiency of smokers and non-smokers. Such studies generally show some superiority of the non-smokers; for instance, in the endurance of telegraph-workers (Baumberger and Martin, 1921); scholarship (E. L. Clark, 1900; Meylan, 1910), growth in youth (Seaver, 1897); resistance to tuberculosis (Flick, 1908). However, it has not been possible to decide whether the apparent inferiority is the effect or the cause of the tobacco-habit: those who are handicapped by inferiority would naturally feel the greatest need for, and succumb most readily to the euphoria of smoking.

Effect on Muscular Work.—Baumberger, Perry and Martin, 1921, found that habitual smoking (outside of working hours) did not appear to affect the work-output of glass-blowers, who require strenuous physical dexterity. Chewing during the work appeared to impair the output (perhaps by a slight curare action?). With the ergograph, Palmen, 1911, found that cigarette smoke at first increased the *muscular work*, but that fatigue set in sooner, and the total efficiency was decreased. Nice, 1912, found that the muscular activity of mice in a revolving cage was not diminished by fairly high and long-continued doses of nicotine.

The blood pressure during smoking rises slightly and slowly in moderate smokers; in inexperienced smokers, it shows a sharp rise at first, and considerable fall when collapse sets in (Lee).

Nicolai and Staehelin, 1910, found that in tobacco users the heart rate averaged somewhat higher, especially in work; no definite changes could be made out in the systolic and diastolic blood pressure or electrocardiograms. Aliprandi and Fornaroli (1905) claim that tobacco chewing causes distinct constriction of the cerebral vessels.

Factors of Psychic Effects.—How much of the psychic effects is due to nicotine, how much to other factors, we can not say. It is certain that the nicotine strength of the tobacco is not the determining feature of this action—rather the aroma. Smoking in the dark does not give as much enjoyment; and simply holding an unlighted cigar in the mouth, the chewing of other objects, etc., give similar, though much weaker, sensations. The truth would seem to be that it depends upon a reflex stimulation, from the mucous membrane of the mouth, nose, etc., in which the nicotine plays a part; and with this may be associated a direct action of the nicotine upon the central nervous system, at once stimulating and depressing.

Chronic Intoxication.—The phenomena resulting from the excessive use of tobacco take many forms; especially local irritation of the respiratory tract; digestive and nutritional disturbances; functional cardiac arrhythmias; depression of various parts of the central nervous system; neuralgias; more rarely impairment of vision.

Local Effects.—The nicotine and other basic constituents of the smoke act as fairly strong irritants, as shown by the biting sensation on the tongue, noted especially when the smoke is concentrated on one point,

as in pipe smoking. This constant local irritation seems to favor the development of *epithelioma* of the lip and tongue, if the quantity consumed is very large or the smoker specially disposed. There is also a more general irritation of the mucous membrane of the mouth, throat, and pharynx, leading to catarrh and hoarseness.

Circulatory Disturbances.—The first warning symptoms are occasional palpitation, quickened heart rate and arrhythmia. These become persistent if the nicotine is continued, but disappear on withdrawal. In advanced cases, the abstinence must be continued for months. The arrhythmia is purely functional, due to extrasystoles (premature beats with long pause), pointing to increased irritability of the cardiac structures. It is similar to that of caffeine, hysteria and neurasthenia. In graver cases, the cardiac irregularity may become extreme and lead to sudden fainting (*syncope*). *Respiratory distress* naturally accompanies the marked cardiac phenomena. Angina pectoris is so rare in these subjects that it must be attributed to causes other than the nicotine. On the other hand, *arteriosclerosis* appears to be favored by it although there is no conclusive evidence of a causal connection.

The extrasystoles are usually auricular. Auricular fibrillation and "flutter," and sino-auricular block have also been encountered (Neuhof, 1916). The block disappeared within three days after stopping the tobacco.

In rabbits, chronic nicotine poisoning produces anatomic arterial and cardiac changes, similar to those of epinephrine (Adler and Hensel, 1905; Baylac, 1906; Otto, 1911; Adler, 1914). These results can be only cautiously transferred to man. Pawinski, 1914, claims that 42 per cent. of 1,000 cases of *coronary sclerosis* had histories of immoderate smoking; and that nicotine produces marked changes in the coronary vessels and heart-muscle in animals. Lissauer, 1914, also describes histologic changes in the cardiac and other ganglion cells.

Digestive and Nutritional Disturbances.—The symptoms next in order are probably those arising from the *alimentary canal*, and depending upon the continued irritant action of the nicotine. These are: Loss of appetite, then dyspepsia and chronic intestinal catarrh, shown by alternating constipation and diarrhea. (With moderate smoking the nicotine seems rather to have a tendency to keep the bowels regular.) These conditions lead to emaciation and anemia.

Smoking inhibits the *hunger contraction* of the stomach, the effect being proportional to the local stimulations of the mouth, etc. (Carlson and Lewis, 1914). The digestive movements of the stomach are presumably not arrested. A direct action upon the blood may also have a part in the *anemia*; the continued administration of nicotine to animals leading to diminution of red corpuscles, and increase of leucocytes. It is also claimed that it diminishes the oxygenating power of hemoglobin. The nitrogen excretion is rather more diminished than the assimilation, so that there may be a gain in body nitrogen. Transitory albuminuria may occur.

Nervous Disturbances.—These are rarely serious. The *psychic functions* show slowness and want of energy. Anxiousness and insomnia are quite frequent. There is general muscular debility, tremors, and want of control over movements.

The reflexes are heightened. Vertigo and a tabetic condition may set in. There is then an increase of excitability in the sensory and pain areas, and consequently headache and neuralgias; but the latter are in part due to referred pain from the cardiac disturbances. They are often early and quite characteristic, and take the form of pain and *hyperesthesia* in the precordial region, left nipple and ulnar surface of left arm.

Nicotine Blindness.—This is relatively rare. It seems to be favored by alcoholism. The sight gradually becomes dim, with central scotoma, impaired accommodation, and often miosis. It is always bilateral. The anatomic changes consist in retrobulbar

optic neuritis, with subsequent atrophy. Until degeneration has set in, a complete cure can usually be effected by abstaining from nicotine; later, this will only arrest the further progress (de Schweinitz, 1896).

Other Toxic Amblyopias.—Many poisons may produce blindness, temporary or permanent, in susceptible individuals, especially on continued administration. This has been recorded for stramonium, cannabis, chloroform, opiates, carbon disulphide, arsenic, lead, iodoform, aspidium, quinine, salicyl, methyl alcohol, etc. For most of these the changes are analogous to those of nicotine. With methyl alcohol, quinine and salicyl, the retinal ganglion cells are also involved. The metals and aspidium may produce primary optic atrophy without preceding neuritis (de Schweinitz, 1896 and 1902).

Of other effects which have been attributed to nicotine but with insufficient cause, may be mentioned: impotence, epilepsy, and insanity (G. W. Jacoby, 1898; Naecke, 1909).

Treatment.—It will be seen that the catalogue of injurious actions to be charged against the abuse of this drug is sufficiently large; but on the other hand, it must be noted that these are absent with moderate use, and can be abolished if the use of the drug is promptly limited on their first appearance. Actual withdrawal is not always necessary. Limitation in quantity, sufficient expectoration, and the avoidance of deep inhalation of the smoke are often sufficient. Quick total withdrawal does not lead to abstinence symptoms, as with morphine (except possibly in some especially neurotic subjects), although it may disturb the function of the bowels for a few days. The principal point in the treatment is to keep the thought of the patient off the topic of tobacco, and to supply the accustomed stimulus to the mouth in some other manner, as by chewing ginger or gentian.

The use of tobacco must, of course, be avoided in pathologic conditions in which there are special contraindications to it—in heart disease, dyspepsia, inflammation of the respiratory tract, etc.

PREPARATIONS

Tabacum (Tobacco).—"The commercial dried leaves of *Nicotiana Tabacum*, Linné (N. O. Solanaceæ)," an annual plant, probably indigenous in tropical America, and now cultivated in most parts of the world. The annual production of the world is estimated at 1,000,000 tons (1,000,000,000 kg.). Other species also contain the nicotine. The plant was introduced into Europe shortly after the discovery of America. Its use by smoking was practised by the natives at the time of Columbus.

The important constituents are nicotine, which is also present to a less extent in all other parts of the plant, and a volatile oil developed in drying and "sweating." The percentage of nicotine varies between 1 and 8 per cent.: In Havana and Maryland, 1.5 to 3; Virginia and Kentucky, 6 to 8; South American, 2 to 6; German, 1.5 to 3. A number of other alkaloids have also been announced to exist in small amount in tobacco (Pictet and Rotschy, 1901).

The dried leaves were formerly official, but are now obsolete in medicine; if used, an infusion may be made. The dose was given as 0.5 Gm.

Nicotine, $C_{10}H_{14}N_2$, is a fluid, volatile, oxygen-free alkaloid, of strongly basic characters. It forms salts, most of which are soluble. It is colorless and almost odorless when freshly prepared; but it partly decomposes on keeping, acquiring a characteristic odor and a brown color. The dose would be to 0.001 Gm.

LOBELIA

The herb *Lobelia inflata* was used by the American Indians as a substitute for tobacco. It was introduced into medicine by Samuel Thompson about the beginning of the nineteenth century as the main basis of his peculiar system of treatment. The chief constituent is the alkaloid *Lobeline* with actions resembling nicotine (Edmunds,

1904). There are also two other alkaloids (B base and lobelidine) with apparently identical but somewhat weaker actions.

Respiration and Circulation.—Small doses of lobeline (about 0.5 mg. per Kg.) lower the CO₂ threshold, and thereby produce a marked stimulation of respiration. This is often quite effective (about 5 mg. per Kg. for rabbits) in overcoming depression of the respiratory center by morphine, rather less effective after chloral (Wieland, 1915; Wieland and Mayer, 1922). The response is uncertain, however, even with morphine (Meissner, 1923). The respiratory stimulation was tried clinically against depressant poisons (morphine, hyponotics) and in pneumonia, laryngeal stenosis, asphyxia of the new-born etc., apparently with good success (Eckstein, Rominger and Wieland, 1921, and others). The maximal hypodermic dose of the crystallized ("alpha") lobeline is 10 mg. for adults, 3 mg. for children. No accidents have been reported. It may be noted that the clinical doses are considerably smaller than those found necessary in animals; and further critical observations are desirable. Lobeline has also been injected intravenously, in about one-third of the above dosage; but this should only be risked in extreme danger. Wieland and Mayer warn specifically against intravenous injection, since it may stimulate the vagus center, slow the pulse and lower the blood-pressure, produce bronchial spasm, and with large doses produce convulsions and paralyze the respiratory center and the cardiac muscle (Muto and Iwakawa, 1910). Van Leeuwen, 1917, claimed that lobeline raises the blood pressure like nicotine.

Excised Intestines.—The effects have been studied by Ikeda, 1916.

Nausea and Emesis.—These are central (Eggleston and Hatcher, 1915).

Oral Administration of Lobelia.—This has also been employed especially in respiratory affections, especially in chronic emphysema, in spasmodic croup, and spasmodic bronchitis. It is a nauseant expectorant, but deranges digestion. As emetic it is effective, but not sufficiently safe.

Poisoning.—The symptoms are often alarming but rarely dangerous, because emesis nearly always occurs. Many of the specimens of the dried drug are almost inactive. Poisoning is treated by gastric lavage and stimulants.

PREPARATIONS

Lobelia, U.S.P., B.P. (Indian Tobacco).—The dried leaves of *Lobelia inflata*.
Dose, 0.1 Gm., 1½ gr., U.S.P.

Tr. Lobel., U.S.P.—10 per cent. *Dose*, 1 c.c., 15 minims, U.S.P. Maximum dose, 2 c.c., 30 minims.

Tr. Lobel. Aeth., B.P.—30 per cent. in Spir. Aeth. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

CONIUM

Conium or "Water-Hemlock," an Umbelliferous herb, contains a number of alkaloids, of which *coniine* is the most important. This is a simple derivative of Piperidine, and was the first alkaloid synthesized. Children are sometimes poisoned by eating the root. The juice is believed to have been the poison administered to Socrates. It was introduced into medicine by Stoerck, 1770, but is now practically obsolete. It was formerly used as a sedative and antispasmodic in chorea, mania, convulsions, whooping cough and asthma; and locally in hemorrhoids and other anal lesions. Its peripheral actions are similar to those of nicotine, but it produces more pronounced paralysis of the central nervous system and of the skeletal muscle-nerve endings. Poisoning is treated by tannin, evacuation and stimulants. A bibliography is given in Cushny's "Pharmacology."

Its action on the excised intestines are also similar to nicotine (Ikeda, 1916).

LUPINES

These have some importance as poisons of grazing stock. They contain bitter alkaloids, one of which appears to be related to coniine (C. D. Marsh, Clawson and Marsh, 1916; Sollmann).

LATHYRISM

The eating of the peas of *Lathyrus* produces in man paralysis of the legs which may be permanent if the consumption is continued (Stockman, 1917). The pea contains small quantities of two active alkaloids with identical central effects: motor paralysis, apparently cerebral; increase, then decrease of spinal reflexes. Both weaken the heart. One also produces a curaroid effect on skeletal muscle endings (Dilling, 1920). Acton and Chopra, 1925, attribute lathyrism to amine bases.

GELSEMIUM

This, the root of Yellow Jasmine, acts similarly to nicotine and coniine. Its central depressant action is relatively more marked (Cushny, 1892). It contains a crystalline alkaloid, *gelsemine*, with weak strychnine action; and several amorphous alkaloids, *gelseminine* and *gelsemoidine* (C. W. Moore, 1910; Sayre, 1910 and 1912; Sayre and Chillingworth, 1914), which are chiefly responsible for the effects of the drug. "Gelseminine" Merck has been shown to consist of gelsemine. Stevenson and Sayre, 1915, describe a further alkaloid, "sempervirine."

Excised Intestine.—Gelsemine depresses the tone and contractions (Ikeda, 1916).

Therapeutic Uses.—Gelsemium (1 to 10 drops of the fluid extract) is employed in neuralgic conditions, especially trigeminal neuralgia, nervous headaches, cerebral hyperemia, and hysteria. There is no pharmacologic explanation of these uses.

Its local application to the eye dilates the pupil, but produces considerable irritation (Putzeys and Romie, 1887). It is no longer used as a mydriatic.

Toxic Effects.—Even small doses sometimes cause toxic symptoms, which may be delayed for hours. The warning signs are ptosis, double vision, dilated pupils, weakness and depression. Fatal doses produce slowing and arrest of the respiration. A drachm of the fluidextract is said sometimes to cause death, and 30 minims are dangerous.

Treatment of Poisoning.—Evacuation, atropine and stimulants.

Standardization.—This is discussed by Pittenger, 1923.

Gelsemii Radix, B.P. (Yellow Jasmine Root).—The dried rhizome and root of *Gelsemium* (nitidum).

Tr. Gelsem., B.P.—10 per cent. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

SPARTEINE

This alkaloid has been used to slow the pulse in cardiac disturbances; but its effects are uncertain, it weakens the heart, and can not take the place of digitalis.

Sparteine is a pyridine derivative, like nicotine and coniine, and has similar actions (Fick, 1873). Its central effects are slight and its toxicity relatively low (Griffé, 1886, took 0.4 Gm., 6 gr., without bad effects, except slight confusion). It has no direct action on the vasomotor center; but the depression of respiration tends to produce asphyxial stimulation (Pilcher and Sollmann, 1915). Peripherally, it has a fairly strong curare action, arresting respiration by paralyzing the phrenic endings (Cushny and Matthews, 1895). Larger doses also paralyze the respiratory center (Muto and Ishizaka, 1903). It has a weak local anesthetic effect (Guinard and Geley, 1894). No habituation could be induced in guinea pigs (Dorlencourt, 1913).

Circulation.—The experimental data give a confused picture of its actions. Small doses produce peripheral *vagus paralysis* (Fick and all subsequent workers). This may sometimes result in preliminary quickening of the pulse (Gluzinski, 1889) and removal of *vagus arrhythmias* (Masius, 1887). The most constant feature is *slowing of the pulse rate*, which is not prevented by atropine, and is therefore due to direct depression of the cardiac muscle. Because of the slowing, the pulse waves appear large; but in contrast to digitalis, the tendency of the heart is diastolic instead of systolic (Cushny and Matthews). Frogs' hearts also show decrease of rate, strength and tone. With intravenous injections, the slowing becomes so extreme that it may be fatal; but this extreme action is of short duration, does not occur on oral administration, and is probably due to direct irritation of the endocardium.

Electrocardiograms of excised mammalian hearts show that sparteine invariably checks the functions in all directions (Sakal, 1919).

The *blood pressure* shows a progressive fall, explainable by the cardiac depression. Excised arteries are dilated (Cow, 1911). Rise of blood pressure has been reported but is of inconstant occurrence (Cerna, 1894), and is perhaps due to the mechanical effects of the injection and to asphyxia. The intraventricular pressure is lowered in dogs, and the kidney volume decreases (Duvillier, E. et al., 1922).

Diuretic Effect.—This has been affirmed and denied, clinically and experimentally (MacNider, 1910; Griffé, 1886). Its existence is very doubtful. Fronmueller, 1878, contended that the reputed diuretic effect of the parent plant (*Scoparius*) is due mainly to *scoparine*, a neutral principle.

Excised Intestine.—Sparteine depresses the tone and contractions (Ikeda, 1916).

Uses.—Sparteine was recommended by Seé, 1885; Laborde and Legris, 1886; and many others, in cardiac disease, valvular and functional, nervous palpitation, Graves' disease, asthma, etc. Clarke, 1887, claimed that it produces marked slowing and strengthening of the pulse, the effect appearing in thirty minutes and lasting for five to six hours. Probably most clinicians consider it useless (Leo, 1887; H. C. Wood). It is certainly devoid of the cardiac tonic action of digitalis; and without this the slowing would be of little value. The influence of drugs on functional cardiac neuroses is difficult to judge. Atropine would be more efficient for paralyzing the vagi:

Sparteine Sulphas (Spart. Sulph.), $C_{15}H_{26}N_2.H_2SO_4.5H_2O$.—Hygroscopic colorless crystals or powder; odorless; slightly bitter. Freely sol. in water (1:1.1) or alc. (1:3). **Dosage**, 10 mg., $\frac{1}{6}$ gr., gradually increased to 0.13 Gm., 2 gr., every six to eight hours. A. Jacobi, 1907, advises not less than 1 gr. per day, even for babies. Overdoses produce nausea and vomiting.

Scoparii Cacumina, B.P.; Broom Tops.—The fresh or dried tops of *Cytisus scoparius*.

Inf. Scopar., B.P.—10 per cent. **Dose**, 30 to 60 c.c., 1 to 2 ounces, B.P.

Succus Scoparii (Succ. Scopar.), B.P.; Juice of Broom.—The juice expressed from the fresh plant and preserved with one-third its volume of alcohol. **Dose**, 4 to 8 c.c., 1 to 2 drachms, B.P.

CURARE

General Statement.—This is practically important in laboratory technic, for paralyzing the skeletal muscles through a selective depression of their nerve endings, as shown in the classical researches of Cl. Bernard, 1857. Further analysis (discussed under the general description of autonomic poisons, and under nicotine) localizes the action more sharply in the "receptive mechanism." It has no effect on sensory nerves and is not an anesthetic. It produces a number of side effects, resembling nicotine in depressing autonomic ganglia (vagus); and strychnine in stimulating the spinal cord. It may produce glycosuria. Intravenously, it causes a temporary fall of blood pressure, returning rapidly to normal with moderate doses. Death occurs by paralysis of the respiratory muscles; animals may be saved by artificial respiration, the drug being rather rapidly excreted by the urine. Curare is mutually antagonistic with physostigmine. It is much less toxic by the stomach, on account of slow absorption and rapid destruction and excretion. It has been used therapeutically against tetanus and other convulsions, but only obviates the fatigue and exhaustion, and is quite dangerous because of the uncertain dosage.

Other Drugs Producing the "Curare Effect."—These are quite numerous.

Among the most important poisons possessing this action are the following:

Certain ammonium bases, amines, choline, muscarine, etc.

Methyl-strychnine, guanidine (Brown and Fraser, 1869).

Delphocurarine, Heyl (Kahn, 1909).

Aromatic series: Pyridine, quinoline, thalline.

Nicotine series, piperidine.

Morphine and related alkaloids.

Cocaine.

Camphor in frogs, but not in warm-blooded animals.

Certain putrefactive ptomaines.

Products of muscle metabolism.

Botulinus toxin.

The curare effect of many of these drugs is an unimportant side-action, which can only be demonstrated in frogs, being obscured by other actions in mammals.

S. Fränkel, 1904, attributes the curare action of the ammonium bases and related drugs to the stereochemic orientation of the valences.

Origin.—Curare, Woorara, Urari or Tiennas, comprises several varieties of extracts, prepared by South American Indians as arrow poisons, from the root-bark of several *Strychnos* plants. It was first brought to Europe from Guyana by Sir W. Raleigh, 1595. Little is known of their preparation. They vary greatly in composition (certain varieties were supposed, probably erroneously, to contain snake venom); and they deteriorate on keeping, especially if moist, so that commercial curare is a very unreliable drug. The naming of the active alkaloids is so confused that they are not much better.

Varieties.—These are designated by the kind of containers in which they reach commerce: *Calabash (Gourd) curare* is obtained principally from *Strychnos toxifera* and contains curarine. *Tube curare*, in bamboo tubes, is of undetermined source, and contains tubocurarine and curine. It is the least desirable but the most common variety. *Pot or jar (Topf) curare* comes from *Strychnos Castelnai* and *Cocculus toxiferus*, and contains protocurarine and protocurine. All the varieties consist of brown masses, intensely bitter, not wholly soluble in water, more soluble in dilute acid.

Active Principles.—All the above-named constituents are alkaloids. Curarine and protocurarine have the most typical effects, and the latter is probably stronger. Tubocurarine has a much weaker muscle-nerve action, a stronger strychnine effect, and increases the heart rate. Curine is devoid of the muscle-nerve action, but first stimulates and depresses the heart. It can be converted into curarine (Boehm).

Curarine is related chemically and in actions to strychnine. Its preparation from calabash curare was described by Boehm, 1887; and by L. Lewin, 1923.

Paralysis of Muscle-nerve Endings.—Ordinarily the only symptoms of "curare" poisoning consist in this paralysis. When the curare is introduced under the skin, it causes a total loss of motion, first of the voluntary and then of the respiratory muscles.

Sequence.—The order in which this disturbance appears is the following: Short muscles of the toes, ears, and eyes; then the limbs, head and neck; finally the respiratory muscles, first the thoracic, then the diaphragmatic, and lastly the abdominal (Chiô, 1912).

The heart is not affected except with very much larger doses.

The muscles which are least affected by curare are those which contain the largest amount of utilizable oxygen, and survive longest after the death of the animal. This supply of oxygen accounts, perhaps, for the lesser susceptibility to the depressing action of curare.

Development of Paralysis.—The first sign of curare action consists in incapacity for sustained effort on repeated stimulation of the nerve; *i.e.*, whereas a single contraction is normal, fatigue sets in more readily than usual (Boehm, 1894). Then the height of contraction is somewhat lowered. Then the current must be strengthened to obtain any response; and finally even the strongest stimulation—of the nerve—is ineffectual.

Location.—This was investigated by Fontana and established by the work of Cl. Bernard, 1857. It is evident that some structure is paralyzed. The paralysis might have its seat in any part of the central nervous system or it might be peripheral. Stimulation of the sciatic does not produce a contraction if the dose has been sufficient. The point of attack must, therefore, be peripheral to the sciatic nerve. This leaves the nerve trunk itself, the nerve-endings, and the muscle fibers. Stimulation of the muscle directly is effective, so that this is excluded. To decide between the nerve trunk and nerve-endings, he placed a ligature around the body of a frog, with the exception of the sciatic nerves, and tightened the ligature so as to entirely exclude the lower extremities from the circulation. He then injected the curare. In this manner the peripheral portions of the sciatic nerves and the endings did not come into contact with the curare

and the nerve trunk was alone exposed to the poison. He found that stimulation of the trunk caused normal contraction, consequently that curare had no action on it, thus leaving only the endings.

He also proved the point in a simpler manner by ligating one leg exclusive of the nerve, and by placing the muscle of one and the nerve of another muscle-nerve preparation into the solution. Garten, 1912, has shown by careful methods that even prolonged exposure to strong curare solutions does not affect the nerve trunk.

Bernard's experiments show that the curare acts on a mechanism between the nerve trunk and the contractile mechanism. This was naturally conceived as the "motor-end plate." The observations that were discussed under the general description of the autonomic system, and under nicotine, show that its action is not on the nerve-endings that degenerate after section of the nerve, but on the receptive mechanism. This may possibly be localized mainly at the end plate (Langley), but the evidence for this is not conclusive.

Direct stimulation of the muscle (in cats) requires a somewhat stronger current under curare, but not if the nerve has degenerated. Epinephrine also restores the threshold of muscular stimulation. Fatigue increases the threshold (Gruber, 1914).

The nerve-endings of *invertebrates* are not paralyzed by curare (Straub).

Sensory Nerves.—These are not affected by curare. The reports of early travelers who describe poisoning by curare arrows mention that sensation is not impaired when motion is entirely impossible. Bernard also studied this action directly on the frog. He ligatured one leg with the exception of the sciatic nerve, injected the poison, and applied the stimulus to one of the upper extremities. This caused a reflex movement of the ligated leg, which would not have been the case had the sensory endings of the foreleg been paralyzed.

Paralysis of Respiration as Cause of Death.—In cold-blooded animals in which the respiratory exchange takes place largely through the skin, and respiratory movements are unnecessary, the poison is gradually eliminated if the animal be kept in a moist atmosphere. Complete recovery occurs after eight to ten days, except when the dose is extremely large, in which case other factors come into play.

Warm-blooded animals die of paralysis of the respiratory muscles. If artificial respiration be kept up and the dose has been only just large enough to produce paralysis they may also recover.

The recovery of the respiratory muscle begins immediately, while the sciatic endings require several hours. The effect of the curare increases progressively with the dose: it is as if an increasing resistance were gradually introduced between the nerve and the muscle.

The seat of the *respiratory paralysis* is also peripheral, for stimulation of the phrenic nerve does not result in contraction of the diaphragm.

The respiratory paralysis, if it is not too profound, is promptly removed by *physostigmine*; stimulation of the sciatic also becomes effective again.

Bronchial muscle is not affected by curare (Trendelenburg).

Metabolism.—Curare paralyzes the *temperature nerves* of the muscles, as well as the motor nerves, so that cocaine, *e.g.*, can not raise the temperature.

The muscular paralysis *lowers the metabolism*. It is claimed that this diminution is far more conspicuous in the nitrogen than in the carbon-metabolism.

Creatine Output.—This has been considered as an index of the tonic functions of muscle, and is supposed to be controlled by the sympathetic system. It is not affected by curare, nor does curare prevent the increase by epinephrine, caffeine, etc. (O. Riesser, 1916).

Glycosuria is a frequent but not constant phenomenon (Morishima, 1899). It is not wholly due to asphyxia, for it can not be completely prevented by artificial respiration (Macleod, 1909). The earlier literature is reviewed by S. Weber, 1904.

Epinephrine Output.—This is markedly depressed by curare in the dosage required to paralyze skeletal muscle (Stewart and Rogoff, 1919).

Peristalsis.—This is often increased, partly by asphyxia, but also with artificial respiration. Bidder, 1865, found no direct effect on intestinal or other smooth muscle, even with the largest doses.

Ikeda, 1916, with excised intestine found stimulation of the muscle and slight increase of tone.

Urinary Bladder.—Edmunds and Roth, 1920 found that curare, like atropine, failed to abolish the motor response to parasympathetic and sympathetic stimulation, in cats.

Autonomic Ganglia.—The vagus, vasomotor, salivary, pupillary, etc., ganglia are depressed but usually not as strongly as with nicotine.

The antagonism to nicotine stimulation indicates that the paralysis involves the ganglion cells. The order in which the ganglia are affected is also the same as with

nicotine (Langley, 1918), and has been discussed in the general section on autonomic poisons.

Effects on the Circulation.—If artificial respiration is maintained, the first effect of curare on the circulation consists in a fall of blood pressure, due to peripheral vasomotor depression (Tillie, 1890; Sollmann and Pilcher, 1910). The action is apparently on the ganglion cells (Langley, 1918). This is soon accompanied by quickened heart beat, from depression of the vagus ganglia.

The depression does not readily pass into paralysis, so that stimulation of the vagus or sciatic is still effective; indeed, the vasomotor reflexes may be increased, through the central action of the curare. Martin and Stiles, 1914, also found that the threshold of the vasomotor center is not raised, even by large doses. The reflex depressor fibers are rendered more sensitive (Langley, 1912), or rather, the depressor response is more nearly proportional to the strength of the stimulus, than in normal animals (Martin and Stiles, 1914). Porter, 1915, finds that the response to sciatic and depressor stimulation may be doubled while the level of blood pressure remains practically unchanged; and interprets this as evidence that the vasotonic and vasoreflex centers are distinct and independent.

These effects on the circulation pass off within fifteen minutes, and the circulation returns to normal, while the muscular paralysis persists. They therefore do not seriously interfere with the employment of the drug in experiments. The main objection which may be urged against the latter is that it does not produce sensory paralysis, while the absence of struggling, etc., might cause the inexperienced operator to neglect a proper enforcement of other means of anesthesia.

Perfusion of frog's vessels slows vasoconstriction, which is not modified by absence of calcium (Pearce, 1913).

Vagus.—The peripheral effects correspond to those of nicotine. Electric stimulation of the vagus does not arrest the heart, but it may be slowed, or beat faster (Dale and Laidlaw, 1911).

The *vagus conduction* is slowed, in the frog heart, analogous to the skeletal muscles (M. Lapique and Veil, 1916).

Perfusion of the medulla oblongata, in the turtle, may stimulate the cardio-inhibitory center somewhat, but more commonly tends to diminish the sensitivity of the center to other stimulants (Bush, 1920).

The *lymph hearts* of frogs are arrested (Bernard).

Central Nervous System.—When curare is applied directly to the spinal cord of frogs, it causes typical *strychnine convulsions*. With ordinary methods of administration these are masked by paralysis of the nerve-endings. Certain samples, however, cause strychnine convulsions before the typical curare action appears.

In *dogs*, the convulsions produced by injecting curare into the spinal canal or cerebral ventricles differ from those of strychnine, being irregular and asymmetric (McGuigan, 1916).

Inactivity by Gastro-intestinal Canal.—The effects of curare are obtained only if it is introduced under the skin or into the circulation, but usually *not if introduced into the stomach*. The experiments on the administration of curare by the stomach (mainly by Bernard) have shown that:

1. It is not destroyed by the gastric juice, pancreatic juice, or saliva.
2. It passes very slowly through the walls of the stomach when the epithelium has been killed, and not at all if the epithelium is still living. (It will be remembered also that strychnine is not absorbed by the stomach in rabbits.)
3. It is to some extent fixed or destroyed by the liver, for it is much less active when injected into the portal than into the jugular vein. However, the discrepancy between the gastric and hypodermic dose persists, even when the liver is largely excluded by Eck's fistula; so that the liver destruction can not be very important in mammals (Polimanti, 1914). It is also destroyed *in vitro* by ox-bile, and by bacteria.

In *frogs* the liver is the main agent in the disintoxication: in normal animals 50 times as much curare is required by mouth as hypodermically; the difference disappears completely if the liver is excised; digestion of curare with liver substance destroys its activity.

4. It is very rapidly excreted unchanged in the urine.

In *mammals* the inactivity of curare by the mouth is due partly to its destruction by the bile and bacteria; but mainly to the capacity for absorption being less than the capacity for its destruction or excretion. If the renal vessels are tied, poisoning occurs quite readily even when it is taken by the stomach. If very large doses are taken on an empty stomach, sufficient may be absorbed to cause symptoms.

Use of Curare in Convulsions.—This is still largely experimental and not very promising. It has been suggested to combat the convulsions of strychnine, tetanus, and

hydrophobia (E. Collins, 1905). It is certainly quite possible to suppress the spasmodic condition by sufficiently large doses. Unfortunately, however, it is impossible to secure this without at the same time paralyzing respiration. This latter may, theoretically, be counteracted by artificial respiration, but this prolonged manipulation is in itself injurious. On the other hand, minimal doses may be considered useless, and, indeed, as has been pointed out, even if the spasms could be suppressed without affecting the respiration, this would not be an ideal treatment for strychnine. In well-chosen cases, however, curare may be the means of saving life. Convulsions certainly tend to heighten fatigue and paralysis of the medullary centers, and if in a case in which the degree of poisoning just exceeded the lethal limit by a very little, a minimal amount of curare were injected, this might, perhaps, reduce the spasm sufficiently to turn the scale, or somewhat larger doses might be given which would require some, but not very much, artificial respiration. This has actually been done, and in desperate cases curare is worthy of a trial; but in addition to the other objections come the very uncertain quantitative effects. It would be justified only to work with tested samples, and these are rarely accessible when needed.

Administration.—The drug should be given hypodermically, using per kilogram of patient one-tenth the fatal dose determined per kilogram of dog; and being prepared for artificial respiration and physostigmine. Curarine, if pure, would give an exact substance, in the dose of 1 to 12 mg. hypodermically. The reliability of the alkaloid is, however, open to doubt.

GUANIDINE AND METHYL-GUANIDINES

Guanidine (imido-urea), $\text{NH:C}(\text{NH}_2)_2$, and methyl- and dimethyl-guanidine occur in urine (Kutscher and Lohmann, 1908; Findlay and Sharpe, 1920; Major, 1924). They are closely related to creatine and arginine, and are also formed in the putrefaction of proteins. They produce more striking pharmacologic effects than the other nitrogenous metabolites. These effects include convulsive phenomena and sustained high blood pressure; and this suggested that retention of the guanidines might be the cause of clinical tetany (Koch, 1912; Paton and Findlay, 1917; Nattrass and Sharpe, 1921; Klinger, 1921); of chorea (Fuchs, 1914); of eclampsia; and of hypertension (Major, 1924, 1925; Major and Stephenson, 1924 and 1925). However, since convulsions and high blood-pressure can be produced in many other ways, the causative relationship could only be established by the demonstration of effective concentrations of guanidine in the blood. This has not been done, and according to the present data, it appears inconceivable that such concentrations would occur; for whilst the effects of guanidine are striking, they can only be evoked in intact animals by quantities that are very much greater than the total normal guanidine output, and considerably greater than the total nitrogen excretion. In man, 3 Gm. of guanidine intravenously, appear to be necessary to raise the blood-pressure, and the effect lasts only an hour. To maintain it for 24 hours would therefore seem to require some 72 Gm., *i.e.*, much more than the total nitrogen metabolized, and very much more than the total normal daily excretion of guanidines (100 to 150 mg.). Convulsions require even more. The retention of a part of the normal small output of guanidine, through impaired kidney function (Major), therefore probably possesses no greater significance than the similar retention of creatine and uric acid.

Striped Muscle.—The effects resemble closely those of nicotine. In excised frog-muscle, concentration above 0.2 per cent. produce a curare-like paralysis, concentrations between 0.025 to 0.06 per cent. cause the characteristic twittings (Meighan, 1917; Grant, 1920). These are mainly fascicular; but in frogs, at the height of the poisoning, they are interspersed with contractions of the entire muscles, in regular sequence; and this is the main phenomenon in toads (Frank and Stern, 1921). Guggens and Baumann, 1876, showed that all the contractions are entirely peripheral; *i.e.* they

persist after destruction of the central nervous system. They are abolished by curare and by atropine (Frank and Stern) and do not occur if the nerve-endings have been allowed to degenerate (Fuehner, 1920). From this it has been argued that guanidine acts on the nerve-endings; but the argument is not convincing, since the excitability of the muscle itself alters after nerve-section as in the "reaction of degeneration." No twittings occur if the application is confined to the nerve-free ends of the sartorius muscle; but this is probably because the sarcolemma is less permeable at these regions. Exactly the same phenomena are shown by barium and by physostigmine; there is even a potentiated synergism between guanidine and barium (Fuehner, 1920). The guanidine twittings are suppressed by weakening the muscle (Langley, 1915); and by calcium or magnesium (Fuehner, 1907 and 1911). Local anesthetic (cocaine, 4 mg.; or procaine) remove the guanidine and nicotine stimulation, but appear ineffective against barium (Frank and Stern, 1921).

Calcium and Phosphate Equilibrium.—Watanabe, 1918, claims that the injection of convulsive doses of guanidine into rabbits greatly increases the phosphate of the serum, and that generally the calcium of the serum is somewhat decreased. Confirmation would be desirable.

Other Substances that Produce Fibrillary Twitching in Skeletal Muscle.—These comprise: nicotine; parasympathetic stimulants, *i.e.*, physostigmine and acetyl-choline; muscular stimulants, *i.e.*, barium, aconitine, veratrine; decalcifying ions, *i.e.*, oxalate, citrate and fluoride, also thiocyanate; and some of the metals.

Blood-pressure.—Intravenous injection of guanidine or methyl-guanidine (0.1 to 0.4 Gm. per Kg.) produces an immediate large rise of the blood pressure, which is sustained for $\frac{1}{2}$ to 4 hours. In man, 0.05 to 0.08 Gm. per Kg., by vein, raises the systolic pressure by 30 to 50 mm. for about an hour. The rise is apparently caused by vasoconstriction, through a peripheral action (presumably analogous to barium). It is independent of the muscular twittings, which only set in later. It may be lowered temporarily by nitrites, and more permanently by the injection of calcium and potassium. The heart is slowed during the rise. Toxic doses produce cardiac irregularity and fall of blood pressure (Loewit, 1912; Major; Major and Stephenson, 1924, 1925).

Frog-heart.—Weak concentrations of guanidine and methyl-guanidine increase the height of the systole; higher concentrations produce diastolic arrest (G. Rosenow, 1921; Burns and Watson, 1920).

Respiration.—This is very greatly slowed, to 4 or 5 per minute, and is arrested by larger doses. The animals may then be saved by artificial respiration (Klinger, 1921; Major; Major and Stephenson). Guinea-pigs are rendered dyspneic by 0.01 Gm. per Kg., and killed by 0.03 Gm. per Kg. The dyspnea gave rise to the theory that methyl-guanidine was the active agent in anaphylaxis (Heyde and Vogt, 1913); but Loewit, 1913 showed the absence of bronchial constriction.

Protection Against Anaphylaxis.—D. Burns states that guanidine confers protection if injected immediately before or after the provocative dose. Confirmation is desirable.

Toxicity.—The comparative toxicity of guanidine and its amino derivatives has been investigated by Garino, 1916.

Fate.—Wishart, 1920, claims that guanidine injection, hypodermic or intravenous, increases the creatine content of the muscles of the animals.

BOTULINUS TOXIN

According to Edmunds and Keiper, 1924, all the phenomena of botulinus poisoning can be explained by stimulation, then depression of the receptive mechanism of the parasympathetic and skeletal muscle.

The phenomena set in after a latent period of about 12 hours. In striped muscle, a single stimulus through the nerve produces good contraction; but repeated stimulation leads to rapid exhaustion and paralysis. The response to direct stimulation of the muscle is not altered. Death occurs by asphyxia, and may be indefinitely postponed by artificial respiration. The recovery of the muscular excitability, however, is so very slow, that this treatment is not feasible clinically. Physostigmine fails to counteract the paralysis; but pilocarpine antagonizes the parasympathetic effects on the eye and heart. Man and guinea pigs are highly susceptible, dogs and rabbits are relatively tolerant. The curare action can be produced in frogs if these are warmed.

An antitoxin has been developed which protects guinea-pigs when it is injected with the toxin, but may fail if different strains are used (Pfenninger, 1924). Methods of standardization have been established (Ida Bangston, 1921). As with tetanus toxin, the antitoxin is ineffective after the nerves have been affected (Edmunds, 1924) and ails therefore after the symptoms have developed. The clinical results are not decisive (Bronfenbrenner and Weiss, 1924); they would doubtless depend on the time interval.

Good success might be expected if the antitoxin were injected promptly after the consumption of the toxin; there might be a fair chance as long as no symptoms had developed; a doubtful chance with mild symptoms, and very little hope if the symptoms were severe.

The course of intoxication is greatly delayed by sedatives, morphine, phenobarbital, ether or nitrous oxide anesthesia. This delay gives a better opportunity for the destruction of the toxin, and perhaps also for the success of antitoxin (Bronfenbrenner and Weiss; Edmunds).

EPINEPHRINE

General Statement.—Epinephrine (also called *Adrenaline*, *Suprarenine* and numerous similar names) is the active principle of the medulla of the suprarenal gland. It is a relatively simple amine derivative of catechol, and can be prepared synthetically. It behaves as a feeble base and might be classed with the alkaloids. Its solutions are very unstable, unless a preservative is added.

Its typical actions consist in a highly specific stimulation of the receptive mechanism of the entire sympathetic system. The effects upon any given organ—whether augmentory, inhibitory, or indifferent—therefore correspond with the effects of stimulation of its sympathetic innervation. Very dilute concentrations may have opposite effects.

The most important practical manifestation of this action consists in a high rise of blood pressure, from peripheral stimulation of the vasoconstrictor mechanism of the systemic vessels, and of the accelerator mechanism of the heart.

Epinephrine is used locally for arresting hemorrhage and enhancing the anesthetic effects of cocaine; hypodermically in bronchial asthma; intravenously, for tiding the patient over acute circulatory collapse.

Epinephrine leaves the blood stream rapidly and is then destroyed, especially in the liver, so that the effects are of an intravenous injection are of very short duration. It is poorly absorbed from mucous membranes, and its absorption from subcutaneous injections is delayed by its vasoconstrictor effect, so that the response is relatively slight, except as regards especially sensitive conditions, such as asthma, or in hypersensitive individuals.

Overdoses, intravenously, kill by acute dilation of the heart.

Historical.—Epinephrine is identical with the "*chromaffin substance*" (giving a green color with ferric chloride, and pink with alkalis, iodine or chlorine, and taking up chromium salts; Henle, 1865), which was discovered by Vulpian, 1856, in the medulla of the adrenal bodies, and also in association with sympathetic cells elsewhere. The suprarenal medulla, as shown by Balfour, is a direct outgrowth of the sympathetic system, and consists at first of neuroblasts. The cortex is of mesoblastic origin, and does not contain epinephrine, but choline (Lohmann, 1907).

The pressor action of the medullary substance was discovered by Oliver and Schaefer, 1895, and by Czybulski and Symonowicz, 1895. This was followed by many attempts to separate the active principle. The researches of v. Fuerth, 1898, and particularly those of Abel, paved the way to its isolation in crystalline form, which was first accomplished by Takamine, 1901, Aldrich, 1901, and Abel, 1903. Its structural constitution was determined by Jowett, 1904, and its synthesis accomplished by Stolz, 1904, Dakin, 1905, and Flücher, 1908. An extensive series of related amines, with similar sympathomimetic actions, has also been prepared (Barger and Jowett, 1905; Barger and Dale, 1910), and some of these, as well as the synthetic epinephrine itself, are marketed.

A good discussion of epinephrine is contained in Barger's "*Simpler Natural Bases*," 1914.

Abel and Macht, 1912, have also found considerable epinephrine (along with the digitaloid bufagin) in the "parotid glands" of the tropical toad, *Bufo Agua*.

Crawford and Watanabe, 1915, believe that it (or a similar substance) exists in pituitary extracts and is partly responsible for their pressor effect.

Extracts of the *retro-peritoneal chromaffin tissue*, of man and mammals, also contain epinephrine or a closely related substance, having the typical action on intestinal and uterine muscle (Fulk and Macleod, 1916).

Chemical Structure.—Epinephrine is dioxyphe nyl (pyrocatechin) ethanol-methylamine, $\text{C}_6\text{H}_3(\text{OH})_2-\text{CHOH}-\text{CH}_2-\text{NHCH}_3$, corresponding to the empirical formula $\text{C}_9\text{H}_{13}\text{NO}_3$ (first established by Aldrich, 1902).

Its structure is rather closely related to that of tyrosine; and it may perhaps be derived from this or similar amines in the body.

Action of Isomers.—The natural epinephrine is levorotatory. The synthetic base is racemic, and has been split into an l- and d-component by Flücher, 1908. The l-component is identical with the natural base. The dextrorotatory base produces qualitatively the same actions, but has only one-twelfth to one-eighteenth the activity; and the racemic mixture, therefore, has about half the activity of the natural base (Loewi and H. Meyer, 1905; Cushny, 1908 and 1909; Abderhalden and Mueller, 1908; W. H. Schultz, 1909). Froehlich, 1909, claims that the d-base has a much more persistent action.

Related Sympathetic Substances.—Barger and Dale, 1910, found that the universal peripheral sympathetic stimulation (which they aptly call "sympathomimetic action") is not peculiar to epinephrine, but is shared by a large number of primary and secondary amines, the simplest being the primary fatty amines, such as amylamine. The catechol nucleus is a rather unessential constituent, and the action of catechol itself is not related to that of epinephrine. However, the intensity and specificity of action increases as the amines approach the composition of epinephrine itself. It is noteworthy that the various sympathetic effects, and the augmentory and inhibitory stimulations, vary independently in these various amines. Nor is there any parallelism between instability and activity.

Sympathomimetic Action of Epinephrine.—The correspondence between epinephrine and sympathetic stimulation, the organs and functions augmented and inhibited and the localization of the effects in the receptive mechanism were described in the general discussion of autonomic reactions.

Effects on Circulation.—The intravenous injection of epinephrine into a normal animal, with intact vagi, produces the striking phenomena depicted in Fig. 9. The blood pressure rises sharply; as it approaches its maximum, the heart beats are greatly slowed and strengthened. The pressure is not sustained, but returns quickly to normal. The heart beats also return to their former rate; but, as may be seen from the tracing, more slowly than the pressure.

These phenomena are due to the interaction of three factors: vasoconstriction, vagus stimulation, and stimulation of the cardiac accelerator mechanism.

The blood pressure may rise to a very high level, especially if the vagi have been divided or paralyzed. In dogs, it may exceed 300 mm. of mercury. The extent of the rise increases with the dose, but not in simple proportion. The main element in the rise is ordinarily the intense vasoconstriction; for the volume of the organs diminishes as the blood pressure rises. The cardiac stimulation, however, is also an important factor, and sometimes it is the more important.

The cardiac slowing is indirect, due mainly to stimulation of the vagus center by the rise of blood pressure. The direct action of epinephrine would be to quicken the heart rate by stimulation of the accelerator endings; this is the result with small doses (Hoskins and Lovelette, 1914); or

in excised hearts; or if the vagi have been divided or paralyzed; or if the heart escapes temporarily from the vagus control, as often happens. With the vagi cut, epinephrine stimulates the auricular, and still more the ventricular efficiency (Wiggers, 1916). At the same time, epinephrine has an injurious effect on the heart-muscle, which may produce ventricular fibrillation and cardiac dilation if the dosage is excessive or the heart hyper-sensitive.

FIG. 9.—*Suprarenal on blood-pressure, dog.* $1\frac{1}{2}$ drops per Kg. of 1:1000 epinephrine injected intravenously at H. P. = Blood-pressure in mm. of Hg.

Double Peak of Blood Pressure.—A typical blood pressure curve after large doses of epinephrine ($\frac{1}{2}$ to 1 c.c. of 1:10,000, by vein) shows the following outline (Fig. 10):

The first rise (1) is due essentially to the peripheral vasoconstriction action. The first fall (2) is interpreted as a beginning relaxation of this peripheral constriction. The second rise (3) has been attributed to stimulation of the vasomotor center, superimposed

FIG. 10.—Diagram of blood-pressure phases after intravenous epinephrine. (See text.)

on the residual peripheral vasoconstriction; for this peak does not occur after decapitation or high section of the cord (McGuigan and Hyatt, 1918).

The final fall (4) is probably due to impurities (Weidlein, 1912), presumably mainly choline (Hunt).

Epinephrine sometimes produced also a *central vasoconstrictor* effect by action on the sympathetic dorsal root and mesenteric ganglia. (Hartman et al. 1918.)

Effect on Venous Pressure.—Capps, 1911 and 1913, found in animals that this is not altered by small doses; it rises with large doses which embarrass the heart.

The rise is due to back-pressure from the arterial constriction, and not to the contraction of the veins (Burton-Opitz, 1922); which epinephrine also produces. The rise

of vein pressure has also been observed in normal men, after the hypodermic injection of 0.4 to 1 mg. of epinephrine (G. Rosenow, 1920).

Blood-vessels.—Epinephrine produces a very powerful vasoconstriction. This is the main factor in the rise of blood pressure, for the organ volume and the outflow of blood from veins are diminished. The site of action is almost entirely peripheral, for the rise occurs if the central nervous system has been destroyed; the perfusion flow through excised organs is slowed or arrested (Bier, 1897); and even rings of excised artery contract if placed in epinephrine solutions (A. B. Meyer, 1907). The vasomotor center is not usually affected directly; but it may respond indirectly, generally by constriction, to the increased pressure; occasionally by dilation, when the increased blood supply relieves a preëxisting asphyxial stimulation (Pilcher and Sollmann, 1915). (Occasionally, there are doubtful indications of direct stimulation of the vasomotor center; E. D. Brown, 1916).

The sympathetic constriction involves the smooth muscle in arteries, veins and capillaries. Its intensity varies with the relative abundance of the muscular tissue; it is therefore more intense in the arterioles. Important differences exist also in the susceptibility of the vascular areas, presumably according to the development of their sympathetic receptive mechanism. The maximum constriction occurs in the splanchnic vessels, especially the kidneys; and in the vessels supplying the voluntary muscles and mucous membranes. The constrictor action is weak in the coronary, cerebral and pulmonary vessels; and in the intact animal these vessels are passively dilated by the displacement of blood from the more powerfully constricted areas. Certain vessels are *dilated directly* (Cow), for instance the coronary in man. In others, dilation occurs only with very dilute solutions, or under special conditions, for instance late in the course of prolonged perfusions, or when the vascular tone is already high. The reactions are also influenced by the presence of other vasomotor drugs. The constriction of susceptible vessels persist as long as effective concentrations of epinephrine are present. Even *very large doses* of epinephrine (7,000 times the effective quantity) do not paralyze the vasomotor mechanism.

The direct effects on the vascular muscle may be observed on excised arterial rings; by the artificial perfusion of surviving organs; and by microscopic examination of the circulation in living animals.

Arterial Rings.—These are suspended in oxygenated Ringer's solution (A. B. Meyer); better results are obtained if a careful technic is followed (Rothlin 1921). Epinephrine constricts most arteries, but relaxes some, for instance the pulmonary vessels (Rothlin). The response is usually much greater with a second exposure of the washed artery. This holds true also for other vascular drugs (Rothlin).

Arterial Rhythm.—Epinephrine also favors the occurrence of rhythmic contractions in the arterial rings. These may also be evoked by other conditions that raise the tone of the arterial muscle, by muscular stimulants (Gunter, 1916; Wachholder, 1921); by oxygen (Helene Friedmann, 1920); and by distention (Bayliss). They are abolished by muscular depressants and by carbon dioxide.

Direct Effect on Veins.—Gunn and Chavasse, 1913, showed that excised veins also react by constriction, although this does not apply to all veins (Crawford and Twombly, 1913). Segments of the superior vena cava, near the heart, enter into rhythmic pulsations. (Active contraction of the veins has also been demonstrated *in situ* by stimulation of the efferent nerves; by reflexes, and by asphyxia (Hooker, 1918).

Perfusion of Organs.—This is usually demonstrated on the hind-legs of the frog (Lewen-Trendelenburg), but the ear of the rabbit, or any mammalian organ, may be used, especially to illustrate differences in the reactions of various areas. Epinephrine and other constricting drugs slow or arrest the outflow; nitrites and other dilating drugs

quicken the flow. The method is delicate, but is somewhat complicated by the formation of edemas. Continued perfusion with Ringer's solution increases the sensitiveness, perhaps by washing out excess acid from the muscles. (Alday-Redomet, 1920). Frog legs three days old and distinctly putrid continued to respond to epinephrine.

Prolonged perfusion with epinephrine may alter the response of the frog-legs to that they tend to react by dilation to increased concentration of epinephrine, and to histamine and pituitary; but preserve their constrictor response to barium, strophanthin and nicotine. Epinephrine thus became antagonistic to barium (Bauer and Froehlich, 1918).

Microscopic Examination.—In the frog's foot, epinephrine may be seen to constrict especially the arterioles; and to antagonize local vasodilators, such as sodium barbital (W. Jacobi, 1920). Krogh, 1919 and his pupils, and others (Carrier, 1922 etc.) have shown that the capillaries are also involved, and Krogh observed that the action is on the smooth muscle fibers that are sparsely scattered over the capillaries, and serve as sluices. They are generally constricted, but may be unaffected or dilate, according to the organ and species.

Skin Reaction to Epinephrine.—The intracutaneous injection of epinephrine (a drop of 1:100,000) produces intense blanching and "gooseflesh," persisting for several hours (Sollmann and Pilcher, 1916). The blanching occurs though the circulation of the skin has been obstructed, so that the action must involve the capillaries (Cotton et al. 1916). It was claimed that modifications of this reaction occur in "hyperthyroidism" (Goetsch); but they are not characteristic and are seen in 20 per cent. of normal individuals (van Wagenen, 1922).

Dilator Action of Epinephrine.—This is the predominant response of certain mammalian vessels (D. Cow, 1911), but may also occur in others under special conditions, especially with very dilute concentrations; late in the course of perfusions; and particularly when the vascular tone is already high. (Brodie and Dixon, 1904; Sollmann, 1905; Ogawa, 1912.) Increase of temperature diminished the contractor response, and at 41° to 45°C., reversed into dilatation. *Frog's vessels* do not show dilation with dilute solutions, nor with increase of temperature, but only in the absence of calcium or after *degeneration of the nerves* (Pearce, 1913).

In the ear of the living rabbit, the constriction is also followed by dilation especially on the succeeding day (Meltzer and Auer, 1904, 1921). The vessels of the *de-nervated ear* were said to dilate with doses that are constrictor for the normal ear (Engeloch, 1915); but Meltzer and Auer, 1921, could not distinguish any special difference after denervation.

Cannon and Lyman, 1913, find that in living animals, small doses will either raise or lower the blood pressure, according to its previous level; and adduce evidence that the lowering is due to a direct dilator action on constricted arterial muscle. The fall occurs after ergotoxine. The dilator reaction is confined mainly to the peripheral vessels, for the fall of pressure which occurs with normal cats (0.002 mg.) occurs also if the splanchnic vessels are ligated, but is replaced by a rise if the splanchnic vessels are intact and the important peripheral trunks ligated (Hartmann, 1915). He therefore supposes that vasodilator nerves exist in the peripheral vessels, but not in the splanchnics. The dilator reaction fails if the vessels are already relaxed, as by hemorrhage or depressor stimulation. However, Swetschnikoff, 1914, on isolated rabbit's ear, observed the same constriction, whether the pressure was high or low.

The vasodilator effects observed in living animals are due partly if not solely to direct action on the vascular muscles; for they may occur after complete degeneration of their nerves (Hartman et al., 1917 and 1918; Gruber, 1918; Dale and Richards, 1918). Hartman et al. believe that there is also a central factor, located in the sympathetic or dorsal root ganglia. This interpretation is not accepted by Gruber, and Dale and Richards.

In cats the dilator reaction is developed to the full degree only 11 weeks after birth. (Hartman and Kilborn, 1918.)

Differences in the Response of Vascular Areas.—The reaction of different vessels to epinephrine varies quantitatively and somewhat qualitatively, depending on the sympathetic susceptibility, and not on the histologic structure of their muscle. In intact animals, most areas are constricted, but some are dilated, passively or directly. Direct dilation is revealed by the excised arterial rings and by perfusion. The older literature is cited by Barbour, 1912; the more recent by Rothlin, 1921).

Differential Reactions of the Arterioles.—Those of the skeletal muscles are dilated by small and constricted by large doses. Those of the skin, bone, and spleen are not dilated by any dose (literature in Hartman, Kilborn and Fraser, 1918). The reactions of other important areas are complex.

The Coronary Vessels.—Arterial rings respond by dilation in most mammals, but by constriction in man and monkeys (Barbour, 1912; Barbour and Prince, 1915; Park

and Janeway, 1912; and others). Perfusion of the arrested heart may cause either dilation (Elliott, 1905) or weak constriction (Wiggers, 1909).

In the beating heart, the coronary flow is certainly increased in most species of animals (excised hearts, Wiggers; Rabe, 1912; Markwalder and Starling, 1913; Morawitz and Zahn, 1914; not in monkeys, Barbour and Prince, 1915) on account of the pumping action of the contracting cardiac muscle. In the intact animal, this occurs even if the blood pressure is kept level by hemorrhage (F. Meyer, 1913); and the increase would be still greater, if the blood pressure, and therefore the coronary pressure are allowed to rise (Bond, 1911). The heart-muscle would therefore be better nourished and thus better able to work against the high resistance. A vasoconstrictor effect on the coronary vessels can be discerned in the excised heart only with doses which are too small to affect the cardiac muscle (Brodie and Cullis, 1911).

In the monkey, however, and therefore presumably in man, the conditions are different. All doses slow the coronary flow of the excised monkey heart, whether this is beating or resting (Barbour and Prince, 1915).

Pulmonary Vessels.—These show a weak vasoconstriction (Plumier, 1904; Wiggers, 1909; Plumier and Clermont, 1912; Tribe, 1912). According to Tribe, negative effects (Brodie and Dixon, 1904; Burton-Opitz, 1907; Heger and Phillipson, 1912; Baehr and Pick, 1913) are attributable to the dilator effect of the chlorethane in certain commercial solutions. Cow, 1911, and Barbour, 1912, found that the reaction of arterial rings varied according to their situation; the intravisceral portion of the artery did not react; the extravisceral portion was constricted.

Macht, 1911, describes powerful constriction; Beresin, 1913, no action or dilation.

Pulmonary Vessels of the Amphibian and Reptilian Lungs.—These are innervated from the parasympathetic, and paralyzed by atropine. Epinephrine dilates in small and constricts in large doses. (Luckhardt and Carlson, 1921.)

Pulmonary Circulation in Living Animals.—Epinephrine generally causes a large rise of pressure in the pulmonary artery (Wood, Jr., 1911). The response is complex, depending on the species, as well as on dosage and other conditions.

With *rabbits*, moderate doses, by vein may show either no effect on the pulmonary circulation, or may increase the pressure in the pulmonary artery, by constriction of the pulmonary arterioles. With *large dose*, the predominant contraction of the systemic arterioles hinders the return of the blood to the heart, and thus lowers the pulmonary arterial pressure. The effects in any case are predominantly vasomotor (Schaefer and Lim, 1919.)

With *dogs* and *cats*, with fairly large doses, the cardiac stimulation tends to predominate, so that the pressure rises in both the pulmonary and systemic vessels. The rise of pulmonary pressure is not usually due to displacement of blood by the contraction of the systemic vessels, as has been suggested (Anderes and Cloetta, 1916); for it may be absent when the systemic vasoconstriction is strong (Schaefer and Lim, 1919).

The increase of pulmonary pressure being largely cardiac, the volume of the blood in the lungs increases (Anderes, 1915) and the pulmonary circulation is quickened, with moderate doses. Large doses delay the pulmonary circulation time (Langlois and Deabouis, 1912), either by injury to the heart, or by constriction of the pulmonary vessels.

Cardiac Dilation.—When this occurs, the diminished efficiency of the heart causes a further rise of the pulmonary pressure with falling arterial pressure (Hallion and Nepper, 1911). This favors the production of *pulmonary edema*.

Portal Vessels.—These are markedly constricted on perfusion, in mammals and frogs (Berezin, 1914) as also in intact animals (Burton-Opitz, 1913). The response is much greater than that to electric stimulation of the nerves (MacLeod and Pearce, 1914).

Edmunds, 1915, confirmed the constrictor effect on excised portal vein; but attributes the changes in living animals to changes in the general venous and cardiac pressure, since the volume changes of the liver vary in different animals and with other conditions.

Cerebral Vessels.—In man, small doses of epinephrine first diminish and then increase the brain volume (Raphael and Stanton, 1919). The dilation is probably passive.

In animals, Wiggers, 1907 and 1914, found constriction; Berezin, 1916 observed constriction, but requiring higher concentration than for peripheral vessels; Dixon and Halliburton claim dilation. Cow observed slight relaxation of arterial rings. Here, again, there is undoubtedly passive dilation in the intact animal (Biedl and Reiner, 1905; Neujean, 1905). The vessels of the pia and retina are constricted (Hirschfelder, 1915).

(The cerebral vessels appear to have a much stronger vasomotor control in man than in the lower animals; for human brain-plethysmograms, under the influence of emotions, show large oscillations that are disproportionate to the changes in the general circulation (Cavazzini, 1918).

Renal Vessels.—These appear to be highly sensitive to epinephrine, so that doses that are too small to affect the general blood-pressure diminish the volume of the kidneys and slow their vein flow (Jonescu, 1908; Hoskins and Gunning, 1917). Perfused kidneys are also constricted; but if the sensitiveness of the vessels has been dulled by prolonged exposure, they may respond with dilation (Sollmann, 1905). Direct inspection of the frog kidney shows swelling of the glomerular vessels when very small doses are injected; and shrinkage with larger doses (Richards and Schmidt, 1924). These authors interpret the swelling as constriction of the efferent arteries, in conformity with a suggestion of Richards and Plant, 1917. However, the observations could be equally well explained by a dilation of the afferent vessels.

Cow, 1914, finds a direct vascular connection between the suprarenal medulla and the kidneys. Through this, epinephrine could reach the kidneys directly, and thus diminish the urine flow, without its existing in discoverable quantity in the general blood stream.

Urine Flow.—The intravenous injection of ordinary doses ($\frac{1}{2}$ mg. per rabbit) diminishes the urine flow and the renal vein-flow in direct proportion to the rise of blood-pressure (Gunning, 1918; Cushny and Lambic, 1921). Hypodermic injection of very large doses (2 mg. per rabbit) produces a strong diuresis that lasts for several hours (Biberfeld, 1907). It is independent of the glycosuria (Konschegg, 1912; Gramenitzki, 1912).

Antagonisms and Synergisms.—The epinephrine vasoconstriction is subject to modification by conditions, and the changes are often more than additive; *i.e.* they often show potentiated synergism and antagonism, sensitization and desensitization, and reversal to dilator response. For convenience, the phenomena may be grouped into antagonistic and synergistic.

Antagonistic Phenomena.—*Ergotoxine*, as *sympathetic paralyzant*, prevents the vasoconstriction; and produces a "*vasomotor reversal*;" *i.e.* epinephrine when injected after ergotoxine lowers the blood-pressure. (Dale, 1905; Sollmann and Brown, 1905.) Hartman and Fraser, 1917, attribute the fall to an unopposed dilator effect on the ganglia. *Apocodeine* also antagonizes the epinephrine constriction (Brodie and Dixon, 1904).

Muscular Depressants.—Nitrites, caffeine, histamine and sometimes pituitary, antagonize the epinephrine rise. The effect of *nitrite* is mutually almost quantitatively additive, (according to Cameron, 1906, 0.0075 mg. of epinephrine is neutralized by 0.6 mg. of nitroglycerine). *Caffeine*, on the other hand, antagonizes epinephrine in doses which are ineffective on the normal vessels (Sollmann and Pilcher, 1911). Mutual antagonism with *histamine* and *pituitary* has been described by Lhosa, 1920. Others have found simple summation of the pressor effects with pituitary (Hoskins, 1915; Boerner, 1915). Pituitary injection does not increase, but rather diminishes the epinephrine hyperglycemia (Stenstroem, 1914).

Parasympathetic Drugs.—*Atropine* antagonizes the epinephrine constriction in frogs, although it has no direct effect alone, nor does it antagonize barium (Hildebrandt, 1920). *Acetyl-choline*, like epinephrine constricts the frog vessels when perfused alone; but the two together produce dilation (Kolm, and Pick, 1820).

Stimulation of Vasomotor Nerves; Nicotine.—Epinephrine diminishes or abolishes the response to depressor stimulation (Oliver and Schaefer, and others), and indeed to all kinds of vasomotor stimulation, pressor or depressor; electric, nicotine, etc.; and this independently of the level of blood pressure (Hoskins, 1915).

Blood-volume and Anesthesia.—The blood-pressure response is diminished by ether anesthesia or hemorrhage; and increased by transfusion (Rous and Wilson, 1919).

Synergistic Phenomena.—Cocaine sensitizes to epinephrine, so that the mydriasis, vasoconstriction, etc., are more pronounced; and this with doses of cocaine which alone have no sensible effect (Fröhlich and Loewi; v. Fishel, 1915). A peculiar synergism has been described with *thionin*. This dye has no effect on the blood pressure with a normal animal; but produces a rise if the animal had epinephrine within 24 hours previously (Gautrelet, 1921). Collip, 1920, also reports that *spleen extract* by vein increases the pressor response of small doses of epinephrine. This was interpreted as depression of a vasodilator mechanism.

Synergism with Thyroid.—Thyroxin, which by itself evokes no reaction of the blood-vessels, sensitizes them to the constrictor action of epinephrine, and also to the dilator response of stimulation of the depressor nerve. (Asher and Flack, 1911; Santesson, 1918; R. L. Levy, 1916.) The epinephrine synergism may also be produced by stimulating the thyroid secretion through the superior laryngeal nerve (Asher and Flack), or through the cervical sympathetic (R. L. Levy, 1916); but it is local, for it occurs in perfused organs (Asher, 1916). The pupillodilator reaction is not sensitized (Levy).

There is no reliable evidence that thyroid injection or depressor stimulation alters the secretion of epinephrine; the statements of Gley and Quinquaud, 1913, and Richards and Wood, 1915, date before the introduction of adequate methods.

Epinephrine Sensitivity as Test for Thyroid Disease.—The quantitative reactions of the skin, of metabolism, etc., to epinephrine have been proposed as tests of "hyperthyroidism." However, no constant relations have been established.

Thyroidectomy was erroneously supposed to influence epinephrine glycosuria. The apparent results can be explained by the natural variations in the intensity of the glycosuria, which occur even in the same animal under apparently identical conditions (Underhill, 1911).

Polycythemia.—Large doses of epinephrine increase the number of red and white blood corpuscles (Lamson and Keith, 1916). This is attributed by Lamson (1916, 1920) to loss of plasma, increased portal pressure leading to increased lymph formation. However, the experiments of Edmunds and Stone, 1924, and Nelson, 1924, indicate that it is due mainly to the expression of blood cells by the contraction of the vascular spaces of the bone-marrow. Physostigmine, strychnine, and stimulation of the sciatic nerve have a similar effect (Edmunds and Lloyd, 1923).

Therapeutic Applications of the Local Vasoconstriction.—This is used for the control of capillary hemorrhage; for the relief of congested mucous membranes, and to diminish the absorption of local anesthetics. Its use in shock and collapse will be considered after its cardiac action.

Epinephrine as a Local Hemostatic.—The powerful vasoconstriction makes epinephrine a most effective agent for arresting capillary hemorrhage in any situation to which it can be applied locally; especially in nasal and laryngeal operations. Solutions of 1:50,000 to 1:1,000 are used for this purpose. The dilutions must be freshly prepared, since they lose their activity in a few hours. The action persists as long as the epinephrine is present; but when this has disappeared, there is often secondary hemorrhage, if the clot fails to adhere to the dilating vessel. Epinephrine is of little use against venous, and still less against arterial hemorrhage (Hanzlik, 1918).

Epinephrine in Internal Hemorrhage.—Injection of epinephrine into the circulation may sometimes control hemorrhage from inaccessible situations (Hanzlik, 1918); but it is often unsuccessful and may be harmful; for the rise in blood-pressure is likely to overcome the local constriction, especially in vessels that react poorly to epinephrine, such as the pulmonary and cerebral. Pulmonary hemorrhage is definitely increased (E. Frey, 1909; Wiggers, 1909).

In *intestinal hemorrhage*, the results of Wiggers, 1909, were somewhat more promising; after a momentary increase, the hemorrhage was reduced, and this effect outlasted the rise of pressure.

However, Hoskins and Gunning, 1917, find that small doses generally dilate the intestinal vessels (increased volume and vein-outflow). G. A. Hartman and McPhedran, 1917, also confirm this, but claim that still smaller doses constrict the vessels of the intestines, kidney, and generally also those of the spleen.

Spleen.—Hoskins and Gunning, 1917, state that effective doses, in intact animals, cause first a brief dilation, followed by contraction of the vessels. The threshold is more sensitive than that for the general arterial pressure. Rhythmic contractions of the spleen are sometimes started.

Coagulability of the Blood.—This is not affected by the direct addition of epinephrine but when epinephrine is injected into an animal, the coagulation time is shortened by small doses (0.002 mg. per Kg.) and retarded by large doses (0.05 mg.); (Cannon and Mendenhall, 1914). If the abdominal organs were removed from the circulation, these effects do not occur, so that the epinephrine acts presumably on the liver cells. Grabfield, 1916, finds that the increased coagulability with small doses is due to increased prothrombin; and Howell, 1914, refers the diminished coagulability after massive doses to diminished prothrombin analogous to hemophilia.

Hemolytic Action.—Epinephrine is strongly hemolytic for beef-blood and to a less degree for other animals. It also produces methemoglobin. Serum weakens the action (Kariga and Tanaka, 1912 and 1913).

Use on Inflamed Mucosæ.—Epinephrine gives symptomatic relief to inflamed surfaces, by contracting the dilated vessels. It is thus used in catarrhal conditions, *e.g.*, in *conjunctivitis*, and especially in *hay fever*. It is best applied in oily solution or ointments, containing $\frac{1}{10}$ per cent. of the free alkaloid; oil prolongs the action. Epinephrine is non-irritant, but its action is brief, and it is claimed that its continued use has caused chronic turgescence of the mucous membrane (Potts, 1906; J. N. Hall, 1910). Against *hemorrhoids* it may be used in suppositories; 1 mg. ($\frac{1}{60}$ gr.) of the alkaloid in 1 Gm. of Theobroma oil.

Epinephrine on Absorption.—Meltzer and Auer, 1904, claim that intravenous injections retard absorption and transudation. Van Lier, 1907, showed that the absorption of sodium iodide from hypodermic injections is markedly retarded, unless very hypertonic (20 per cent.) solutions are injected. The local effect on intestinal absorption is inconstant for iodide, but more marked on phenol and especially alcohol (Hanzlik, 1910, 1912, 1913).

In non-corrosive poisoning (cyanide, strychnine, aconite, etc.) Jona, 1913, suggests the administration of epinephrine by mouth (10 to 15 c.c. of 1:1,000) to retard absorption. This would need to be supplemented by evacuation and chemic antidotes. It is probably useless.

Infantile Paralysis.—Meltzer, 1916, urged the intradural injection of epinephrine, to arrest and cause the absorption of the spinal edema, especially when the respiratory center is threatened. He advised 2 c.c. of 1:1,000 solution, every 4 to 6 hours. The suggestion was tried on experimental poliomyelitis, with beneficial but not curative results (P. F. Clark, 1912). Clinical trials by Fraser, 1914, gave equivocal results, but they were confined to advanced cases.

Marie, 1913, claims that epinephrine neutralizes the *antitoxins* of tetanus and diphtheria *in vitro*, but not in the presence of hemoglobin. It has been tried against *tumors*, but without certain benefit. Engel, 1912, claims marked effects on rat tumors, not entirely explainable by ischemia.

Cardiac Effects.—In intact animals these are complicated by the vasomotor phenomena. The pulse rate is sometimes slowed, mainly in response to the rise of blood-pressure; but the heart tends to escape from the inhibition and to be greatly quickened by direct stimulation of the accelerator receptive mechanism. If the vagi had been previously divided, epinephrine produces pure acceleration. The direct effects on the cardiac muscle are better analyzed by its perfusion through excised mammalian or cold-blooded hearts. The most conspicuous result of the ordinary experimental dosage consist in marked increase of the rate, excursions and irritability. Existing irregularities are removed, and the effects of muscular depressants are counteracted (aconite, MacNider; strychnine, Januschke, 1910; phenol, chloral and chloroform, Gunn, 1913, 1915; potassium, etc.). A heart which has ceased to beat may often be revived by this drug.

If the epinephrine is continued, the stimulation becomes less and may be complicated by depression; and there is reason to believe that epinephrine always produces an injurious as well as a stimulant action on the heart; the injurious effect increasing with the concentration, whilst the stimulation is confined to an intermediate optimal range of concentration; so that the depressant effects predominate for very dilute and for high doses; as also for the prolonged action of intermediate doses (Sollmann and Barlow, 1926).

Normal Effects on the Perfused Frog Heart. Dilutions of 1:10¹³ to 10⁰ produce pure depression. Dilutions of 1:10⁷ to 10⁴ produce powerful stimulation, but this wears off quite rapidly, even when the concentration is kept constant; or rather, it is overcome by the progressive depression. With concentrations above 1:10⁶ this gives place promptly to arrhythmia and cardiac arrest. Entirely analogous phenomena are produced

in isolated strips of cardiac muscle; the auricular muscle is more responsive than the ventricular, both as to stimulation and depression. The stimulant concentrations diminish, but usually do not remove the Luciani type of irregularity. The lower concentration increase the irregularity (Sollmann and Barlow, 1926; Loewy and Harries, 1920; Sasaki, 1921).

Tortoise Heart.—This behaves essentially like the frog-heart. With auricular strips, it strengthens the rhythmic contractions and abolishes the tonus waves (Gruber and Markel, 1918; Snyder and Andrus, 1919; Gruber, 1920). It antagonizes the stimulant effect of nicotine and digitalis on the tonus waves; and it partially antagonizes barium (Gruber, 1921).

In birds, the cardiac effects of epinephrine, pituitrine and barium differ considerably from those in mammals (Paton and Watson, 1912).

Excised Mammalian Heart.—This responds very markedly to the epinephrine stimulation, which is often utilized in experimental technic to start hearts that have become arrested by injury or asphyxia (Hedborn, Cleghorn, Gottlieb, Boruttau; perfused apex strips, Leetham, 1913; muscular strips, Taussig and Meserve, 1925). The oxygen metabolism of the heart is increased in proportion to its activity and rate (Bancroft and Dixon, 1907; Evans and Ogawa, 1914). The fact that epinephrine may start a heart many hours after excision, or when it has been depressed by chloral, goes to show that the heart may contract independently of ganglia; for the epinephrine action is pretty certainly not ganglionic (Gunn, 1915).

Electrocardiograms.—In human subjects, normal or with "irritable hearts," 0.5 mg. of epinephrine, intramuscularly, decreases somewhat the height of the T wave. The conduction time is not altered (Clough, 1919). Electrocardiographic studies have been made on rabbits by F. R. Fraser, 1915.

Response to Stimulation of the Cardiac Nerves.—With perfused frog-hearts, stimulant doses of epinephrine make the heart more responsive to stimulation of the vagus nerve, *i.e.*, they lower the threshold; the response to stimulation of the accelerator is diminished or abolished, since the heart cannot go much beyond the augmentation produced by epinephrine (Barlow and Sollmann, 1926; Langecker, 1925). With intact mammals, large doses of epinephrine abolish the vagus response (Langley, 1901; Kuroda and Kuno, 1915); perhaps because the accelerator response is too strong; or more probably, because these large doses produce idioventricular rhythm (Winterberg).

Epinephrine on Heart Rate of Intact Animals.—Epinephrine tends to have a twofold action on the heart rate: acceleration through direct cardiac stimulation; and slowing through reflex vagus stimulation. When the vagi are intact and in good tone, ordinary doses of epinephrine invariably slow the rate (Meek and Eyster, 1915). When the vagus tone is low, quickening may result (Hoskins and Lovelette).

Vagus Effects.—The vagus stimulation is purely central, since no slowing occurs when the vagi are cut. It is due mainly to the rise of pressure, for it is very slight if the pressure is kept from rising by hemorrhage, or by paralyzing the vasomotor endings; or by a compensating device (Brooks et al., 1918). However, there is some evidence that the vagus center is also stimulated directly (Biedl and Reiner, 1898; Verworn, 1903). This is confirmed by the slowing which may occur when epinephrine is perfused through the medullary centers (E. D. Brown, 1916). Perfusion of the medulla of turtles, however, does not seem to affect their heart-rate (Bush, 1920).

The degree of slowing varies much in different individuals, but it always tends to lessen the rise of pressure, and this mounts much higher if the vagi are cut.

Vagus Synergism with Morphine.—Heinekamp, 1919 claims that the epinephrine slowing is generally absent unless the excitability of the vagus center has been raised by morphine.

A secondary increase of the pulse rate is sometimes seen, and is attributed to central and peripheral stimulation of the accelerator nerves (Neujean, 1905).

Blood Pressure Changes on Heart-rate.—The rise of blood pressure would tend to slow the heart—partly by direct stimulation of the cardioinhibitory center through the increased blood pressure; partly through reflex stimulation of this center. These cardioinhibitory reflexes originate largely from the thoracic aorta; for local distention of this slows the heart, whilst increased intraventricular pressure alone does not cause slowing. Both the afferent and efferent fibers of the inhibitory reflex run largely if not solely in the vagus; for the slowing occurs after section of the accelerator nerves (Eyster and Hooker, 1907 and 1908).

Bruecke, 1917, found that depressor stimulation slows the heart, but Kochmann, 1906, thinks that the effective endings are not in the heart. The pulmonary branches of the vagus are more effective in producing reflex slowing than the cardiac branches (Brodie and Russel, 1900).

Bruecke's results indicated that the slowing also involves inhibition of the accelerators; but this was not confirmed by Bainbridge, 1914.

Complete Heart-block.—Epinephrine quickens and strengthens the ventricles and auricles (van Egmond, 1913). Clinically, the acceleration occurs without changing the block; it is often interrupted by long pauses with syncope, and may be followed by several days of extreme retardation (Lutembacker, 1921).

Normal Epinephrine Output and Cardiac Activity.—Stewart and Rogoff, 1919, found that temporary exclusion of the adrenal blood from the circulation sometimes influenced the heart, especially when irregularities were present; and that in these cases, the disturbances disappear when the adrenal blood was re-admitted, or if corresponding doses of epinephrine were injected. Cannon, 1921, reported that the *denervated* heart is quickened by stimulation of the adrenals; (also by stimulation of the cervical sympathetic and by massage of the thyroid: thyroid massage lasting 2 minutes producing quickening persisting for several hours).

Antagonisms.—The epinephrine stimulation of the frog heart is mutually antagonistic with the sympathetic depressant ergotoxine (Langecker, 1925; Amsler, 1920), and with the parasympathetic stimulant muscarine (Gottlieb) and acetylcholine (Barlow and Sollmann, 1926). The depressant action of epinephrine may be additive to the acetylcholine inhibition, a phenomenon that Kolm and Pick, 1920, interpret (probably erroneously) as reversal of epinephrine to parasympathetic stimulation. A similar additive depression may occur with nicotine and ergotoxine (Amsler, 1920). The antagonism to the anesthetics, aconite etc. has been mentioned.

Influence of Ions.—The epinephrine acceleration is hindered by excess or absence of calcium, whilst potassium has relatively little influence (Libbrecht, 1920). The absence of calcium tends to render epinephrine depressant (Burridge, 1914).

Carbon Dioxide.—This increases the response to epinephrine; although it is depressant when used alone (Patterson, 1916).

Serum.—This gives a potentiated stimulation with epinephrine (Moog, 1914).

Therapeutic Use of Cardiac Stimulation.—This is utilized especially in acute arrest of the previously healthy heart; for instance from anesthetic accidents or asphyxia, especially of the new-born. Epinephrine may resuscitate hearts that have apparently stopped, although the chance of revival diminishes rapidly, and permanent success is scarcely possible if the circulation had stopped longer than 10 minutes. If the collapse is merely threatened, the epinephrine ($\frac{1}{50}$ to $\frac{1}{10}$ mg.) may be injected into the jugular vein or carotid artery (toward the heart), and repeated at intervals. If the pulse cannot be felt, epinephrine should be administered by intracardiac injection; $\frac{1}{2}$ to 1 mg. ($\frac{1}{2}$ to 1 c.c. of 1:1,000) is injected slowly, directly in the heart (right ventricle) by a long fine needle, thrust through the fourth intercostal space, close to the sternum. This heroic procedure would be justified only in otherwise hopeless cases; but it is sometimes successful, when joined with artificial respiration and cardiac massage. Strophanthin, 1 mg. has sometimes been added, but may do permanent harm to the myocardium. It would be better to inject it intravenously if the pulse is unsatisfactory after the heart has been started by the epinephrine (Gunn and Martin, 1915; Volkmann, 1918; J. A. Gunn, 1921; E. Vogt, 1921; Guthmann, 1921; Petit-Dutaillis, 1924).

Persistent Cardiac Weakness.—Epinephrine is useless, since its action is too fleeting; and it is dangerous, because the weakened and unstable heart-muscle is especially susceptible to the direct injurious effects of the epinephrine, and to the high blood-pressure that it produces.

Traumatic Shock.—Epinephrine may aid temporarily to tide the patient over hemorrhagic shock, by diverting a larger proportion of the blood-stream to the coronary and cerebral vessels; but it would need to be promptly supplemented by transfusion (Rous and Wilson, 1918). The epinephrine would be given intravenously, very slowly, carefully watching the pulse; 0.1 mg. has produced alarming symptoms. In *shock proper*, epinephrine is essentially useless, partially because it does not remedy the

chief difficulty, *i.e.*, the persistent loss of capillary tone, and partly because its action on the arterioles cannot be maintained sufficiently long. This inefficiency is confirmed experimentally in anaphylactic and peptone shock (Simonds, 1916). The danger probably exceeds the possible benefits.

Toxic Effects of Epinephrine.—These fall under two headings: (1) *Major accidents:* Acute cardiac dilation, pulmonary edema, ventricular fibrillation, terminating in death. These usually follow intravenous injection, and are especially liable to occur if the heart is already weakened or overexcitable, in cardiac disease, or as the result of chloroform or other cardiac poisons. The induction period of chloroform anesthesia is especially dangerous, although it may be necessary to take the risk. Such accidents should be treated with artificial respiration.

Danger in Cardiac Insufficiency.—In this condition, the hypodermic injection of 1 mg. generally produces distinct dilation and extrasystoles (M. Loeper *et al.*, 1918; D. Roth, 1914). Fatalities have occurred from 0.4 mg., hypodermically (Fridericia, 1915).

In *poisoning by cardiac depressants* (*f.i.*, chloroform, phenol or caffeine) the intravenous injection of epinephrine will temporarily restore blood pressure, and this may give the heart a chance to recover. But if the blood pressure is raised much above the normal, the heart may stop suddenly, and usually irrecoverably; and this may occur from doses of epinephrine which would be quite safe in healthy individuals (phenol, Sollmann; chloroform, Levy and Lewis, 1912; Nobel and Rothberger, 1914).

Epinephrine Pulmonary Edema.—This occurs more readily if the vagi have been divided, or if asphyxia is present; conversely, artificial respiration tends to prevent the occurrence of the edema (Gates and Auer, 1917).

Fatal Effects in Animals.—Excessive doses of epinephrine produce vomiting, excitement, debility, bloody diarrhea, hematuria, ascending central paralysis, great fall of temperature, occasionally convulsions, complete prostration, and death by respiratory (cat) or cardiac (dog) paralysis.

Rabbits show multiple pulmonary hemorrhages, probably associated with edema (Leo Schmidt, 1919).

The *fatal dose* varies considerably (usually 0.1 to 0.6 mg. per kilogram intravenously, or 2.5 to 10 mg. per kilogram hypodermically), but is about 500 times the therapeutic dose. A noticeable rise of blood pressure can be seen after $\frac{1}{100}$ of the fatal dose.

Guanine is said to lessen the toxicity and glycosuria (Desgrez and Dorleans, 1913).

Atropine is also claimed to decrease the toxicity (Leo Schmidt, 1919).

The toxic effects are the result of the peripheral actions: for as Cushny, 1909, has pointed out, the ratio of activity of the different isomers is the same for the toxic as for the blood-pressure effects.

(2) *Minor Accidents; Hypersusceptibility.*—The local application or hypodermic injection of epinephrine in ordinary doses does not normally evoke noticeable symptoms. Not infrequently, however, excitable or susceptible patients respond in a few minutes by tremors, anxiety and nervousness, palpitation, precordial distress, increased rate of pulse and respiration; rise of blood pressure and temperature, and sometimes hyperglycemia (Seifert, *Nebenwirk.*, 1915, page 234; Hewlett, 1918; Matsuo and Murakami, 1918). The symptoms may be very alarming to the physician as well as to the patient. They usually pass away in a short time, but they may be fatal (Fischer, 1920). This hypersusceptibility occurs especially in patients of nervous temperament; most markedly in those with toxic goiters; also in hypertension (O'Hare, 1920). It has been used ($\frac{1}{2}$ mg., intramuscular) as a test for neurasthenia and "irritable heart" (Peabody *et al.*, 1918; Wearn and Sturgis, 1919; D. M. Lyon, 1924).

Epinephrine Atheroma.—If rabbits receive frequently repeated injections of large doses of epinephrine, atheromatous changes and calcareous patches are often observed in the aorta (Josué, 1903) and other large vessels (d'Amato, 1905). These degenerations are never seen in dogs (Pearce and Stanton, 1906), or in monkeys, and presumably not in man. Dogs also give negative results with nicotine, lead, or toxins (Adler, 1914).

Identical lesions often occur spontaneously in rabbits which have never received epinephrine (Miles, 1907; Benneke, 1908; Hill, 1910, etc.). The frequency of these spontaneous lesions varies in different series from 3 to 30 per cent.; but they are so markedly more frequent after epinephrine treatment, that this must at least exaggerate the tendency to the degeneration (I. Levin and Larkin, 1910). Success depends on frequent repetition of the epinephrine rather than on the size of the dose (Fleisher, 1909).

The injury has been attributed to high blood pressure, and to direct toxicity by epinephrine. The older experiments undertaken to decide between these views (summarized by I. Adler, 1908), did not take account of the spontaneous occurrence of the lesions (M. K. Meyers, 1909; M. C. Hill, 1911) and the question can not be considered settled. The toxic theory seems the more probable; although Dixon, 1913, still states that all pressor agencies, when repeatedly applied, produce degenerations of the middle coat. It is highly doubtful whether these atheromas of rabbits have any relation to human atheroma.

Atheroma is also produced by feeding cholesterol, cottonseed oil, the aldehydes of fatty acids, hydrochloric acid and by paracresol (Adler, 1914; Denney and Frothingham, 1914).

The high blood pressure of *Clinical Hypertension* is definitely not due to epinephrine; for epinephrine would cause other marked disturbances, for instance of peristalsis, in doses much smaller than are required materially to raise the blood-pressure.

Epinephrine Myocarditis.—Rabbits also often show chronic myo-, endo-, and pericarditis, after repeated epinephrine injections. This lesion—which is apparently independent of the atheroma—is much more frequent (60 per cent.) if a single intravenous injection of epinephrine (0.2 mg.) is combined with sparteine (12 mg.) caffeine (25 mg.), or strophanthin (these drugs never cause the lesion if they are used without the epinephrine). The changes in the heart-muscle start at once, progress for some seven days, persist about six weeks, and then retrogress completely by sixteen weeks (Fleisher and Leo Loeb, 1909; Strickler and Fleisher, 1910; Christian and Walker, 1911).

Fleisher and Loeb, 1910, attribute the lesions to "excessive mechanical strain," from excessive contraction of the muscle fibers: For the lesions are situated mainly at the base of the left ventricle, where the strain is greatest; the changes are analogous to those shown by striated muscle subjected to overexertion; and the lesions do not appear in the relatively stronger and more resistant hearts of dogs. H. A. Stewart, 1912, prefers a toxic theory.

Hearts which show the microscopic changes are physiologically inferior to the normal; they are less able to cope with extra demands; and the animals appear more disposed to edemas (uranium) and to bacterial infections.

Influence of Dosage on the General Effects.—The effects of intravenous injection vary with the dose. The results of increasing doses may be tabulated as follows (Langley, 1901):

- (a) Rise of blood pressure.
- (b) Inhibition of bladder, mydriasis.
- (c) Contraction of uterus, vas deferens, and seminal vesicles; salivation and lachrymation; inhibition of stomach and gall-bladder; increased bile secretion; inhibition or stimulation of internal anal sphincter.
- (d) Contraction of ereciores pilorum.
- (e) Uncertain effect on tunica dartos and on sweat.

Relation of Dosage to Rise of Blood Pressure.—With intravenous injection in atropinized dogs, this is somewhat as follows (from the data of Hunt, 1901, and others): 0.00008 mg. per kilogram = rise of 5 mm.; 0.00025 = 7 mm.; 0.0005 = 15 mm.; 0.0007 = 20 mm.; 0.0017 = 25 mm.; 0.004 = 45 mm.; 0.006 = 66 mm.; 0.03 = 150 mm. The degree of rise, however, diminishes as the initial blood-pressure rises; so that the response obeys the Weber-Fechner law (D. M. Lyon, 1923).

Differences According to Methods of Administration.—Epinephrine produces practically no systemic effect when administered by mouth, and is uncertain by rectum (Hoskins, 1921), so that it evidently does not pass readily through the epithelium. It is very much less effective by hypodermic or intramuscular injection, or from the serous cavities, than it is by intravenous injection. These differences are due to the rate of absorption; and this in turn to the vasoconstriction. With subcutaneous injection, the vasoconstriction may be so complete, that the epinephrine must enter mainly through the lymphatics (D. M. Lyon, 1923). However,

the richness of the local vascular supply is an important factor (Fornet, 1922). The interference is less with intramuscular and peritoneal injections (Meltzer and Auer, 1905; Lappom, 1915) and with intradural injections (Auer and Meltzer, 1912, 1918). Injection under pressure in the nasal submucosa may be almost equivalent to intravenous injection (Pilcher, 1914). The placenta appears to be impermeable to epinephrine injected into the mother (Shimidzu, 1920).

The unabsorbed epinephrine at the site of the injection is apparently not destroyed, for the local blanching may persist for one to eight hours (root of rabbits' ear, Auer and Meltzer, 1917; Meltzer and Auer, 1921; scarified skin, Sollmann and Pilcher, 1917). When this epinephrine becomes gradually absorbed, it exerts its systemic actions; and the product of degree $\times$ duration of action is not much less than with intravenous injection (Fornet, 1922; Lyon, 1923).

Blood-pressure Response in Man.—This is usually practically unchanged on oral administration; but marked reactions may occur (Menninger, 1925). Hypodermically, 0.5 to 1.5 mg. ($\frac{1}{100}$ to $\frac{1}{40}$ gr.) gives uncertain results, usually a rise of 10 to 12 mm., rarely higher (to 45 mm.). The same doses intramuscularly give more constant and higher rise, usually 8 to 25 mm.; but sometimes much higher, over 90 mm., so as to produce alarming symptoms (Halsey, 1909).

Intratracheal Injection.—Auer and Gates, 1915, found that the injection of epinephrine into the lower trachea produces a prompt rise of blood pressure; presumably by aspiration and absorption from the alveoli. If the vagi have been divided, fatal pulmonary edema often follows. This may be prevented by atropine.

Direct Central Actions.—Lumbar injection of epinephrine may cause muscular spasm and tremor. Injection under the dura or into the substance of the cerebrum produces an apparently natural sleep, lasting two to five hours, with regular respiration and reflexes, and fall of temperature (Bass, 1914). Bass does not believe that these effects can be explained by vasoconstriction.

Cause of the Brief Action of Epinephrine.—When epinephrine is injected intravenously, the effects are of very short duration, disappearing within a few minutes after the injection ceases (Fig. 9). This goes parallel with the disappearance of epinephrine from the blood, and is due to the rapid destruction of the substance. Epinephrine is readily oxidized and thus rendered inactive. The oxidation occurs presumably in all tissues, including the blood, but with very different velocity. The blood vessels and especially the liver probably have the largest share.

On the other hand, the vessels continue to respond practically uniformly and indefinitely to whatever epinephrine may be present in the blood. Its effects may therefore be repeated by repeating the intravenous injection, and they may be rendered continuous by continuous infusion. A uniform infusion will maintain a uniform moderate rise of blood pressure for a considerable time.

Persistence of Action if the Concentration of Epinephrine Is Maintained.—In excised kidneys, the perfusion flow may be arrested for a long time, sometimes for hours, by a single injection of epinephrine. This illustrates that epinephrine is not destroyed (at least in the absence of oxygen) in the tissue (blood vessels) on which it exerts its main action. It also shows that the stimulation can be continued indefinitely, and that it does not give way to "fatigue," or to depression, no matter how much epinephrine is used.

This corresponds exactly to what is observed in the living animals: *Repeated injections* of the same dose, on the same animal, give quantitatively the same pressor effect (Bayac, 1905), for at least 20 successive injections (Kretschmer, 1907). Sufficient time must elapse between injections for the circulation to return to normal; otherwise, there will be superposition.

Kretschmer also found that *if the injection be made continuous* the pressure rise is maintained uniformly so long as the rate of injection is uniform. The blood-pressure

level rises as the rate of injection is increased, from the minimal effective dose until a maximum is attained. In rabbits, this occurs when the rate of injection corresponds to about 0.01 mg. per kilogram per minute. Up to this point, the destruction must keep step with the injection, else the rise would be progressive. Further injection produces no further rise, but, when the injection is arrested, the return to normal is inverse to the rate at which the epinephrine has been introduced, since it will take a longer time to destroy the excessive epinephrine.

The Uniformity of Response Is Not Unlimited.—Froehlich and Pick, 1912, found that if large doses are given in rapid succession, the rise becomes less pronounced and finally disappears, although the blood pressure may remain normal. This is perhaps due to an altered distribution of the blood; for Froehlich, 1910, found that a single dose of d-epinephrine, which has a much more prolonged action, may abolish the response to ordinary l-epinephrine.

Epinephrine Is Not an Antigen.—No antibody is produced, even if the (hypodermic) injections are continued over three months (Elliott and Durham, 1906); nor is there any habituation (Pollak, 1910). Halperm, 1913, claims that intraperitoneal injections of suprarenal extracts (not of epinephrine) leads to the production of a dilator substance.

The Return to Normal Pressure Coincides with the Disappearance of the Epinephrine from the Blood.—De Vos and Kochmann, 1905; D. E. Jackson, 1909; Trendelenburg, 1910, showed that the disappearance of epinephrine from the blood goes perfectly parallel with the return of the blood pressure.

The Disappearance of Epinephrine Is Not Due to Excretion.—Fuerth found that the urine contains at most traces, even after large injections; and the pressor effect disappears even when access to the excretory organs is excluded by clamping the aorta (Jackson, 1909). This experiment also shows that the visceral organs are not necessary for the destruction of epinephrine.

Artificial Destruction of Epinephrine.—Epinephrine is readily oxidized, especially in dilute and alkaline solutions (B. Moore, 1895), with complete loss of activity. Through its amido-group, it is also promptly inactivated by formaldehyde (Ciame, 1911). Artificial oxidation does not destroy all the activities at the same rate (McGuigan and Mostrom, 1913). Blood *in vitro* has a curiously slow destructive effect, so that the activity is prepared for many hours (Oliver and Schaefer, 1895; Emden and Fuerth, 1903); indeed, small quantities of serum retard the destruction materially (Schwetschnikoff, 1913). The oxidation proceeds much faster in the presence of blood vessels (Tatum, 1912). Cerebro-spinal fluid destroys epinephrine much more rapidly than does serum (Meltzer, 1911).

Destruction in Tissues.—Gioffredi, 1907, found that when epinephrine was perfused through the liver, it was rapidly destroyed; more slowly in skeletal muscle; not appreciably in the kidney, lung and brain. The destruction is therefore a special vital function of the liver.

Kretschmer, 1907, found that the destruction is hastened (*i.e.*, the action is shortened) by lessening the alkalinity of the blood by the injection of acids; and *vice versa*.

Bronchial Muscle; Use in Asthma and Anaphylactic Reactions.—The bronchi are relaxed, especially when spasmodically contracted, by stimulation of the sympathetic bronchodilator endings. The hypodermic injection of epinephrine, 0.1 to 1 mg., therefore gives prompt relief in spasmodic asthma (Kaplan, 1905; Matthews, 1910; Hoover and Taylor, 1915). It is also the most effective treatment of acute anaphylactic reactions from foreign serum etc.; and of the "nitritoid crises" of arsphenamine injection etc. In all these the bronchial dilation plays a part; but there may be other factors which are not understood. Epinephrine, for instance, diminishes the wheal reaction of the skin by codeine, which is allied to the edemic reactions of anaphylaxis. This response is apparently secured only by systemic, and not by local administration (Pilcher, 1926) so that it cannot be due to vasoconstriction.

The bronchodilatation has been confirmed in intact animals by Januschke and Pollak, 1911, and others; on excised lung by Baehr and Pick, 1913; on excised tracheal muscle by Trendelenburg, 1912; on excised bronchial muscle by Titone, 1913. Golla and Symes, 1913, find differences between the bronchial and tracheal muscles, and claim that normal bronchioles are constricted by epinephrine and that it dilates only when the bronchioles are spasmodically contracted by pilocarpine, etc.

Respiration.—This changes with the blood pressure (Nice, Rock and Courtright, 1914). It becomes deeper but irregular during the rise of blood pressure, and is generally arrested at its height (Langlois and Garrelon, 1910). In man, 1 mg. hypodermically is said (Fuchs and Roth, 1912) to increase the respiration volume by 8 to 94, mean 50 per cent.; the rate being unchanged or also increased. The effects on the perfused respiratory center are variable (E. D. Brown, 1916).

Voegtlin and Wiggers, 1918, tried epinephrine against narcotic depression of the respiration, with doubtful results.

Action on Pupil.—Epinephrine has a mydriatic effect. This occurs readily in frogs; but only under specially favorable conditions in mammals.

Conditions for the Occurrence of Epinephrine Mydriasis in Mammals.—This may be procured by large doses intravenously. With local application, the mydriatic effect may be obtained if the oculomotor tone is low (weak illumination, W. H. Schultz, 1908); if the absorption is hastened (conjunctivitis, H. Straub, 1919); or if the excitability of the sympathetic is increased.

Such an increase is supposed to occur in Basedow's disease and in pancreatic insufficiency. O. Loewl, 1907 and 1908, accordingly proposed a mydriatic response to epinephrine as a diagnostic sign in these diseases (with certain limitations). Later work, however, showed that the increased mydriatic reaction occurs in all types of hyperglycemia; and that it can therefore be prevented in pancreatectomized dogs by lowering the blood-sugar through phlorhizin (A. Loewy and Rosenberg, 1914). The sensitiveness appears also somewhat increased in chronic nephritis (Kato and Watanabe, 1920).

The mydriatic response to epinephrine is also obtained a few days after excision of the superior cervical ganglion (Meltzer and Auer, 1904; Joseph, 1912; Githens and Meltzer, 1916), or after removal of the ciliary ganglion (Joseph, 1915). This may likewise be attributed to increased excitability of the sympathetic distribution, accompanying the degenerative changes which follow the excision (H. Straub, 1910). An analogous increase of excitability in degenerating structures to epinephrine occurs in the ear vessels (Meltzer and Auer, 1903; Shimidzu, 1924), and in other organs (Elliot, 1905); also in skeletal muscle on degeneration of the sciatic nerve (Langley, 1905; Edmunds and Roth, 1909).

G. N. Stewart, Rogoff and Gibson, 1916, find the mydriatic responses of the denervated pupil the most sensitive and reliable test for the discharge of epinephrine; *f.i.* on stimulation of the peripheral end of the divided splanchnic nerves.

Sensitiveness of Different Mammals.—After excision of the superior cervical ganglion, cats are less sensitive than rabbits to the mydriatic action when the epinephrine is instilled into the eye; but they are more sensitive to intravenous injection. However, the response is more lasting in rabbits (Meltzer). On the other hand, the blood pressure response on intravenous injection is greater in rabbits than in cats, both as to height and duration (Githens, 1916).

Localization of Mydriatic Action.—Lewandowsky, 1898, showed that the mydriatic effect occurs after degeneration of the sympathetic, so that the action must be peripheral to the endings (*i.e.*, on the receptive substance).

The excised sphincter of the mammalian iris is also relaxed by epinephrine. This is counteracted by physostigmine, with mutual antagonism (Joseph, 1915, 1917). Pituitary also counteracts the mydriasis in intact animals (Githens and Meltzer, 1917).

Other Evidences of Ocular Sympathetic Stimulation.—The mydriasis is accompanied by separation of the lids, protrusion of the eyeball, and withdrawal of the nictitating membrane.

Intraocular Tension.—According to Rupert, 1909, this is first lowered, then increased.

Mydriatic Reaction in Frogs.—Frogs are especially susceptible to the mydriatic action; and this may be produced by systemic application (1 c.c., 1:100,000 into lymph sac) as well as in the enucleated eye (1:5,000; Meltzer and Auer, 1904; Meltzer, 1909). The dilation is prompt and persistent, submaximal, indifferent to light.

Epinephrine Miosis.—After repeated injections or local instillations, epinephrine may produce constriction of the pupils, in mammals. This altered response is attributed to a change in the pupillo-dilator muscle (Kato and Watanabe, 1920).

Reactions of Other Smooth Muscle.—These were discussed in the general description of autonomic muscle. The following notes may be added:

Action on Intestines.—Peristalsis is inhibited and the tone relaxed. Very dilute solutions increase the contractions (Hoskins, 1912).

The *ileo-colic sphincter* differs from the ordinary intestine, being contracted by epinephrine or splanchnic stimulation (Elliot, 1904).

Excised Stomach.—This is relaxed in most mammals, but contracted in some. The gastric sphincters are always contracted (M. Smith, 1918).

Gall-bladder.—This is relaxed (Lieb and McWhorter, 1915).

Action on the Uterus.—The effects correspond to stimulation of the hypogastric nerve (see general section on Autonomic Poisons); in pregnant cats it produces contraction; in non-pregnant cats relaxation (Cushny, Kehier, Dale); in non-pregnant guinea pigs, relaxation; in dogs, contraction followed by relaxation; in rabbits, increased tonus (Biagi, 1905). Surviving human uterus is stimulated (Ruebsamen and Kligermann, 1912), whether pregnant or not (Lieb, 1915). The Fallopian tubes are also stimulated to contraction (Gunn, 1914).

Through an artificial abdominal wall of celluloid, Ludwig and Lenz, 1923, observed that epinephrine arouses peristalsis in the uterus of the gravid rabbit or cat; but in the non-gravid and puerperal animals it produces prompt arrest and fixation of the uterus in whatever tonus happens to pertain at the moment.

Epinephrine could be used locally to arrest postpartum hemorrhage; not intravenously, since the increased blood pressure would increase the bleeding.

Reversal of Epinephrine Inhibition by Pituitary Extract.—The uteri of guinea pigs and non-pregnant cats are ordinarily relaxed by epinephrine. If, however, they are first treated with pituitary solution, the epinephrine produces contraction. The differences in the normal response of different uteri to epinephrine may therefore depend on the content of pituitary. This sensitizing action seems to be in the peripheral nervous mechanism, and not in the muscle itself (Cow, 1919).

Excised Ureter.—Epinephrine (1:500,000) increases the rate and tone, or starts the contractions. The effect is reversed by ergotoxine (Macht, 1916).

The response of the epinephrine isomers differs only quantitatively, the levo being much more stimulant than the dextro (Macht, 1918).

Urinary Bladder.—This was discussed in the general section on Autonomic Poisons.

Spleen.—This apparently may respond either by relaxation or contraction. Hartman and Lang, 1919 (literature), obtained active dilation by action on the dorsal root ganglia, semilunar ganglia and some terminal structure in the spleen; and constriction by ganglionic or more peripheral action.

The **pigment cells** in the frog's skin are contracted into spheres (Lieben, 1906). This also occurs in the melanophores of fishes, the effect being reversed by ergotoxine (Spaeth and Barbour, 1917).

Epinephrine in Annelids.—Chromophile material exists in the ganglia of a number of species, including the earthworms and leech. These possess vascular systems whose contractions are accelerated by epinephrine (Gaskell, 1919).

Protozoa.—The pulsations of the vacuoles of paramaecium are accelerated by epinephrine, pituitary and pineal extracts (Feather, 1919).

Skeletal Muscle.—Epinephrine, when applied to excised skeletal muscles, has practically no effect on their contraction, even in concentrations up to 1:15,000 (Kuno, 1915; Takayasu, 1916). However, the injection of epinephrine into living animals increases the efficiency (height of contraction and irritability) of their muscles, the increase persisting after the muscle is excised (Oliver and Schaefer, 1895). The improvement is particularly marked if the muscles (of cats) have been previously fatigued, or weakened by acids (Gruber, 1914; Gruber and Kretschmer, 1918). The epinephrine effect is also noticeable when post-mortem changes have started (Gruber and Fellow, 1918).

The increased efficiency is probably an indirect effect on the epinephrine, attributable to improved circulation through the muscle whilst this is still in the body (Cannon and Nice, 1916; Hoskins *et al.*, 1916; Gunning, 1917).

The **creatine formation**, which is considered an index of a tonic function of skeletal muscle controlled by the sympathetic system, is increased by epinephrine, even after curare (Riesser, 1916).

Nerve trunks are not affected.

Effect on Secretions.—Epinephrine may provoke secretion of the salivary and lachrymal glands (Langley, 1901); and of the skin glands of frogs (Ehrmann, 1905). These would not be suppressed by atropine. The increased secretion of the submaxillary glands is accompanied by increased blood flow (Solem and Lommen, 1915). In most glands, however, secretion is diminished or arrested through the vasoconstriction. This is notably the case with *pancreatic secretion* (Benedicenti, 1906; Edmunds, 1909).

This is apparently due to diminished blood supply; for the volume of the pancreas is decreased even by small doses, and independently of the general blood pressure (Mann and McLachlin, 1917).

Sweat.—This is increased in animals (Muto, 1916). (He finds that the sweat glands are innervated by both the sympathetic and parasympathetic. The sympathetic predominates in horse and sheep; whereas man, cattle and cats are more subject to the parasympathetic.)

The action is peripheral, for Dieden, 1916, found that the injection of epinephrine into a cat's paw produces sweating when the sciatic or posterior nerve roots have been divided. Injection at a distance or intravenously was ineffective.

Bile Secretion.—Downs and Eddy, 1919, claim that this is increased by epinephrine. Confirmation is needed.

Cerebro-spinal Fluid.—The secretion is not affected, the pressure varying merely with the blood-pressure changes (Dixon and Halliburton, 1916).

Lymph Secretion.—The thoracic lymph flow increases parallel to the rise of arterial pressure; the effect, therefore, being apparently circulatory (Yanagawa, 1916).

Epinephrine Hyperglycemia and Glycosuria.—The injection of large doses of epinephrine (much beyond the therapeutic) into animals produces marked hyperglycemia and glycosuria by converting the hepatic glycogen into sugar. The effect is analogous to asphyxial glycosuria, diabetic puncture, or stimulation of the hepatic, splanchnic or sensory nerves; all acting probably on sympathetic nerves controlling the glycogenic functions.

In human subjects, clinical doses of epinephrine (1 mg. hypodermically) do not produce glycosuria; but it increases the sensitiveness to alimentary glycosuria (Landau, 1914); and in epinephrine-sensitive patients it produces hyperglycemia.

Clinical Response.—In epinephrine-sensitive patients, the intramuscular injection of 0.5 mg. increases the blood sugar to 0.045 per cent., whilst in "negative" patients it is 0.03 per cent. (Peabody *et al.*, 1918). The hyperglycemia is accompanied by decreased reserve alkali in the blood (Peters and Geyelin, 1917).

Historical.—The occurrence of glycosuria after hypodermic injection of large doses of epinephrine was discovered by F. Blum, 1901. Intravenous and intramuscular administration are less effective, even if larger doses are used (Pollak, 1909; Underhill, 1911). The phenomenon was investigated by Herter and Wakeman, 1902, Noel Paton, 1903, and many later observers. An extensive discussion of the literature is given by G. M. MacKenzie, 1917. The glycosuric action of *other sympathomimetic drugs* is described by Morita, 1915.

Mechanism of the Glycosuria.—The glycosuria is generally proportional to the hyperglycemia (Gramenitzki, 1912). It is *not asphyxial*. The hyperglycemia occurs even after excision of the kidneys (Zuelzer, 1901; Metzger, 1902), showing that it is *not renal*.

There is conclusive evidence that the glycosuria is due to *increased glycogenolysis in the liver*. The degree of hyperglycemia and glycosuria depends upon the glycogen content of the animal; they are more intense in well-fed animals (Vosburgh and Richards, 1903), or in animals rich in glycogen; and conversely there is no glycosuria in animals whose glycogen has been completely removed by phlorhizin; and an existing phlorhizin glycosuria is not increased by epinephrine (Ringer, 1910).

The evidence for the hepatic origin of the sugar is also convincing. The blood of the hepatic vein contains more sugar than that of the portal; sugar formation is increased on perfusion of the excised liver, and conversely, there is no glycosuria when the functions of the liver have been injured by phosphorus (E. Frank and Isaac, 1911).

Habituation.—The glycosuria response diminishes and finally disappears on continued administration of epinephrine, in proportion to the exhaustion of the glycogen store. Hyperglycemia persists somewhat longer than the glycosuria, so that continued injection of epinephrine evidently decreases the permeability of the kidneys for glucose (Pollak, 1909, 1911; Korschegg, 1912); perhaps by vasoconstriction. At this stage, diabetic puncture also produces only hyperglycemia, and not glycosuria. Phlorhizin, however, still causes glycosuria (Biberfeld, 1916).

Parallelism of Vasoconstriction and Glycosuria.—The results of Straub, 1909, and Ritzmann, 1909, show that both effects are strictly parallel, and proportional to the

rate of injection (intravenous). Smaller doses suffice for the glycosuria than are required for the rise of blood pressure (Grämenitzki, 1912); and Ransom believes that the pressor and glycosuric action are connected with different groups in the molecule. This is supported by the observation that, with partial oxidation of epinephrine, the glycosuric action is lost first (McGuigan and Mostrom, 1913).

Interfering Factors.—Epinephrine glycosuria is prevented by ergotoxine (Loewi) which lessens the hyperglycemia and also the permeability of the kidney for sugar but not for chloride; Miculicich, 1912). It is also prevented by nicotine (Hirayama, 1911); by lymphagogues (peptone, hirudin; Miculicich); and by repeated hemorrhage (Wilenko, 1912). Urethane increases the activity (Underhill, 1911).

Epinephrine glycosuria is suppressed by antipyretics (Starkenstein). Since the hyperglycemia is not diminished, the action of the antipyretics must be on renal permeability (Mansfield and Purjesz, 1915).

Relation of Adrenals to Other Glycosurias.—Removal of the adrenals prevents the usual glycosuric response to diabetic puncture (A. Mayer), theobromine (Miculicich, 1912) and splanchnic stimulation (Macleod *et al.*, 1911, 1912). This seems to indicate that these glycosurias occur through the mediation of the adrenal glands. Later work, however, indicates that these results were the result of shock. Stewart and Rogoff, 1918, 1920, abolished practically the total epinephrine output by removal of one adrenal and denervation of the other. This had no effect on the liver glycogen; nor did it interfere with the production of hyperglycemia by diabetic puncture, ether or asphyxia. Also, they could find no evidence that diabetic puncture increases the output of epinephrine.

Suprarenals and Pancreas.—The fact that both glands may affect the sugar-metabolism led to theories of a special inter-relation between them. These lack all real foundation. The glycosuric mechanisms of epinephrine and of the pancreas are absolutely different; the epinephrine lacking entirely the metabolic disturbances that are characteristic for pancreatic diabetes—the inability to use sugar, the altered urea-ammonium ratio (Underhill and Closson, 1906; Rosenbloom and Weinberger, 1912); the increase of acetone substances, etc.

Some of the earlier work on epinephrine glycemia was done by painting the pancreas with the drug; and it was supposed that there was a direct action on this organ. This was erroneous, for no effect is obtained unless there is absorption of the epinephrine from the peritoneal cavity (Kleiner and Meltzer, 1917).

Gaseous Metabolism.—The hypodermic injection of 0.5 mg. of epinephrine increases the basal metabolism of human subjects by 15 to 40 per cent., according to their susceptibility. This has no relation to the thyroid activity (Boothby and Sandiford, 1920; Marine and Lenhart, 1920). The respiratory quotient often rises (Peabody *et al.* 1918; Tompkins *et al.*, 1919). The mechanism of the increased metabolism is not understood. It is out of proportion to the mobilization of glucose (Boothby and Sandiford). It does not appear to be due to the excitement.

Heat Regulation.—Excision of the suprarenals lowers temperature (Hultgren and Andersson, 1898); while the injection of epinephrine (and other internal secretions) produces fever (Freund and Marchand, 1913). Hirsch, 1913, found, presumably under different conditions, that the injection of epinephrine or pancreas lowers temperature by decreasing heat production. Cloetta and Waser, 1915, describe rise of brain temperature and cooling of skin, with 0.2 mg. in rabbits, intravenously. Intracerebral injection acted similarly. The rise was not prevented by ergotoxine.

Nitrogen Metabolism.—Epinephrine, by vein or hypodermically, has little or no influence on the nitrogen excretion (Kraus and Hirsch; Puest, 1908; Lusk, 1914). In dogs, large doses, hypodermically, increase the excretion of uric acid and especially of allantoin (Falta, 1914).

Urea Excretion.—Addis *et al.*, 1918, believe that the hypodermic injection of epinephrine into rabbits increases the urea-excretion capacity. Maximal doses, however, diminish the output. The efficiency is smaller if the urea concentration of the blood is high.

They believe that the increase is not related to the circulatory changes, and suggest a "sympathetic receptive substance" in the kidney cells. They also claim antagonism with epinephrine.

Further work is needed to make the conclusions convincing.

Physiologic Functions of Epinephrine.—The striking actions of epinephrine invite the theory that it plays an important rôle as a hormone for maintaining the tone of the sympathetic system, particularly the blood pressure; and that it is concerned in pathologic conditions of the sympathetic system, Basedow's disease, diabetes, arterial hypertension, etc. However, not enough epinephrine passes into the blood normally, to exert any effect on blood pressure, or even on the much more sensitive intestine; although it can be demonstrated in the blood of the adrenal vein by the blood pressure and by the pupil test (Stewart and Rogoff, 1916).

The output of epinephrine may be increased by stimulating the sympathetic nerve supply of the adrenal glands, directly, or through a dorsal center (*idem*); the increase, however, is never sufficient to affect the blood pressure. In fact, the output of epinephrine is so limited, even under the most favorable conditions, that it may be doubted whether it has much physiologic significance; nor has the causation of any pathologic condition been definitely connected with altered epinephrine content of the blood.

Epinephrine secretion is certainly not essential to life; for animals, including monkeys, live without noticeable disturbance when their output of epinephrine has been practically suppressed by excision of one adrenal, and section of the nerves of the other (Stewart and Rogoff, 1917, 1919).

It is possible, but scarcely probable, that epinephrine is mainly a waste product temporarily stored and perhaps destroyed in the adrenal glands. The very high blood-flow of the suprarenals, which is surpassed only by that of the thyroid (Burton-Opitz and Edwards, 1917), indicates that the gland has important functions; but these might be quite apart from the epinephrine.

Chemic Control of Body Functions.—The organism of animals as well as of plants produces, as direct or by-products of its activities, chemic substances of decided pharmacologic actions. Some of these are probably waste products; but others serve to regulate important functions. In this way, the body is under the constant influence of "drug therapy," and the correction of faulty functions by "drugs" is not an artificial but a natural process of the body. A striking instance of such regulation is the carbon dioxide (Bayliss and Starling, 1906), with its controlling effect on the respiratory and vasomotor centers, etc.; and there are numerous other instances of the importance of the "hormones" of internal secretion, such as the regulation of the pancreatic secretion by secretin; the chemic control of the sexual functions; etc. (Starling, Harvey Lectures, 1908)

Constrictor Substance of Serum.—Normal serum has a constrictor effect on blood vessels. This was at first attributed to epinephrine (Trendelenburg); but it was shown by G. N. Stewart, 1911, and confirmed by others, that serum stimulates all smooth muscle directly, and lacks the sympathomimetic inhibitory action of epinephrine, for instance, on the intestines. This constrictor substance has therefore no relation to epinephrine. It is formed mainly in the process of clotting (O'Connor, 1912) and increases with the age of the serum (Handovsky and Pick, 1912).

Presence of Epinephrine in Blood.—Epinephrine can be demonstrated in the blood of the adrenal veins; under special conditions and by especially sensitive methods also in the vena cava. The normal discharge in the cat and dog is about 0.00025 mg. per minute per kilogram of body weight (Stewart and Rogoff, 1917, 1923).

Epinephrine Output and Blood Pressure.—The concentration in the blood never reaches the level where it could affect the blood pressure.

Hoskins and McClure, 1912, point out that if epinephrine persisted normally in the circulation, it would result in inhibition of peristalsis, since the intestines are much more sensitive than the blood vessels. Trendelenburg, 1915, also finds that the concentration in normal blood could not be over 1 in 1 or 2 billions, and is probably smaller—too small to affect the blood pressure or intestine. Further, Hoskins and McPeck, 1913, emphasize that the small quantity which could possibly reach the circulation would dilate instead of constricting the blood vessels.

The fact that the adrenal glands do not normally contribute to the maintenance of vascular tone is also shown by temporarily clamping the adrenal vessels. The blood

pressure does not fall while the clamp is applied (within 40 hours; Austmann *et al.*, 1917); but only as death approaches (Trendelenburg, 1914); nor does it then rise when the clamp is removed (Hoskins and McClure, 1912. The positive results of Strehl and Weiss are attributed to obstruction of the vena cava or stimulation of afferent nerves; however, Hoskins and McPeck, 1913, also found positive results in pregnant cats).

Response to Splanchnic Stimulation.—This may increase the rate of epinephrine discharge to about four times the normal (Stewart and Rogoff, 1916). An actual discharge of epinephrine from splanchnic stimulation is shown by the mydriatic and blood-pressure reaction in the animal itself (Stewart *et al.*, 1916).

Stimulation of Sensory Nerves.—This does not influence the epinephrine output (Stewart and Rogoff, 1924, 1916).

Older methods gave deceptive results; partly because they did not really measure epinephrine; and partly because they overlooked the important influence of the rate of blood flow through the adrenals. If the epinephrine output is constant, as is ordinarily the case, then the concentration must vary with the rate of the blood flow through the adrenals. This is indeed the case (Stewart and Rogoff, 1917).

Role of Epinephrine in Splanchnic Pressor Response.—A part of the blood-pressure changes on splanchnic stimulation is due to the discharge of epinephrine. Asher, 1910 and 1912, found that splanchnic stimulation in eviscerated animals does not raise the blood pressure if the suprarenal vessels are clamped. The splanchnic rise under these conditions must therefore be due to secretion of epinephrine. The rise can be made continuous, showing that the epinephrine is secreted and not merely washed out.

With the normal animals the pressor effect of splanchnic stimulation is ordinarily interrupted by the temporary "dip," soon after the stimulation is started. This dip is absent if the adrenals are clamped and is therefore due to the discharge of epinephrine. The earlier observers (V. Anrep, 1912; Burton-Opitz and Edwards, 1916) believed that the epinephrine discharge caused the pressure to rise, when the direct stimulation of the vessels by the splanchnic had begun to fade; but Perlman and Vincent, 1919, propose the more probable explanation that the dip itself is due to the discharge of vaso-dilating concentrations of epinephrine acting mainly on the skeletal and splanchnic vessels.

The phenomena are not constant (Gley and Quinquaud, 1913). They are affected by the anesthetic (Parsons and Vincent, 1917) and are sometimes abolished by caffeine, curare and morphine (Perlman and Vincent).

Spinal Center.—In cats, epinephrine is liberated after section of the cord as low as the last cervical, but not after section of the mid-dorsal region (Stewart and Rogoff, 1917). This may be interpreted as an "epinephrine center" in the thoracic spinal cord.

Influence of Drugs on Epinephrine Output.—This is increased by strychnine, and by the central action of physostigmine, depressed by nicotine and curare; unchanged by strophanthin, atropine and pilocarpine (Stewart and Rogoff, 1919, 1920, 1921).

Low Blood Pressure and Shock.—It has been claimed that the epinephrine output is increased in conditions of low blood pressure, however induced, presumably in an effort to compensate the falling pressure. These claims were based on faulty methods.

Stewart and Rogoff, 1914, have shown definitely that the output of epinephrine and its concentration in the general circulation is not altered by low blood pressure. The concentration in the adrenal vein rises, but merely because the blood flow through the glands falls with the blood pressure, and the epinephrine is therefore less diluted. Etherization tends to lower the epinephrine store.

Emotional States.—Imperfect methods of epinephrine estimation also led to claims that emotion, fright, etc., increase the epinephrine output (Cannon *et al.*), and diminish the epinephrine store (Elliott, 1912). Exact methods failed to confirm these claims (Stewart and Rogoff, 1917).

Total Amount of Epinephrine in Glands.—In man, this is normally about 4 to 5 μ r. per gland (Goldzieher, 1910; Elliott, 1914); in dogs, 2 mg.; in cats, 0.19 mg. (Marchetti, 1915); in sheep, to 7 mg. (Folin, Cannon and Denis, 1913). The percentage is about 0.1 per cent. of the moist weight, in all animals. The content does not vary with the seasons (Seidell and Fenger, 1914).

In glands obtained from autopsy material from various diseases, the epinephrine content is generally somewhat low, about 0.35 per cent. of the dry weight, in place of the normal 0.4 per cent. (Lucksch, 1917).

Epinephrine is present very early in fetal animals (Fenger, 1912; McCord, 1915). In the human fetus, it is absent at six months, but present at full term (J. H. Lewis, 1916; Moore and Purinton, 1900).

Elliott (1905) believes that epinephrine is also present in special cells in other situations, but always closely associated with sympathetic ganglia (*f.i.* in the intercarotid body). This has been taken to indicate that sympathetic stimulation is effected by both a chemic and a nervous mechanism.

Choline.—Suprarenal extracts contain some choline. This is responsible for the depressor effects produced by such extracts after the removal of their epinephrine (Hunt, 1900).

The Adrenal Cortex.—This contains no epinephrine, and is supposed to have relations to growth and sexual development. Voegtlin and Macht, 1913, announced a crystalline lipo-soluble constrictor principle. Barlow and Sollmann, 1925, showed that the cardiac depression and heart block produced by extracts is due to potassium. It has been suggested, but without adequate evidence, that epinephrine is formed in the cortex (Hartman and Hartman, 1923).

Addison's Disease.—This is associated with destruction of the suprarenal glands. The therapeutic administration of preparations of the glands has therefore been tried (Rowntree, 1924), also in rickets, diabetes insipidus, etc. The results have generally not been very good, which is scarcely surprising when the rapid destruction of the substance is considered.

Feeding of Suprarenal.—With normal white rats, the ingestion of suprarenal for 2 to 9 weeks resulted in some hypertrophy of the testicles. The growth of other organs was not affected (Hoskins and Hoskins, 1916).

Suprarenal Testing.—Commercial preparations of epinephrine vary greatly in activity (Hunt, 1906; Sollmann, 1906; W. H. Schultz, 1910). This is partly due to the ready decomposition of solutions; but even the dry commercial base is often far from pure (Schultz, 1909). Assay is therefore desirable. Quantitative methods are also needed for scientific problems. Gravimetric and volumetric methods are not applicable and recourse must be had to colorimetric and physiologic methods. For fairly large quantities, the effect on the blood pressure of mammals is commonly used. A standard procedure is described in the U.S.P. The Trendelenburg method of frog perfusion has also been widely employed. Various other methods are discussed in the papers of Crawford, 1907; Schultz, 1909; G. N. Stewart, 1911; Tiffeneau, 1915.

Colorimetric methods also give good results. A process is described in the U.S.P. IX, and by Seidell, 1913 (with critical discussion). Folin, Cannon and Denis, 1913, describe another very sensitive test, which gives good agreement with the blood-pressure method. The method of Krauss is unsatisfactory (Hale and Seidell, 1913). The various color reactions are described by Barger, *Simpler Natural Bases*, 1914, page 89.

PREPARATIONS

Epinephrina (Epineph.), U.S.P.; *Adrenalinum* (Adrenal.), B.P.; Epinephrine (Adrenaline, L-Suprarenine, etc.); Levo-methylaminoethanol catechol, $C_9H_{13}NO_3$.—White or light brown powder, very slightly soluble in water or alcohol. Insoluble in ether, chloroform, acetone and fixed or volatile oils. *Dose*, hypodermic, 0.5 mg., $\frac{1}{120}$ gr., U.S.P.; ordinary maximum, 2 mg., $\frac{1}{30}$ gr.

**Liquor Epinephrinae Hydrochloridi* (Liq. Epineph. Hydrochlor.), U.S.P.; *Liquor Adrenalini Hydrochloricus*, B.P.—Contains 0.1 per cent. of epinephrine, sometimes with small quantities of antiseptics. The undiluted, aseptic solutions keep fairly well. On dilution they deteriorate in a few hours, by oxidation, acquiring a pink to brown color. This is favored by alkalis, delayed by acids. The alkaloid is a reducing agent and gives a pink or red color with oxidizing substances such as iodine (Ewins, 1910). Ferric chloride produces an emerald green color, which turns purple and carmine on adding an alkali. The U.S.P. requires the solution to be assayed by its effect on the blood-pressure of atropinized dogs. *Dose*, hypodermic, 0.5 c.c., 8 minims, U.S.P.; 0.6 to 1.8 c.c., 10 to 30 minims, B.P.

Suprarenalum Siccum (Supraren. Sicc.), Dried Suprarenals.—One part of Dried Suprarenals represents approximately 6 parts of fresh glands, free from fat, and about 0.5 per cent of, epinephrine. *Dose*, 0.25 Gm., 4 gr.

EPHEDRINE

This alkaloid was isolated by Nagai 1887 from a plant (Ma Huang) used as medicine by the Chinese since antiquity. Its chemical structure is very closely related to epinephrine and tyramine; and it has strongly specialized sympathomimetic actions. These effects on the circulation, intestines, bronchi, iris, etc., agree in nearly every detail with those of

epinephrine. The chief differences are that the rise of blood pressure is more lasting (10 to 15 minutes after intravenous injection); and that the cardiac augmentation plays a large share, perhaps because the accelerator ganglia are stimulated as well as the receptive mechanism. The cardiac stimulation makes it more effective than epinephrine in the lighter grades of hemorrhages, and in histamine, peptone, anaphylactic and traumatic shock; but it cannot overcome the more severe degrees of circulatory depression. It is being tried clinically against these conditions and other hypotensions, and against asthma (Amatsu and Kubota, 1917; Chen and Schmidt, 1924; Chen, 1925). The usual dose is 60 to 90 mg., 1 to 1½ grains, by mouth. A 10 per cent. solution of ephedrine sulphate, with or without the addition of 0.1 per cent. of hematropine hydrochloride, is a useful mydriatic for routine ophthalmic examinations (Groenouw, 1895; Middleton and Chen, 1926).

UZARA

This African drug—the root of an Asclepiadaceous plant—resembles epinephrine closely in its peripheral effects, except that these are more gradual and lasting. It is used by the natives against dysentery, and seems to be effective in amebic dysentery and other diarrheas (Merck's Report, 26:464.)

The actions have been studied especially by Guerber, 1911, 1920.

Constituents.—The drug contains neither alkaloids nor tannin; its antidiarrheal action is therefore not astringent. The active constituents are a series of glucosides, the most important being the crystalline Uzarin (Hennig, 1917). This is very easily hydrolyzed by acids into glucose and the inactive uzaridine. It is therefore much less effective by stomach than by rectum. *Uzaron* is a purified extract of secret composition.

COTOIN (METHYL-TRIOXY-BENZOPHENONE)

This has been used in diarrhea. It is not antiseptic nor astringent, but decreases the tone of excised intestines and uterus (Impens, 1913).

In transfused frogs, it contracts the blood vessels and diminishes reflex excitability (Jodlbauer and Kurtz, 1916). It is not toxic to rabbits, nor to infusoria. Its excretion occurs by the urine, partly as benzoic acid (Jodlbauer and Kurtz).

It is used in cholera; also to check the night sweats of phthisis. *Dose*, 0.06 to 0.6 Gm., 1 to 10 gr.

It is a glucoside, derived from Coto, the bark of an unknown Bolivian plant. This and the related "paracoto" barks also contain other related trioxyphenones, differing by the number of methyl groups (Jodebauer and Kurtz, 1916).

TYRAMINE

(Para-hydroxyphenyl-ethylamine, Ergotamine,¹ Uteramine).

This is closely related to epinephrine in structure and produces almost identical sympathomimetic stimulation of the receptive mechanism. It is somewhat less powerful and more persistent (Dale and Dixon, 1900; Quagliariello, 1914). It occurs in ergot, and participates in the pressor effect, and to a minor degree in the uterine action of this drug.

¹ The term ergotamine is also applied to ergotoxine.

Chemistry.—Its relation to tyrosine and epinephrine are shown by the formulas:

It occurs commonly in the products of putrefaction, autolysis, and fermentation; and must therefore be present in the alimentary tract. It was isolated from ergot (which contains 0.01 to 0.1 per cent.) and was prepared synthetically from hordenine (its dimethyl derivative) by Barger, 1909. Further syntheses were made by Barger and Wampole, 1910. It occurs also in the common American and European mistletoes (*Phoradendron flavescens* and *Viscum album*). It has not been demonstrated in other species of *Phoradendron* (Crawford, 1914; Ostenberg, 1915). It constitutes the "salivary" poison of certain cephalopods (Henge, 1913). In the body a part is converted into para-hydroxy-phenylacetic acid. This change is also effected by surviving liver and uterus. It is completely destroyed by the isolated heart (Ewins and Laidlaw, 1910). The de-aminization of tyrosine in the animal organism was studied by Kotake et al., 1922.

Circulation.—Intravenous injection of tyramine produces considerable rise in blood pressure, lasting 2 or 3 minutes. The heart is slowed reflexly.

The rise appears to be purely vascular, judging by the diminished volume of the kidneys and intestines, and by the decreased vein flow (Bickel and Pawlow, 1912).

The constrictor action is generally considered peripheral, since it occurs also on excised arteries, even on the coronaries, (Barbour, 1913).

However, Baehr and Pick, 1916, claim that the pressure rise of tyramine and related bases does not occur after nicotine.

The injection of tyramine into mice may produce temporary stasis of the capillary circulation, similar to that of inflammation (J. Wolf, 1923); but tyramine does not blue the comb of the rooster acutely (Crawford, 1913); nor produce gangrene on repeated injection (Bickel and Pawlow). Harvey, 1911, asserts that long-continued administration to rabbits produces arterial sclerosis and chronic nephritis.

Clinical Effect on Human Circulation.—Hewlett, 1918, observed the response of 60 to 80 mg., injected hypodermically into the loose tissue below the clavicle. (The local vasoconstriction may prevent absorption in other situations.)

This dosage usually results in slowing of the pulse and in marked rise of the systolic blood pressure and much smaller rise of the diastolic pressure. The pulse-pressure and volume-pulse are therefore markedly increased. The T wave of the electrocardiogram is also increased. These changes point to increased output of the heart. They start within a few minutes, and last for about half an hour.

Considerable and prolonged rise of blood pressure was also described by A. Clark, 1910; Findlay, 1911, and Hoyt, 1912, after 20 to 80 mg. hypodermically.

The rise reaches its maximum in 10 to 12 minutes, and returns to normal within 15 to 45 minutes. *Polycythemia* and *lymphocytosis* are observed, as with epinephrine (J. J. G. Brown, 1920).

Oral administration is practically ineffectual (Sharp, 1911).

Use in Collapse.—Injections of 5 to 20 mg. ($\frac{1}{12}$ to $\frac{1}{3}$ gr.) have been tried without much success. Even with 60 mg., Hewlett, 1918, obtained only a transient response in infective diseases. After operations, there was generally permanent improvement; but it is difficult to exclude spontaneous recovery.

Hemostatic Efficiency.—Tyramine is fairly effective in arresting superficial capillary hemorrhage, both by local and systemic application; but its efficiency is far below epinephrine (Hanzlik, 1918).

Cerebrospinal Pressure.—This varies with the circulatory changes (Dixon and Halliburton, 1913, 1914).

Uterus.—The usual effects, as observed through the celluloid abdominal window, consist in stimulation of peristalsis and tonic spasm, analogous to ergotoxine (Ludwig and Lenz, 1923). The reactions show the same species differences as for epinephrine (Dale and Dixon, 1910; Acton and Chopra, 1925; human uterus, Lieb, 1915).

Clinical Use of Uterine Action.—Tyramine has been tried clinically as a substitute for ergot in labor, post-partum hemorrhage, operations and various gynecologic conditions. Favorable results have been reported by some (Haimann, 1912; K. Abel, 1914). Others found it unreliable (Guggenheim, 1912; Sharp, 1911; Kehrer).

The doses used in these earlier experiments were probably too low. With larger doses (40 mg. plus 16 mg. of morphine, hypodermically) Barbour, 1917, records distinct increase of the strength and rate of labor pains; without undesirable side-effect. On the contrary, the tyramine counteracts the respiratory depression of morphine; so that the respiration is slightly quickened by the above combined dosage. The actions of morphine on other functions are not antagonized (Barbour, Maurer and Glahn, 1916; Barbour and Maurer, 1920).

Other Actions. *Respiration.*—The effects have been studied by Bry, 1914.

Bronchioles.—These are contracted by tyramine (Rachr and Pick, 1913, Golla and Symes, 1913). Accordingly, tyramine does not relieve asthmatic attacks (Hewlett and Kay, 1918).

Excised Stomach.—This is constricted (frogs).

Excised Intestines.—These are stimulated in rabbits; relaxed in dogs; first stimulated and then relaxed in cats (Manysek, 1914).

Spleen.—This is contracted.

Gastric Secretion.—Tyramine sometimes stimulates this in cats, but not in other animals (Keeton *et al.*, 1920).

Pancreatic Juice.—Secretion after pilocarpine or secretin is inhibited by large doses of tyramine (Kageyama, 1916).

Hyperglycemia.—Continuous slow intravenous injection of 0.05 per cent. tyramine into rabbits may raise the blood-sugar to 0.1–0.17 per cent., and the urine sugar to 2 per cent. (Kageyama, 1916).

Anemia.—Long-continued hypodermic injections into guinea pigs (2 to 8 mg. daily for one to two weeks) produce severe anemia with the characteristics and course of pernicious anemia (Iwao, 1914).

A similar result with hemosiderosis of the spleen, mesenteric lymph glands, cecum and bone marrow is produced in rabbits by intravenous injection of 0.1 Gm. of tyramine (Iwao, 1916).

Growth.—McCarrison, 1924, found that the long continued administration of tyramine to young animals retarded growth, and this was associated with diminished weight of the thymus and thyroid, and increased weight of the adrenals. The effects did not disappear when the tyramine was discontinued. Adult animals were but little affected.

HORDENINE

This is an alkaloidal amine derivative (p-hydroxy-phenylethyl-dimethylamine) obtained by Leger, 1906, from germinated barley. Its actions were studied especially by Camus, 1906. Small doses stimulate the vagus. Larger doses paralyze the vagus center, quickening the heart and raising the blood pressure. The bronchioles are dilated by stimulation of the sympathetic endings, sufficiently powerful to antagonize most constrictor drugs (D. E. Jackson, 1914). Fatal doses paralyze respiration. The substance is not very toxic. It has been used (0.5 Gm. per day) in heart disease and digestive derangements (Sarbazes and Guerine, 1909). It arrests diarrhea in dogs (30 to 40 mg. per kg., hypodermically; Charmoy, 1912).

ERGOTOXINE (ERGOTAMINE-STOLL, HYDROERGOTININE)

This is the active alkaloid of ergot and the historical and chemical data will be discussed under that drug. Large doses have a selective paralytic action on the augmentary sympathetic mechanism, and therefore antagonize the augmentary, but not the inhibitory actions of epinephrine (Dale, 1905, 1906, 1913). However, it also acts on the responsive mechanism directly, moderate doses stimulating and large doses paralyzing smooth and cardiac muscle. It produces a powerful and prolonged peripheral stimulation of smooth muscle, particularly in the arteries and uterus. It is used therapeutically in the form of ergot and is chiefly concerned in the stimulation of the uterus; the vasoconstriction; the bronchial constriction; the intestinal irritation; the gangrene; and the vasomotor reversal produced by that drug.

Uterine Stimulation.—Although ergotoxine stimulates the uterus very similarly to ergot (which see), the pure alkaloid did not appear to be as satisfactory in the clinic (Kehrer, 1911; Sharp, 1920). However, ergotamine appears to be efficient.

Vascular Effects.—The rise of blood pressure with ergotoxine is purely vascular (diminished organ volume). The constrictor action is exerted directly on the arteries, for it occurs after the medulla has been divided, and the vascular ganglia excised or paralyzed by nicotine.

If now, during this rise, the vasomotor nerves be stimulated—either electrically, or by epinephrine or nicotine—a fall of pressure results, instead of the customary rise. The ergotoxine has therefore paralyzed the peripheral sympathetic vasoconstrictor mechanism, leaving the central dilator mechanism active. This *vasomotor reversal* is obtained in pithed cats by 0.5 mg. per kilogram, intravenously. Since ergot itself and barium are still capable of producing vasoconstriction, the arterial muscle can not be paralyzed; and the constrictor paralysis would be referred to the receptive mechanism. Very large doses finally paralyze the muscle fiber.

The antagonism of ergotoxine and epinephrine can also be demonstrated on excised arteries (Macht, 1915) and on the *stomach* (M. Smith 1918).

Ergotoxine also reverses the expanding action of epinephrine on the *melanophores* of fish (Spæth and Barbour, 1917). The *central actions of epinephrine, f.i.*, the fever, are not antagonized (Cloetta and Waser, 1915).

Mammalian Heart.—With ordinary doses; the effects are slight and mainly consequences of the vascular changes; the amplitude being first diminished, then increased (Wiggers, 1911). After repeated injections, the heart becomes slowed by a direct muscular action, for the slowing occurs even after atropine. However, the excitability of the vagus to electric stimulation and to acetyl-choline is also increased (Rothlin, 1923). In the excised mammalian heart, Wiggers, 1911, observed diminished systolic contraction and increased tone with decreased amplitude and output.

Frog-Heart.—Ergotoxine abolishes the response to accelerator stimulation, and diminishes the inhibition on vagus stimulation. Excessive doses arrest the heart; this may be antagonized by the atropine, camphor, epinephrine and caffeine, but not by accelerator stimulation (Langecker, 1925).

Intestines.—Ergotoxine increases the sensitiveness of the intestines to distention, and therefore increases peristalsis (Planelles, 1924).

Bronchioles.—These are scarcely affected (D. E. Jackson, 1914).

Ureter.—Ergotoxine inhibits or reverses the epinephrine stimulation, but does not interfere with the parasympathetic stimulants (Macht, 1916).

Iris.—Smaller doses, like epinephrine, produce mydriasis, which is increased by excision of the sympathetic ganglion and antagonized by physostigmine. With larger doses, this is followed by miosis (Zunz, 1924).

Temperature.—In rabbits, this is raised by 3 to 4.5°C. through the intravenous injection of 2 mg. per Kg. Some rise occurs even after curare, so that it is not muscular. There is no rise in decapitated animals. The action must therefore be central, and probably involves both increased heat production and diminished heat loss. Cats also respond by a rise of temperature; whereas rats, mice and pigs exhibit a fall (Githens, 1917).

Sugar.—Ergotoxine arrests the epinephrine and theobromine glycosurias, diminishing the hyperglycemia, and rendering the kidneys less permeable to sugar; the permeability to chlorides is not affected. The epinephrine diuresis is somewhat decreased by it, but not the theobromine diuresis (Miculicich, 1912).

Toxic Effects.—These vary with the dose and species, but bear a resemblance to those of *ergotism*; i.e., *convulsions* and *gangrene*. The latter has been observed in the tail of rats as well as in the comb of fowls (Rothlin, 1923).

ERGOT

General Statement.—Ergot (*Secale cornutum*) is a fungus (*Claviceps purpurea*) growing in the grain of cereals; the official being obtained from rye. The fungus goes through several stages of development, the resting stage (sclerotium) constituting the drug. It is used mainly to contract the uterus (by peripheral action) and thus check postpartum hemorrhage. It also stimulates other forms of unstriated muscle, especially the intestine and blood vessels. The consumption of grain infested with

ergot leads to gangrene and spasmodic effects. Epidemics of this "ergotism" were formerly frequent and must have occurred in antiquity, although the causal connection was not recognized. It is now very rare in civilized countries, the ergot being removed by the modern methods of treating the grain. The uterine effect was learned from midwives and is first mentioned by Lonicer, 1565. Its use in regular medicine dates practically from Stearns, 1807 (N. Y. Med. Repository).

Active Constituents.—The composition of ergot is complex; several active constituents have now been isolated in pure form. The most important are: the alkaloid ergotoxine or ergotamine, several aromatic amines, especially tyramine and histamine, and choline derivatives. The numerous names applied to these and to impure mixtures render the literature very confusing.

Ergotoxine or Hydroergotinine, $C_{35}H_{41}N_5O_6$, is an amorphous alkaloid occurring in alcoholic extracts. It is responsible for the characteristic action on the cock's comb and is concerned in the uterine and vascular effects. It is rather unstable and by loss of H_2O changes into its lactone.

Ergotinine or Ergotone, $C_{35}H_{39}N_5O_5$, is a crystalline alkaloid with very weak actions.

Both alkaloids exist ready-formed in ergot, but can be easily converted into each other by chemical means (Barger and Ewins, 1910). Both are insoluble in water and petroleum ether, sparingly soluble in ether, and readily soluble in most other organic solvents. Ergotoxine is easily soluble in cold alcohol; ergotinine but sparingly. They dissolve in dilute NaOH, but the ergotinine is partly converted. Their salts form colloidal solutions with water, but these are precipitated by electrolytes (salts or mineral acids).

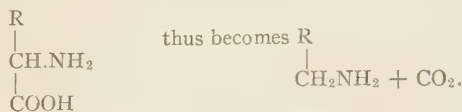

Ergotamine-Stoll is closely related to ergotoxine, if not actually identical. Its pharmacological effects at least are the same (Dale and Spiro, 1922).

Tyramine, ergotamine, uteramine, or para-hydroxyphenylethylamine: this is closely related to epinephrine in structure and action. It is mainly responsible for the pressor effect, and aids in the uterine action.

Histamine, ergotidine, ergamine, beta-iminazolyl-ethylamine, 4-beta-aminoethylglyoxaline: lowers the blood pressure, and stimulates the excised uterus powerfully.

A number of other aromatic amines occur casually; such as *agmatine*, guanidobutylamine (Engeland and Kutscher, 1910), which has a weak stimulant action on the excised uterus; isoamylamine, etc.

These aromatic amines are also produced in the putrefaction of meat, and in the intestinal tract, and have been prepared synthetically. They are generally insoluble in ether or chloroform, readily soluble in water; precipitated by phosphotungstic acid. Chemically, they are derived from the amino-acids by the elimination of CO_2 .

In this way, Tyramine is prepared from Tyrosine; Histamine from Histidine; Agmatine from Arginine; Isoamylamine from Leucine. An authoritative discussion is contained in Barger's "Simpler Natural Bases," 1914.

Acetyl Choline.—This was found in ergot by Ewins, 1914. It is responsible for the cardiac inhibition.

Investigations of the Composition of Ergot.—A large number of *constituents* has been described in ergot: Alkaloids, amines, resinous acids, glucosides, betaine, and choline, fat (35 per cent.), some peculiar sugars, coloring matter, etc. The red pigment (*Sclererythrin*) is important for discovering the presence of ergot in bread.

There has been much animated discussion as to the rôle of the several constituents in the actions of the drug, and the matter is not yet altogether decided. The *confusion* of the older literature is explained partly by the instability of the principles, but mainly by the difficulty of isolating them pure. The impurities alter their characters sufficiently so that successive investigators have repeatedly described the same principle, somewhat differently contaminated, as different substances. Physiologic actions have been ascribed to substances which these owed solely to their contaminations.

The *modern conceptions* date mainly from the work of Barger, Carr and Dale, 1906 and 1907, on the isolation of the ergot alkaloids. Their papers also give the historical details. By the discovery of the crystalline phosphate of ergotoxine, they succeeded for the first time in preparing this principle uncontaminated; and in determining its properties and its relation to ergotinine, which Tanret had isolated in 1875. Kraft, 1906, arrived independently at the same results. Dale found that the ergotoxine produces the characteristic effects of ergot. Barger and Dale also showed that the alkaloidal and resinous principles (sphacelinic acid, sphacelotoxin, etc.), isolated by earlier investigators, contain large proportions of this alkaloid; and that their apparent activity can be fairly attributed to the latter. On the other hand, they pointed out that the methods of preparing extracts of ergot tend to eliminate this alkaloid; and that it is therefore necessary to assume the presence of other, water-soluble principles. In 1909, Barger, Dale and Dixon found these to consist of tyramine and histamine (1910).

Impure Principles.—These are still important for understanding the older literature. They are classified by Barger and Dale as follows, in chronological order:

Wenzell, 1864: *Ecbolline* and *Ergotine* = mixtures of the alkaloids, containing chloine (Meulenhoff, 1899).

Tanret, 1875: *Amorphous Ergotinine* = impure mixture of ergotinine and ergotoxine.

Dragendorff, 1877: *Picrosclerotine* = ergotinine, possibly mixed with some ergotoxine.

Podwyssotski, 1883: *Sclerocrystalline* = ergotinine.

Kobert, 1884: *Sphacelinic Acid* = inactive resin with adherent alkaloids.

Cornutine = alkaloidal resin, probably containing some ergotoxine, and perhaps some active alkaloidal decomposition products.

Ergotinic Acid = a sapotoxin.

Keller, 1896: *Cornutine* = impure mixture of ergotinine with ergotoxine.

Jacobj, 1897: *Chrysotoxin* = inactive yellow coloring-matter with small proportion of adherent alkaloid.

Secalintoxin = mixture of ergotinine and ergotoxine.

Sphacelotoxin = impure ergotoxine.

Secalin = impure ergotinine.

Kraft, 1906: *Hydroergotinine* = synonym for ergotoxine.

Vahlen, 1906 and 1908: *Clavin* = inactive mixture, consisting of nearly equal parts of leucine, isoleucine and valine (Van Slyke, 1909).

Marino-Zuco and Pasquero, 1911: *Clavisepsin*: claimed to be an active glucoside; not confirmed.

Ergotine is a name applied to a variety of pharmaceutic extracts, generally prepared in such a way that they must contain mainly the amines, and relatively little of the alkaloids.

ACTIONS OF ERGOT

Uterine Actions.—The most important use of ergot is in obstetrics. Ergot preparations stimulate the uterus, especially when pregnant. The clinical effects are well described by Sharp, 1911. In labor, the ordinary doses improve the uterine tone, and collect small irregular and non-effective pains into larger effective contractions. Small doses may inhibit the contractions. Excessive doses produce prolonged tonic constriction.

These effects have been also observed directly through a celluloid window inserted in the abdomen of animals (Ludwig and Lenz, 1923).

When proper doses are used during labor, with the os fully dilated and no obstruction, they tend to *hasten normal delivery*. Really effective doses, however, are rather dangerous to mother and child. The firm contraction may hinder delivery, and compress and asphyxiate the fetus; even rupture of the uterus has been reported; but these accidents are very rare.

The most extensive employment of ergot is *after* the delivery, to hasten and sustain the normal retraction; thus obliterating the open sinuses, and checking *postpartum hemorrhage*. In early pregnancy, its effects are much less certain. Contrary to popular opinion it is not abortifacient unless dangerous doses are long continued.

The uterine effects are due mainly to ergotoxine in some form, somewhat aided perhaps by the histamine and tyramine.

Ergot has also been used in other forms of uterine hemorrhage and in chronic metritis; but is probably of little value apart from obstetric conditions.

Administration.—The usual *dosage* is 2 to 5 c.c., $\frac{1}{2}$ to 13 of the fluid-extract, or the equivalent of the solid extract, which is eight times as strong. They may also be used hypodermically or intramuscularly. The response to ergot is quite prompt even when taken by mouth; it appears in fifteen to thirty minutes and lasts half an hour (Brady, 1910). Opium delays but prolongs the effects; moderate chloroform anesthesia does not modify them (Sharp).

Mechanism of Uterine Action.—The action is peripheral, since it occurs also in the excised uterus (Kurdinowski, 1906; Fellner, 1906; human, Ruebsamen and Kligermann, 1912). Moderate concentrations increase the tone and the automatic contractions; high concentrations produce tetanus of the uterus. (François, 1912, cautions about the interpretation of the phenomena.)

La Torre, 1912, found interesting histologic changes in the uteri of dogs treated with ergot.

Relation to Tone and Calcium Salts in Excised Uterus.—Calcium excess, which depresses the tone of the virgin guinea pig uterus, increases the response to the contractor action of ergot (M. Chio, 1922).

Blood Pressure.—This is practically unchanged, in man (Sharp, 1911), or animals, unless the ergot is injected into a vein. This produces considerable, but inconstant and complex changes. The variability is largely explained by the conflicting actions of the different constituents, and by dosage and other conditions.

Sometimes there is a large but brief fall from direct cardiac depression, followed by a slight but prolonged rise from direct cardiac and vascular stimulation (Sollmann and Brown, 1905). The fall is presumably due to histamines and acetyl-choline; the rise to ergotoxine and tyramine. Other experiments show very little fall and somewhat greater rise (Cronyn and Henderson, 1909; Edmunds and Hale, 1911). This rise is greater if the vasomotor center has been destroyed, and is therefore due to a direct peripheral action on the vessels (Jacobj, 1897; Wood and Hofer, 1910). Excised arteries (except the pulmonary) are also constricted (Cow, 1911). The vasoconstriction occurs also in calcium-free solutions (Pearce, 1913), and is due to ergotoxine and tyramine. The vasomotor center is not affected by ergot or ergotoxine (Pilcher and Sollmann, 1915).

The pressure in the *pulmonary artery* is increased, whether the carotid pressure is rising or falling (Wood, 1911). Mellin, 1904, Plumier, 1903, and Anderes, 1915, attribute the rise to constriction of the pulmonary vessels; Dixon to increased output of the right ventricle. Wiggers, 1911, showed that ergotoxine produces both effects

Very large doses of ergot paralyze the vagus center, and the vasomotor endings (epinephrine becoming ineffective whilst barium is still active) (Sollmann and Brown, 1905). This "vasomotor reversal" is due solely to the ergotoxine (Dale, 1905).

Ergot as General Styptic.—The efficiency of ergot in postpartum hemorrhage, and the vasoconstriction observed in animal experiments, have led to its use against hemorrhage in other situations. However, the conditions here are altogether different; for, as ordinarily administered, it does not affect the blood vessels or blood pressure. Its use is therefore irrational (Bradford and Dean, 1894). It is also useless in pulmonary hemorrhage (Frey, 1909). It has been praised rather uncritically in a great variety of other conditions, which it would be useless to enumerate.

Cyanosis of the Comb of the Fowl.—When ergot preparations are administered to roosters, in about an hour the tips of the comb and wattles become blue and cold, the effect lasting several hours. It may be preceded by temporary blanching. This reaction is used for testing the quality of ergot (see below). It is due to ergotoxine; histamine produces a similar but much prompter effect (Crawford, 1913); tyramine is ineffective. These changes are probably due to injury of the capillary endothelium, producing vascular stasis and eventually thrombosis, analogous to the phenomena of acute inflammation, as in "frost-bite."

It has been attributed to vasoconstriction; but the cyanosis does not occur after other vasoconstrictor drugs; whilst it is produced by paraldehyde which lowers blood pressure (Crawford), by cantharidin (Ellinger, 1908) which injures capillaries; and by other drugs which cause vascular injury (large hypodermic doses of cane-sugar, piperazine, chromic acid, etc.).

Gangrene Action.—This is a characteristic feature of chronic ergot poisoning in man and in many animals. It is most readily studied in roosters.

If ergot is given repeatedly to roosters, the bluing persists in the tips of the comb, and gradually involves the entire comb and the wattles. Eventually, these appendages undergo gangrene and may drop off. The extremities may also be involved; in one experiment, the entire wing fell off after a few days.

Histologic Changes.—v. Recklinghausen, 1883, showed that the larger arteries, but not the veins, of the gangrened comb are occluded by hyaline thrombi. The capillaries are congested with red corpuscles. These results were confirmed by Gruenfeld, 1890. They are generally referred to very violent constriction of the small arteries, interrupting the blood stream. This explanation is entirely hypothetical. Krysyński observed formation of thrombi in a variety of conditions; and it is probably a result of a toxic effect on vascular endothelium. No histologic changes are found in the acute cyanosis.

Susceptibility of Different Animals to Gangrene.—Pigs are quite susceptible to the gangrene action of ergot. They react especially by pustular eruptions on the skin; the ears are particularly susceptible. Horses and cattle show similar changes. Man is quite subject to the gangrene, which begins in the extremities. The fingers, toes, or an entire member may slough off. Dogs and rabbits do not seem to be susceptible to this action.

The cause of the varying susceptibility has not been demonstrated. It may be due to physiologic peculiarities, or merely to anatomic differences. The gangrene always begins in those situations in which the circulation is weakest. It differs in no essential from gangrene produced by any other cause. It may be dry or wet, according to whether liquefying bacteria are absent or present.

Salant and Hecht, 1914, describe a habituation tolerance to the action of ergot on the cock's comb and to the fatal dose.

Alimentary Canal.—Injection of ergot or ergotoxine (10 mg. for rabbits, intravenously) results in marked increase of peristalsis through the whole alimentary tract. The sensitiveness to distention is increased (Planelles, 1924), as also the intestinal motor response to vagus stimulation (Meltzer and Githens, 1916). This produces violent

diarrhea and vomiting. The emesis, however, is largely central (Eggleston and Hatcher, 1915).

In chronic poisoning, these direct effects are aggravated by vascular stasis, advanced cases showing ecchymosis, ulcer formation, etc. The ulcers involve particularly the lymph follicles, in which the blood supply is poorest. The stasis may lead to effusion of blood into the lumen of the intestine. The appetite is lost. This action on the alimentary canal is also most marked in the animals mentioned, but occurs in others. The liver of roosters shows peculiar degenerations, resembling amyloid.

Isolated Bronchial Muscle.—Ergot has no effect (Titone, 1913).

Central Nervous System.—This is affected both directly and indirectly, and the effects are correspondingly variable. With moderate doses, the flow through the cerebral vessels is increased. Small doses may cause medullary stimulation (vagus slowing; increased respiration, convulsions, etc.). Large doses of ergot cause *death* by medullary paralysis. It has a narcotic effect for roosters.

ERGOTINIC ACID

This has a typical sapotoxin action. Taken by the mouth it produces no effects beyond *local irritation*, as sapotoxins are not absorbed. If injected subcutaneously or intravenously, it will produce paralysis of the central nervous system and of protoplasm generally. It causes peripheral paralysis of blood vessels, and thereby lowers the blood pressure.

ACUTE ERGOT POISONING

This is rare in man, but may occur by attempts at abortion. The symptoms are vomiting, diarrhea, vertigo and confusion, precordial distress, dyspnea, muscular pains, paresthesias and anesthetics, disturbances of vision and speech, epileptoid convulsions, small pulse, loss of consciousness. In pregnancy, uterine hemorrhage and abortion of the dead fetus are frequent. Recovery after severe poisoning may take several days.

Rosenbloom and Schildecker, 1914, isolated ergotinine crystals from a patient dead of acute ergot poisoning.

CHRONIC ERGOT POISONING, "ERGOTISM"

This is now mainly of historic interest. The initial symptoms are fairly uniform but they develop into two distinct types, the gangrenous and convulsive. These are so dissimilar that they were long classed as separate diseases. Toward the end the symptoms become similar.

Historical.—Ergotism was formerly very frequent endemically in consequence of the presence of ergot in flour, and the population of large tracts of country have been poisoned. The last large epidemic in the United States occurred in New York in 1825. Since the cause has been recognized these epidemics have been less frequent, but in Russia they still play quite an important role (Schmack, 1897). A comprehensive discussion of the history of ergot is given by Kobert, 1889.

Symptoms.—The initial stage is ushered in by *disturbance of the peripheral sensory apparatus*. There is *formication* in the skin and various other disturbances of cutaneous sensation. *Hyperesthesia and anesthesia* exist at the same time in different parts, or even in the same part, the skin being hyperesthetic to some forms of stimulation and anesthetic to other forms.

These disturbances of sensation *begin at the extremities and spread upward*. This distribution favors the view that they are manifestations of changes in the circulation, since these would make themselves felt first of all in the extremities. The disturbance in sensations also involves the *alimentary canal*. There is apt to be at once *voracious hunger and loss of appetite*. Digestion is much impaired on account of the disturbed circulation. Diarrhea and vomiting are very common. The vomiting is partly due to the disturbed circulation and partly to the action on the center. The *central sensory apparatus* also shows changes at this time. There is violent and persistent headache and central disturbances of the *special senses*. The *motor system* also begins to show abnormal symptoms, such as *twitchings* and tremors, most marked in the extremities and in the tongue.

In all these effects of ergot it is extremely difficult to say to what extent the phenomena are caused by the central, and to what extent by peripheral, actions. They are probably largely dependent on disturbances in circulation, and these may in some cases be more prominent in the central nervous system; in others, peripherally.

At this point the sensory symptoms have reached their acme, and do not become any worse, but persist as they have been described. But the motor phenomena go on increasing; the twitchings pass into *spasms*, and then into permanent and often very painful *contractures*. Always beginning at the extremities, they involve the terminal phalanges of the fingers and ascend to the other joints. The facial muscles also participate. The type of these contractures shows that their origin is central. They are not absolutely persistent, but last for about half an hour; then pass off for a time, and reappear. This is very different from spasms of peripheral origin, such as those of lead-poisoning. The smooth muscles may also participate in these contractures; especially that of the bladder; so that there may be involuntary evacuation of the urine, *tenesmus*, etc.

The **pulse** is always *hard and small*, pointing to a high blood pressure. Its frequency, however, is variable. It is usually slow, due probably largely to the high pressure.

So far the symptoms, the initial stage, are common to all the different forms of ergotism; they can be accounted for partly by the changes in the circulation and partly by the direct action of the ergot principles themselves. In the **second stage** the circulatory disturbances become more marked. The phenomena already seen—the disturbances of sensation and the contractures—persist; but to these are added secondary effects due to the prolonged slowing of the circulation. These may be most marked in the central nervous system or in the extremities. The former give rise to the so-called *spasmodic form* of ergotism. The predominance of stasis in the extremities produces the *gangrenous form*.

Why one action should predominate in some individuals, and another action in others, is not explained. Perhaps there may be some differences in the anatomic arrangement of the blood vessels or extent of the innervation.

(A) The **gangrenous form** may have been indicated somewhat earlier. *Pustules* may have formed in the skin, which are due to this defect of circulation. In more marked degrees it affects the extremities. The entire member may be involved in the gangrene, which differs in no respect from any other gangrene; it has its line of demarcation, and may be *wet or dry* according to bacterial infection. The finger, toe, or limb may slough away without bleeding.

(B) In the **spasmodic form** the contractures pass into *tonic and clonic convulsions or epileptiform spasms*. Since any part of the central nervous system may be affected, the exact symptoms may be extremely variable. It may be repeated that they are due to a defective circulation in the central nervous system, which leads to stimulation and then to paralysis. Both forms, the gangrenous as well as the spasmodic, are therefore due to changes in circulation, and are determined by the ergotoxine.

The **treatment** of ergot poisoning can only be symptomatic.

DETERIORATION

The ergot alkaloids and amines are rather unstable substances; and it has long been observed that ergot loses its activity with age. Ergotism is said to have occurred only during the first four months after harvest (Poulssohn). Many pharmacopeias therefore direct that ergot must not be older than one year. The fluidextracts on which the reputation of ergot is mainly based have probably all been aged for a year before being sold (Eldred, 1913). They are said to deteriorate chiefly within the first six months after their manufacture, then very slowly (Assoc. Amer. Drug Manufacturers, 1923).

The uncertain activity of ergot makes it advisable to employ only such preparations as have been assayed, although the assay-methods are not very accurate.

Bio-assay of Ergot.—The complex composition of ergot necessitates biologic methods. These fall into two groups, which estimate respectively the ergotoxine and the histamine, and their related principles. The U.S.P. cock's comb method measures the ergotoxine, which is probably more representative of the clinical value of ergot. This shows that the U.S.P. fluidextract is over 20 times as active as the British or French preparations (Broom and Clark, 1923).

The **ergotoxine tests** include the cock's comb method, and the reversal of the epinephrine-effects on the rabbits' uterus or the cat's blood-pressure. Their results agree satisfactorily.

The **cocks' comb** test was described by Lorinser, 1824; used experimentally by Gruenfeld, 1892 and 1895, under Kobert; and applied commercially by Houghton, 1898. The details are described by Edmunds and Hale, 1911, and in the U.S.P. It estimates mainly the ergotoxine but is also affected by the histamine.

The **epinephrine-reversal** test is described by Broom and Clark, 1923.

The **histamine methods** include the direct effects on the excised uterus of the guinea pig, and the uterus of the cat.

Relative Activity of Different Ergot Preparations.—Tested on excised virgin guinea pig uterus, the best commercial preparations were found over 1,000 times as active as the poorest (Halphen, 1922).

Relation of Uterine Efficiency to Folin Color Reaction.—These are generally parallel (guinea pig uterus) according to Wiechowski and Halphen 1921. The meaning is doubtful, since none of the recognized oxytocic constituents of ergot gives this color reaction when pure.

PREPARATIONS—ERGOT

Ergot U.S.P., B.P.; **Ergot**¹ (*Secale cornutum*).—A fungous growth, *Claviceps purpurea*, from rye. Generally collected in Russia or Spain. Should not be older than one year. *Dose*, 2 Gm., 30 gr., U.S.P.; 1 to 4 Gm., 15 to 60 gr., B.P.

Ext. Ergot, U.S.P.—A pilular extract, prepared by defatting ergot with benzin, extracting with acidulated alcohol, and evaporating. *Dose*, 0.25 Gm., 4 gr., U.S.P.

Ext. Ergot, B.P.; **Ext. Ergot. Purif.** (*Ergotine Bonjean*).—A soft watery extract, purified by partial precipitation with alcohol. *Dose*, 0.12 to 0.5 Gm., 2 to 8 gr.

Ergotine.—This name has been applied to very different preparations.

Those that occur most extensively in the older literature are:

Ergotine Bonjean: Aqueous solid extract, purified with alcohol.

Ergotine Wernich: Dialyzed extract, marketed both as a liquid, and as a soft extract.

Ergotine Wiggers: Dried, alcoholic, purified solid extract.

Ergotine Yvon: Fluid extract prepared with dilute solid tartaric acid.

Haskell, 1914, found that "ergotine" and powdered extract produced all the typical effects of ergot, but that the effects on the uterus are weakened much more than those on blood pressure.

* **Fluidextractum Ergotæ** (Fldext. Ergot.), U.S.P.—Prepared with acidulated dilute alcohol. *Dose*, 2 c.c., 30 minims, U.S.P.

Ext. Ergot. Liq., B.P.—An aqueous solution, preserved with alcohol. *Dose*, 0.6 to 1.8 c.c., 10 to 30 minims, B.P.

Inf. Ergot, B.P.—5 per cent. *Dose*, 30 to 60 c.c., 1 to 2 ounces, B.P.

Inject. Ergot. Hyp., B.P.—33 per cent. of Ext. Ergot, B.P., preserved with 1 per cent. of phenol. *Dose*, 0.3 to 0.5 c.c., 5 to 10 minims, B.P.

Tr. Ergot. Ammon., B.P.—25 per cent., with dilute alcohol and ammonia. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

Claviceps paspali, growing on a Southern forage grass, *Paspalum*, produces toxic effects on feeding. They have not been studied in detail (H.B. Brown, 1916).

Ustilago Maydis.—*Corn Smut*.—A fungus analogous to Ergot, found on the corn plant. Little is known about its composition or action, although it has been employed by the negroes for abortion, and stock-raisers have also observed that it has an ecboic effect. Kobert states that it does not produce the ergot action on the cock's comb. He may have worked with old samples, since the author obtained the typical darkening from several samples. However, the action is quite weak, and the drug does not deserve much attention unless it should be possible to isolate the principles in more active form. It contains resins.

HISTAMINE

Histamine (*beta-iminazolyethylamine*; *ergamine*, *ergotidine*) is partly responsible for the actions of aqueous extracts or ergots. It occurs also, mostly in combined form, in all tissues, and is liberated in putrefaction.

It is destroyed in the digestive tract and therefore gives but little effect when administered by mouth; but when injected subcutaneous or intravenously, it produces intense direct stimulation of the tone of

¹ From the French "ergot," a cock's spur, which it resembles in appearance.

rhythm of smooth muscle, similarly to pituitary extract; and lowers blood-pressure, by dilating the capillaries, similarly to peptone or anaphylactic shock. There is considerable difference in the susceptibility of the various autonomic organs, and this has no relation to their nerve supply. In organs that are inhibited by epinephrine, the latter is a more powerful antagonist to histamine than is atropine.

Structure.—Histamine is derived from histidine as follows:

Occurrence in Tissues.—Histamine occurs in extracts of all tissues, animal and vegetable. Some is perhaps free, but the greater part is liberated by protein cleavage, whether this be effected by acids, by ferments, or by bacteria.

The occurrence of histamine in pituitary extract, peptones, vasodilatin, secretin and other organ extracts, and especially those prepared with acid and heat, and the striking resemblance of their effects to those of histamine, suggested that histamine was responsible for their actions (Abel and Kubota, 1919; bibliography). However, a closer study of the actions reveals important differences, qualitative as well as quantitative; and the histamine would play only a minor part, even if it exists preformed, which is doubtful; for decarboxylation of amino-acids does not seem to occur in the tissues of living organisms (K. Spiro, 1923).

Occurrence of Histamine in the Digestive Tract, Absorption and Destruction.—Considerable quantities of histamine, tyramine and other aromatic amines are liberated in the intestines by bacterial action. A single stool (human) normally contains 5 to 7 mg. of histamine; and probably considerably more is formed, since it is rapidly broken down by other bacteria (Mellanby, 1916). It is conceivable that the histamine may be in sufficient concentration to produce local stimulant actions on the stomach and intestines, but this has not been proven. Very large doses are tolerated by mouth without any toxic effects, (300 mg. by guinea pigs; 225 mg. by man), although 1 mg. by vein produces very alarming symptoms in a full-grown man. The protection is not due to the liver, but to the rapid destruction of the histamine in the intestines (Koessler and Hanke, 1924). This also disposes of the possibility that histamine (or tyramine, which behaves similarly) could be the cause of the symptoms that ensue from constipation or so-called "intestinal autointoxication" (vide Mellanby, 1916; Meakins and Harrington, 1922; Alvarez, 1924).

Susceptibility of Different Muscles and Glands.—The stimulation of smooth muscle is most marked in the uterus; the bronchioles are also highly sensitive; the intestine, arteries and spleen are less susceptible; the bladder and iris do not respond. (Quagliariello, 1914). Cardiac muscle is mildly stimulated; skeletal muscle is not affected. It has a weak pilocarpine action on glands (Barger and Dale, 1910; Dale and Laidlaw, 1910; Kutscher, 1910; Ackermann, 1910).

Uterus.—This is contracted *in situ* in virgin guinea pigs and non-gravid cats. It increases especially the tonus of the excised uterus of cats, rabbits and guinea pigs (Barger and Dale, 1910); but relaxes that of rats (Fuehner, 1913). The latter constitutes the distinction from pituitary extract, which stimulates the rat uterus (Tate, 1921).

The experiments of Kehrer, 1911, and Guggenheim, 1914, indicate that the tone of the human uterus is also increased; but it would have to be used cautiously on account of its toxic effects (respiratory disturbances and convulsions). Koch, 1913, reports successful results in uterine inertia from the intramuscular injection of 1 mg.; Jaeger, 1913, found 8 mg. necessary. Even 1 mg. produces some unpleasant side actions; with effective doses there may be headache and violent vomiting. Its use is therefore not advisable. It has little effect by mouth.

Urinary Bladder.—This is not stimulated in living animals (Abelin, 1910).

Bronchioles.—These are strongly constricted by peripheral stimulation (D. E. Jackson, 1914), so that the lungs bloat as in anaphylaxis (Baehr and Pick, 1913).

Cerebrospinal Fluid.—This is under higher tension, due simply to the asphyxial effect of the bronchial constriction (Dixon and Halliburton, 1914).

Intestines.—The stimulating action is much weaker than for most other smooth muscle; dilute solutions may even inhibit (Olivecrona, 1921; Planelles, 1924). Calcium salts intensify the stimulation (Vanysek, 1914).

Digestive Secretions.—The intramuscular injection of histamine stimulates the secretion of gastric and pancreatic juice and of saliva (Keeton *et al.*, 1920). It is probably closely related to gastrin and secretin.

Coagulability of the Blood.—This is not affected, in distinction to peptone (Dale and Laidlaw, 1911; Loewit, 1913).

Circulation.—In most species of animals the injection of histamine produces an extensive fall of blood-pressure, which may be short or persistent, according to the dose. With large doses it is very persistent, and presents the essential phenomena of "traumatic shock" (Mellanby). The fall is due to dilation and increased permeability of the capillaries, and is analogous to inflammation. The blood-volume is decreased by the loss of plasma, and the circulation is slowed by this and by stagnation in the vastly enlarged capillary bed (Dale and Laidlaw, 1919; Dale, 1920). Entirely analogous effects occur in peptone, anaphylactic and traumatic shock, and the latter may be due to the formation of substances with histamine actions (Dale and Richards, 1918).

Capillaries.—Observing these with the microscope in the living animals, by Lombard's method, Hooker, 1920, noted that the injection of histamine into cats produces prompt dilation, sometimes preceded by brief constriction. The effects are not influenced by section of the nerves, and are therefore peripheral. The production of dilation of the capillaries and small arterioles and venules have also been observed in the omentum of the cat (A. R. Rich, 1921) and in the mesentery of mice (J. Wolf, 1923), and in the human skin (Carrier, 1922). The production of skin edema will be discussed below. The capillaries of frogs are not dilated (Krogh).

Susceptibility of Different Animals.—Man, dog, cat, monkey and fowl respond by fall of pressure; rabbits and guinea pigs show a rise (Dale and Laidlaw, 1911). The acute toxicity varies considerably with the conditions (Dale and Laidlaw, 1920).

Heart.—The isolated frog's heart is slowed; the perfused mammalian heart shows a short and slight slowing, followed by considerable quickening with increased excursions (Einis, 1913).

Vasomotor Center.—This is not affected directly, but the fall of blood pressure, and the respiratory disturbances usually produce moderate stimulation (Pilcher and Sollmann, 1915).

Denervation.—Dale and Richards, 1918, confirm that the depression response to histamine as well as to epinephrine and acetyl choline are peripheral, and are indeed generally increased when the nerve-supply has completely degenerated.

Excised Arteries.—These are constricted by histamine, in all species, and in all situations (Dale and Laidlaw, 1910, 1911), including the coronary (Barbour, 1913) and the pulmonary arteries (Berezin, 1914; Anderes and Cloetta, 1916; but not the liver veins (Berezin, 1914).

Perfused Organs.—These respond by vasoconstriction if the histamine is perfused in saline; but in the presence of blood and epinephrine, histamine dilates, and therefore reproduces the depressor effect of intact animals (Dale and Richards).

Relation to Arterial Tone.—Whilst the dilator effect of acetyl choline shows a definite relation to the tone and reactivity of the arteries, this parallelism does not hold for the dilator effects of histamine (Dale and Richards).

Pulmonary Vessels.—These are apparently constricted even in intact animals, for the pressure in the pulmonary artery rises and the volume of the lung diminishes, even when the pressure in the systemic arteries is unchanged (Anderes, 1915). Berezin, 1914, states that the constrictor effect in the excised vessels is removed by atropine.

Abe, 1920, attributes the fall of blood-pressure by histamine, peptone, serum, etc. to interference with the pulmonary circulation; partly by bronchial spasm, and partly by direct contraction of the pulmonary vessels.

Theory of Deficient Blood Return.—Mautner and Pick, 1917, suggested that the fall of pressure after histamine, peptone, etc., could be explained by obstruction to the return of the blood to the heart; for instance, by spasmotic contraction of the intercostal

arterioles, and of the lung vessels; or by choking of the liver capillaries. There is, in fact, congestion of the liver and of the splanchnic vessels in peptone shock or anaphylaxis; but not, according to Dale and Richards, in the evanescent histamine fall. It is therefore more probably a secondary result. With histamine, at least, portal obstruction is not the essential factor, for a fall occurs in eviscerated animals. The latent period of the fall is also suggestive. It is shortest when the injection is made into an artery; longer with a vein; and longest with the portal vein. This indicates that the action is on a structure between the arteries and veins, that is, on the capillaries.

Hemostatic Effect.—This is uncertain, with local application (Hanzlik, 1918).

Antagonism with Epinephrine.—Schenk, 1921, 1922, claims that with hypodermic injection in man 15 mg. of histamine and 1.5 mg of epinephrine practically neutralize the effects of each other, except the epinephrine glycosuria. Frank and Spohr, 1921, believe, but without adequate evidence, that all the histamine actions consist in paralysis of the sympathetic receptive mechanism.

Toleration.—As with muscarine, histamine, produces its effects only when a given concentration is applied suddenly; if it is added very slowly (*f.i.*, to the excised uterus), it is inactive. Again, a given concentration soon loses its effect, but raising the concentration again induces contractions. Similarly, rapid intravenous injections are much more toxic than slow injections (Oehme, 1913).

Histamine Urticaria.—The application of a drop of histamine, 1:1,000, to the scarified skin produces a brief pallor, followed by reddening and the formation of a temporary urticarial wheal (Eppinger, 1913). The hypodermic injection of 0.5 to 1 mg. of histamine may be followed by erythema over the entire skin. Entirely similar reactions are caused by a variety of substances, for instance, peptone, morphine and its derivatives; to a small degree by atropine, cocaine, formaldehyde, calcium and a number of amino compounds; in susceptible individuals also by quinine, etc. and by certain proteins and anaphylactic poisons (Sollmann and Pilcher, 1917). No definite relation of the urticaria to other actions, or to chemical constitution, has been recognized. The urticaria is a particular, light or limited type of dermatitis (Sollmann, 1917, literature), consisting in congestion by direct dilation of the local capillaries, reflex dilation of the neighboring arterioles, and increased permeability of the capillaries, leading to local edema. Identical phenomena occur in other irritations of the skin, for instance mechanical or thermal burns; Th. Lewis and Grant, 1924, suggest that these are due to the liberation of the histamine-like substance. This, however, lacks proof.

Long-continued Administration of Histamine.—McCarrison, 1924, claims that this retards or inhibits the growth of young animals.

Deterioration.—Histamine hydrochloride is hygroscopic, and tends to deteriorate, especially when in solution (Nelson, 1923).

Imidazol and Other Histamine Derivatives.—They also stimulate smooth muscle, but are less active than histamine (Auvermann, 1918; Dale and Dudley, 1921).

PARAPHENYLENE-DIAMINE

Occurrence of Poisoning.—This substance, $C_6H_4(NH_2)_2$, also called *orsin*, is used extensively for dyeing hair and furs brown and black. Its use is dangerous since the wearing of such furs often results in violent local dermatitis and sometimes in serious systemic poisoning (Cole, 1924). The susceptibility, however, appears to vary. The workers exposed to the poison likewise suffer the effects. Paraphenylene-diamine, and its dimethyl and diethyl derivatives and metaphenylene-diamine, which have similar actions, are employed to accelerate the vulcanization of rubber, and form a toxic hazard in this industry. They are probably decomposed in the vulcanization, but it is not known whether the products that are formed are toxic.

Bibliography.—The subject is reviewed by Hanzlik, 1923.

Clinical Phenomena.—The local effects consist in obstinate dermatitis. The systemic phenomena, sometimes observed after the application of hair-dyes, comprise vertigo, gastritis, asthenia, diplopia, lachrymation, chemosis, exophthalmos, asthma, exfoliative dermatitis. Industrial workers suffer chiefly from eczema and asthma.

Autonomic Action.—The effects agree in principle with those of histamine; that is, (1) stimulation of smooth muscle, regardless of its innervation. This includes bronchial constriction which is partly responsible for the asthma; and (2) increased permeability of the capillaries, resulting in the inflammatory and edematous phenomena.

Edema-production.—The oral or subcutaneous administration of paraphenylene-diamine (0.2 Gm. per Kg.) to rabbits is followed in about 1½ hours by an intense watery edema of the entire head (Meissner, 1919). This increases to the next day, and gradually disappears, by the sixth day, if the animal survives. Not all rabbits develop the edema. It occurs generally in cats and dogs, but not in rats. It is due to increased permeability of the vessels, and may be prevented by diminishing the local blood-supply (Tainter and Hanzlik, 1924; Gibbs, 1923). The reason for this restriction of the edema to the head is not known. The meta-isomer does not produce head edema, but instead causes hydrothorax, which does not occur with the para-compound.

Other Systemic Effects.—All the phenylene-diamines produce rise of blood-pressure, stimulation of respiration, fall of temperature, tremors, convulsions, coma and death. With large doses, the animal may die before the edema can develop. Frogs show a narcotic action.

Quinone-diimine.—On exposure to air, paraphenylene-diamine in solution is promptly oxidized to this compound, $C_6H_4(NH)_2$, which is presumably the dyeing agent. It has been suggested that it is also responsible for the toxic effects, but the evidence is not conclusive; especially since solutions that have become oxidized do not produce the edema.

Edema by Other Aromatic Amines.—The hypodermic injection of phenylene-diamine, metatoluylene-diamine, acetyle-phenylhydrazine (pyrodine) and toluyld-hydrazine produces effusions into the serous cavities. These are not due to hydermia, the blood being rather thickened. Probably the permeability of the capillaries is increased (L. Hess and Mueller, 1915).

Urticaria.—Many amines produce urticaria when applied to the scarified skin; for instance, phenylethylamine, phenylene-diamine, hydroxylamine, etc. (Sollmann, 1917).

Phenylethylamine.—This occurs in putrid meat. Its formula, $C_6H_5.C_2H_4NH_2$, is related to epinephrine. Small doses stimulate the cardiac muscle, large doses depress. All doses contract the coronary vessels; this is followed by relaxation with large doses (Barbour and Frankel, 1915).

When phenylethylamine or tyramine are fed to rats, or injected, they increase catabolism and lower the glycogen content of the liver (Abelin and Jaffe, 1920).

Barbour, 1916, has made a comparative study of the sympathomimetic and other actions of a series of phenylethylamine derivatives.

Indolethylamine.—This stimulates plain muscles, especially the arteries, iris and uterus. It also has stimulant central effects (Laidlaw, 1911). Perfusion through excised liver converts it into indolacetic acid. Dogs excrete 30 per cent. as indolacetic acid (Ewins and Laidlaw, 1913).

Ethylenediamine, $NH_2.CH_2.CH_2.NH_2$.—This has been investigated especially by Barbour and Hjort, 1920. It is comparatively innocuous, the minimum fatal dose for mice being 0.75 Gm. per Kg. hypodermically.

Symptoms.—With frogs its effects resemble those of the aliphatic narcotics.

With rabbits, nearly fatal doses (0.4 Gm. per Kg. by vein or hypodermic) produce temporary respiratory stimulation; lowering of the temperature; slight general depression and transient diarrhea. The blood pressure falls (often with 1 mg., hypodermically) by a central action.

Smaller doses (0.1 mg. per Kg.) produce only a fall of temperature. Daily injections decrease the susceptibility to this effect.

Excised Intestine.—The drug depresses the tone and activity.

Hydrazine, $(NH_2.NH_2.H_2SO_4)$.—When injected into dogs, hydrazine sulphate lowers the percentage of sugar in the blood, and the hepatic glycogen, without any glycosuria. The hepatic cells degenerate, but recover if the injection was not fatal.

The hypoglycemia appears to be due to increased sugar combustion, as indicated by the respiratory quotient. Injected dextrose is also oxidized more rapidly. There is no specific influence on heat production (Underhill and Murlin, 1913).

The production of anhydremia and anemia by hydrazine, *phenyl hydrazine* and other hydrazine derivatives has been studied by Bodansky, 1924.

PTOMAINE BASES

Amine bases are formed in the putrefaction of proteins, and many of these ptomaines have been isolated in crystalline form, (Barger and Walpole, 1909; Barger and Dale, 1909; Dixon, 1913; Hanzlik, 1916). Their pharmacologic actions are on the autonomic system (Blankenhorn, Harmon and Hanzlik, 1916); but the phenomena of so-called "ptomaine poisoning" are due chiefly to bacterial toxins (Ecker and Rademaekers, 1926).

PITUITARY GLAND (POSTERIOR)

In analogy with the suprarenal gland and the pancreas, the pituitary gland contains two portions that differ absolutely in function and in pharmacology. It is remarkable that the parts of the suprarenal and pituitary that are most important to life have the least pharmacologic actions; whilst the parts whose extracts produce very striking pharmacologic effects—the suprarenal medulla and the posterior pituitary—appear to be of minor importance to the organism.

Effects Produced by Extracts of the Posterior (Infundibular) Lobe of the Pituitary.—These cause powerful stimulation of smooth muscle; varying in degree, however, in different situations and under different conditions; there may even be relaxation, or a sequence of relaxation and contraction. The effects are peripheral, for they occur in denervated organs, but the peculiarities are not related to the origin of the autonomic innervation, and are therefore more closely related to those of histamine (Fuehner, 1912) or the protein "shock" poisons, and are quite distinct from those of epinephrine (Dale, 1910). Pituitary extract also produces characteristic changes in the flow of urine and milk; and of cerebrospinal fluid. The active constituents have not been isolated in pure form.

Therapeutically the extract has been used hypodermically with success to accelerate labor and to check uterine hemorrhage; and with more doubtful results in paresis of the bladder, in intestinal paresis and in collapse conditions. It also controls diabetes insipidus. Oral administration is practically ineffective.

Responses of the Uterus.—The strongest and most important action of pituitary extract is on the uterus. Experimentally and clinically, this responds by increased functional activity; increase of tone; initiation or reinforcement of peristaltic contractions; or firm spasm. The degree of response varies with the excitability of the uterus. This effect is utilized in obstetrics, to rouse flagging labor pains; but this use may be dangerous unless the cases are carefully selected and the dosage properly adjusted. The third stage of labor presents a safer field. It is also used for the induction of labor in the last weeks of pregnancy.

In the body and on the excised organ, even very small doses of pituitary have a marked augmentary effect (first described by Dale, 1906); and they increase the excitability to hypogastric stimulation (Dale, 1907; Frankl-Hochwart and Froehlich, 1910). This occurs in all animals, pregnant or non-pregnant (Fuehner, 1913; Gunn and Gunn, 1914; abdominal window: Ludwig and Lenz, 1923). The action has been used for the bio-assay (Dale and Laidlaw, 1912; Roth, 1914; U.S.P.).

Human uterus, non-pregnant or pregnant, in vitro or excised, is also thrown into extreme contraction (Gunn, 1914; Charteris, 1917; Webster; Sollmann).

The *tubes* are not contracted by pituitrin, in distinction to epinephrine (Gunn). The round ligament also does not respond (Webster).

Excessive concentrations of pituitary (also of histamine) depress the excised uterus of mice and guinea pigs; but rats' uterus is not depressed by pituitary in any concentration (Abel and Macht, 1919).

Interaction of Epinephrine and Pituitary.—Epinephrine normally relaxes the excised uterus of guinea pigs and of non-pregnant cats; but if these uteri are first treated with pituitary, the addition of epinephrine causes them to contract (Cow, 1919). This reversal of the epinephrine action was denied by Athias, 1921, but confirmed by Tate and Clark, 1921).

Relation to Sexual Activity.—This influences somewhat the quantitative response, so that special precautions must be taken in bio-assays; but the influence of pregnancy is not as marked as was described by Lieb, 1914, 1915. Castration does not greatly modify the response (Athias, 1921).

Use in Obstetrics.—This was introduced by Blair Bell, 1909. It is very efficient for hastening delivery and checking post-partum hemorrhage, so that it has largely displaced the use of ergot. However, it is dangerous when used in excessive doses, or under unsuitable conditions. The powerful contraction may prevent delivery, asphyxiate the fetus, produce excessive compression, intracranial hemorrhage, premature separation of the placenta, deep laceration of the cervix, or fatal rupture of the uterus.

In view of these accidents pituitary should not be administered in normal labor, and never as a routine; but only for definite indications, and with careful precautions. Its employment should be limited to *uterine inertia*, when the head is well engaged, and the cervix completely dilated. It must not be used if the pelvis is relatively small or if the uterus is weakened or scarred. The usual dosage of 1 c.c. is perhaps too large; $\frac{1}{3}$ to $\frac{1}{2}$ c.c. may be repeated whenever the effect wears off (Maxwell, 1920). This does not produce cumulation (Watson, 1920).

Against Atonic Hemorrhage in the Third Stage of Labor.—The hypodermic injection of 1 c.c. of pituitary extract after the delivery of the placenta causes the uterus to contract promptly and firmly, and thus checks hemorrhage. As the action is short, it is advisable to inject ergot at the same time. Pituitary has also been advised to hasten the expulsion of the placenta (Ryder, 1921); but J. W. Williams advises strongly against this, since it may give rise to hour-glass contraction.

Uterine Operations.—Clarence Webster injects a few drops of pituitary extract directly into the uterine muscle, to secure a firm and bloodless field for incision, f.i. in Cesarean section.

Clinical Effects.—These have been studied by introducing into the cervical canal of parturient women a Vorhees bag connected with a mercury manometer (Haskell and Rucker, 1922). The administration of 0.1 to 0.5 c.c. produces marked peristalsis and increased tone of the uterus, perceptible in 2 minutes and persisting about half an hour; the tone being greater than the top of the contraction waves before the pituitary. The effects are therefore very similar to those of ergot, except in the *time relations*: the response to ergot starts only after 20 minutes, even with hypodermic administration; and passes away in about 2 hours (Clark).

The uterine stimulation may be produced by the oral administration of pituitary extract (Hamill, 1921); but the effect is too variable.

Pituitary does not produce abortion and is most effective when the os begins to dilate (Malinowsky, 1919).

Dangers of Pituitary.—The degree of danger, and the justification of the use of pituitary is still under discussion. Rucker and Haskell, 1921, conclude from their statistics that the risk is so great that pituitary should never be used. Pauliot and Truchard, 1923, reviewing the same statistics, believe that all the accidents would have been avoided had unsuitable patients been excluded. Watson, 1923, also reports a very favorable

series. It seems probable that some accidents are bound to occur, but that they would be few if patients are properly selected.

Other Sexual Organs.—The vaginal muscle and prostate respond like the uterus; the vas deferens, however, does not react to pituitary, although it is stimulated by epinephrine, pilocarpine and barium (Waddell, 1916, 1917).

Effects on Circulation.—Intravenous injection of pituitary extract raises the blood pressure (Oliver and Schaefer, 1895). This may be preceded by temporary fall of pressure. The rise is not as high, but is more sustained than that of epinephrine, lasting ten minutes to one-half hour. It is due mainly to widespread vasoconstriction, from direct stimulation of the arterial and capillary muscle. The kidney vessels, however, are passively dilated in the intact animal. The heart is generally depressed and this produces usually a primary fall of pressure before it is overcome by the vasoconstriction. The heart rate is usually slowed, at first from reflex vagus stimulation, and later by direct cardiac depression. *Repeated injections* of large doses produce less and less rise, and the depressor effect becomes more and more prominent. The latter is perhaps due to a histamine or shock-like action—a dilation of the capillaries, which would diminish the return of blood to the heart, and therefore impair the output of the heart. This histamine action is obscured in the earlier injections by the arterial constriction.

The pressor action has been tried in shock (1 c.c., intramuscularly), but without definite benefit. It has also been used in the place of epinephrine in local anesthesia, but requires high concentrations (20 per cent. of the commercial solutions; Otrich, 1921).

Method of Administration.—Intravenous or peritoneal injection is much more effective and typical than hypodermic (Pankow, 1912) or intramuscular; but the last acts longer (Klotz, 1911). When given by mouth, there is practically no effect.

Cardiac Effects.—In intact animals, these are complicated by the interference of the vagus and muscular actions. The total result is generally slowing and weakening of the beat.

Rate.—This may be unchanged or even quickened, but is slowed in most cases. The slowing is much less if the vagi have been divided, and is due largely to stimulation of the center by the rise of blood pressure (Beco and Plumier, 1913). Some slowing occurs even after atropine and in excised hearts (Cleghorn and others) and this part must be ascribed to direct muscular depression. Werschinin, 1913, believes that the peripheral slowing is due to increased vagus tone; and Claude, Porak and Routier, 1913, attribute it to slowed auriculo-ventricular conduction by an action on the His bundle.

Strength.—The excursions of the mercury manometer are increased, but this is due simply to the slower rate. Direct cardiac tracings show decreased excursions and increased tone. These and the slowing diminish the output, occasionally with a preliminary increase (Wiggers, 1911). The decrease occurs even when the blood pressure rises, showing that the rise is purely vascular. The ventricular efficiency is diminished (Wiggers, 1916).

The pressure in the *pulmonary artery* falls, by weakening of the right ventricle (Wiggers, 1911); or it may be unchanged (Anders, 1915). The *vein pressure* is not affected by moderate doses; it rises with large doses by cardiac dilation (Capps and Matthews, 1913; Rosenow, 1920).

Oft-repeated injections are said to produce *cardiac hypertrophy*, with lasting rise of pressure (Etienne and Parisot, 1908).

Excised Mammalian Heart.—This also reacts with decreased rate and amplitude (Wiggers; McCord, 1911). Einis, 1913, however, attributes this to the chlorotone in the solutions; with pure solutions he describes primary slowing and weakening with subsequent quickening and increasing excursions.

Isolated Frog's Heart.—The excursions are generally increased; small doses quicken, large doses slow to final standstill (Einis).

Evidence of Vascular Action.—Oliver and Schaefer, and subsequent workers, have shown that the rise of pressure is accompanied by diminished organ volume (except in the kidneys), so that it can not be cardiac and must be vascular. Tigerstedt and Airila, 1913, also found that the aortic blood flow decreases with the rise of pressure (and still more in the fall). The vasomotor center is not affected directly; but may be somewhat depressed or more often moderately stimulated, by the rise of blood pressure or respiratory embarrassment (Pilcher and Sollmann, 1915; McCord, 1911). The vasomotor stimulation must therefore be peripheral; and accordingly a rise of pressure occurs after the cord has been cut; and perfusion of excised organs shows direct constriction (Rischbieter, 1913). Segments of excised arteries and veins are also constricted (de Bonis and Susanna). Unlike epinephrine, the effect is not abolished by ergotoxine, so that it is probably directly on the arterial muscle.

Human Blood Flow.—The changes in the pulse-flow of the arm, after intramuscular injection of 1 c.c. of pituitary solution, indicate some vasoconstriction (Hewlett, 1917).

Capillaries.—Application of pituitary solution (1:100) to the *scarified skin* produces a local blanching. This is a distinction from histamine which produces flushing and urticaria in dilutions of 1:10,000 (Josefson, 1915; Sollman and Pilcher, 1916; Carrier, 1922). Krogh found that the muscle fibers on the capillaries are constricted by quite dilute solutions of pituitary extract (1:100,000), which do not act on the arterial muscle. As the blood contains a diffusible substance that also constricts the capillaries, he suggested that this might be the pituitary principle; but no evidence for this assumption is available.

Specific Differences in Vessels.—These are quite unlike those of epinephrine. Pituitary contracts the *pulmonary*, *cerebral*, and *coronary* areas which are scarcely affected by epinephrine. The *coronary circulation* is therefore slowed, notwithstanding the rise of blood pressure (Morawitz and Zahn, 1914). The behavior of the renal vessels will be described under the Urine Flow.

The *brain-volume* in man is increased (Raphael and Stanton, 1919).

Injection at the root of the ear, in rabbits, produces blanching, but less intense and less persistent than with epinephrine (Auer and Meltzer, 1919). The vessels of *frogs* are dilated (Froehlich and Pick, 1913). The reactions of *excised arteries*, in comparison with those of epinephrine and histamine, are reviewed by Rothlin, 1921.

Duration and Repetition of Action.—The rise of blood pressure lasts for about half an hour after intravenous injection. (Mummery and Symes, 1908, state that it persists for several hours if the brain and cord have been destroyed). The effect may be repeated after one-half to three-fourths of an hour, or more frequently if small doses are used (0.06 to 0.1 c.c. of pituitrin for dog (Hoskins and McPeck, 1913). In this way, the blood pressure rise may be utilized for bio-assay (Hamilton, 1912).

Frequently repeated injections of large doses, however, become less and less effective (Howell, 1898) and may finally lower the pressure (Schäfer and Vincent, 1908). The secondary depressor action does not occur as easily in dogs as in cats or rabbits (Hamilton, 1912). The mechanism of this action has not been established.

It is not due to cardiac effects, for these remain constant; nor is it due to fatigue of the vessels, for it does not occur in perfusion experiments (McCord, 1911). Mautner and Pick, 1923, attribute the fall to contraction of the portal vein, interfering with return of the blood to the heart (analogous to their histamine theory).

Action on Depressor.—Pituitary injection decreases the efficiency of depressor stimulation, especially in rabbits, less in cats. The action is stronger than that of epinephrine, and occurs when the blood pressure does not rise (Auer and Meltzer, 1913).

Synergism with Epinephrine.—This has been reported by Kepinow (Gottlieb, 1911). The pituitary rise is not due to stimulation of epinephrine secretion; for it is not modified by ligation of the adrenal vessels (Hoskins and McPeck, 1913).

Primary Fall of Blood Pressure.—This is cardiac, but not vagal, for it occurs after section of these nerves (Paukow, 1912). The fall is more pronounced with large doses (Sollmann; Auer and Meltzer, 1913). Schäfer and Vincent, 1899, believe that it is due to a distinct depressor constituent.

Circulatory Effects in Birds.—These are different than in mammals. There is a marked fall of blood pressure by peripheral vasodilation, antagonized by epinephrine or barium. The ventricular and auricular contractions are stimulated (Paton and Watson, 1912).

Different Portions of Pituitary Gland on Blood Pressure.—Howell, 1898, showed that the pressor effect is confined to the posterior lobe of the gland.

The *hypophyseal portion* (which has a structure resembling the thyroid) produces a distinct fall of blood pressure, usually accompanied by acceleration and weakening of the heart (W. W. Hamburger, 1904 and 1910). The *Pars Intermedia* also produces a fall preceded and followed by rise (Lewis, Miller and Matthews, 1911). The pituitary gland does not contain iodine, even after excision of the thyroid (Simpson and Hunter, 1911). The active principles appear very early in fetal life (McCord, 1915).

CLINICAL USE IN SHOCK AND COLLAPSE

Mummery and Symes found experimentally that the pituitary rise of pressure is more pronounced and sustained if the pressure has previously been lowered, as by hemorrhage, traumatic shock, choline, peritonitis, etc. Blair Bell, 1911, claimed similar beneficial results in patients. The usual *dose* (1 c.c. of the commercial solution = about 0.2 Gm. of the moist gland, intramuscularly) may raise the blood pressure 10 to 40 mm. for an hour, with slightly slowed heart rate (Beck and O'Mally, 1909; Klotz, 1911), but the response is uncertain. This may explain why the drug has not commanded confidence. The slowing might be useful in cardiac irregularities (Werchinin, 1913). Hewlett, 1914, finds that the intramuscular injection of 1.5 c.c. converts the dicrotic febrile pulse into a normal pulse, with diminished pulse volume, but without definite change in blood pressure or blood flow in the arm; these changes corresponding to vaso-constriction.

H. B. Schmidt, 1917, confirmed that the intramuscular injection of 1 to 1.5 c.c. of the commercial extract produces no change in the systolic pressure of febrile patients; but that the diastolic pressure often shows a slight rise, reaching its maximum in about one-half hour.

Local application is effective against capillary hemorrhage, ranking next to epinephrine. Intravenous injection is uncertain (Hanzlik, 1918).

Wiggers, 1911, believes that it may be of some use in *pulmonary hemorrhage* by depressing the heart.

Urine Flow.—The injection of pituitary into animals may increase the urine flow; probably by improving the renal circulation; but the increase is inconstant and of very short duration. The *daily* output of urine tends to be diminished; and this is the usual result of the clinical use. The decrease concerns mainly the water of the urine, and is especially marked in polyuria. This has found an important *clinical application in diabetes insipidus*: The pituitary suppresses the polydipsia and polyuria, and restores the concentration of the urine. The effect, however, persists only as long as the administration is continued. The action is apparently renal; *i.e.* the kidneys do not filter off the water as readily. Accordingly, excessive consumption of water whilst the patient (or animal) is under the influence of pituitary injection, leads to water retention, and to the nervous symptoms of cerebral edema.

The diuresis was described by Schaefer and Herring, 1908. V. Korschegg and Schuster, 1915, find that small doses cause temporary diuresis, followed within ten minutes by diminished urine flow. Larger doses diminish the flow from the start. Injection during the inhibition again starts diuresis. Diminution of urine flow is especially likely to occur if the urine-formation was abnormally high (Brunn, 1920).

The *daily output of urine* and its specific gravity are usually not altered (M. H. Rees, 1918); but the compensatory decrease may be delayed until the following day (Stoland and Korb, 1920). These observers found that the intravenous or hypodermic injection of 1 c.c. of pituitary solution into unanesthetized dogs increased also the nitrogen, urea and ammonium excretion, the maximum being reached in 4 to 8 hours. At the end of 12 hours, the blood nitrogen and urea were lowered by 40 per cent.

Urea Excretion.—Addis *et al.*, 1918, claim that the hypodermic injection of pituitary into rabbits markedly lowers the capacity of urea excretion; and that this constitutes a mutual antagonism with epinephrine.

Urine Response in Normal Human Subjects.—With ordinary doses, the normal effect consists in diminished volume and increased concentration, reaching its maximum in about 3 hours, and returning to normal by the tenth hour (Konschegg and Schuster, 1915; Misasi, 1922; J. L. Miller, 1917; Frey and Kumpless, 1914).

The transformation of benzoic into *hippuric acid*, in nephritis, is reported to be increased by pituitary, independent of any diuresis (Farini and Ceccaroni, 1915).

Urate Retention.—The administration of dried pituitary (0.01 Gm. per day, for 3 weeks) to normal human subjects increased the urate content of the blood, presumably by diminishing the permeability of the kidneys (Hammett *et al.*, 1920).

Mechanism of Pituitary Diuresis.—This does not appear to be direct stimulation of the renal cells, as was assumed by Schaefer and Herring, 1908; for the oxygen consumption of the kidneys is not increased (Knowlton and Silverman, 1918). On the other hand, the diuresis is generally accompanied by increased kidney volume (Magnus and Schaefer, 1901), and increased renal blood-flow (Cushny and Lambic, 1921), which would favor urine formation; and the parallelism appears sufficiently close to justify the assumption of a causal connection. However, Richards and Plant, 1922, describe diuresis that occurred with diminished blood-flow, but increased kidney volume; and they ascribe this to contraction of the efferent arterioles. It is conceivable that the dilation and increased kidney volume might be due either to dilation of the afferent or to contraction of the efferent vessels, according to dosage and other conditions; both would result in increased filtration. Direct observation of the renal glomeruli of the frog shows dilation and increase of functioning glomeruli with small doses, and the reverse with large doses (Richards and Schmidt).

The dilator response is mainly passive, *i.e.* by the increased blood-pressure and by the displacement of blood from the splanchnic area; for perfused kidneys generally respond by constriction (McCord, 1911; Backmann, 1917), sometimes followed by dilation. The ureter-flow follows the volume curve (Sollmann). The larger renal arterioles are dilated (Cow).

Pituitary Factor in Water Diuresis.—Cow, 1915, found that injection of extracts of duodenal mucous membrane increases the urine flow. He attributes this to stimulation of the pituitary gland; and believes that water diuresis is due to absorption of the duodenal pituitary stimulant. Further confirmations are needed for this theory.

Use of Pituitary in Diabetes Insipidus.—Hypodermic injections of solutions of the posterior lobe greatly diminish the thirst, and the volume of the urine, and increase its specific gravity and the percentage of chlorides and nitrogen (Velden, 1913; Rosenfeld, 1916). The kidneys resume the power of concentrating the urine considerably (Christie and Stewart, 1917). It requires at least two injections per day (1 c.c. of the ordinary extract of the posterior lobe), six hours apart. Other channels of administration (oral, rectal, intranasal) may also produce some improvement, but are less effective, and generally unreliable (see Rosenfeld, 1916; Barker and Mosenthal, 1917; Blumgart, 1922; Rees and Olmstead, 1922). Gibson and Martin, 1921, claimed that histamine has a similar effect, but Blumgart, 1922, and Rowntree, 1924, were unable to confirm this.

Mechanism of Anti-polyuric Action.—This consists apparently in diminished water-permeability of the kidneys; for it is accompanied by hydermia (Brunn, 1920); and if the pituitary administration is combined with excessive water-income, either in diabetes insipidus or in normal animals, alarming and even fatal symptoms pointing to acute cerebral edema supervene in a few hours: headache, nausea, asthenia, incoordination; vomiting, convulsions, and coma. The intracranial pressure is increased. Intravenous injection of hypertonic salt solution causes prompt improvement (Rowntree, 1924; Larso, Weir and Rowntree). M. H. Rees, 1920, claims that injection of pituitary slows the absorption of water from the alimentary tract; but this evidently plays at most a minor role.

Polyuric Center.—Since pituitary lesions are often associated with diabetes insipidus, and this can be produced experimentally by injury to this region, the response to pituitary medication might appear as an example of "replacement therapy." In fact, however, the lesion is probably in the surrounding nervous tissue (hypothalamus), which has very important relations to the sympathetic system. Polyuria may also result from lesions of the floor of the fourth ventricle; this is accompanied by increased output of chloride, while the hypothalamic polyuria shows diminished chloride excretion, (see Veile, 1920; Camus and Roussy, 1921; Towne, 1922).

Intestines.—Experimentally these respond by contraction or relaxation or both, according to the species and conditions. Clinically, pituitary injection sometimes relieves post-operative gas-distention (Bell and Hick, 1909); it is less powerful and less certain than physostigmine, but is also safer.

Variability of Intestinal Reactions.—The response varies with the species: The small intestines of guinea-pigs generally show only augmentation; of rabbits and cats, first depression and then augmentation; inhibition predominates in the large intestines of cats (Fuehner, 1916). Different preparations vary considerably (Shamoff, 1916; Hoskins, 1916), and in some of the commercial extracts this is complicated by the presence of chloretone, which has a dilator action (Roth, 1917). It has been claimed that the intestinal activity of pituitary extracts is influenced by the diet of the animals from which they were derived (Degener, 1922). Similar variations of response, however, are found also in connection with the related histamine.

Excised Stomach.—This is stimulated by pituitary, for all the animals that have been tried (Galan, 1921).

Frogs' Esophagus.—The circular and longitudinal muscles are both depressed by pituitary (Waddell, 1916), not by histamine; whilst the *turtle's* esophagus is stimulated by histamine (Bercovitz, 1922).

Urinary Bladder.—The vesical muscle is stimulated and the excitability increased to pelvic, but not to hypogastric stimulation (Frankl-Hochwart and Froehlich, 1910; Abelini, 1919; Streuli). This has been utilized in postoperative paralysis of the bladder (Hoffstätter, 1911; Fellenberg, 1911; Serdinkoff, 1922).

Bronchial Muscle and Asthma.—In guinea pigs the bronchi respond by violent spasm (Froehlich and Pick, 1913; Baehr and Pick, 1913). Dogs usually do not show constriction (Jackson and Mills, 1919); at least the response is much less than for histamine. Pituitary has been tried clinically in asthma (Brochardt, 1913); but the results are not promising. Lanari, 1915, even reports a patient in whom injection of pituitary provoked asthmatic attacks.

The smooth muscle of *necturus lung* is not constricted by pituitary, nor by barium (Luckhardt and Carlson, 1921).

Respiratory Center.—This is affected, both directly and through the circulatory changes. With intravenous injection, Paukow, 1912, describes a primary arrest during the fall of pressure, then an increase and a second stoppage during the rise. Nice, Rock and Courtright, 1914, describe the characteristic effects as primary increase of depth, followed by shallow and generally slow, but sometimes quickened respiration. These disturbances set in with the circulatory changes, but are not as lasting. They fail to occur after a few injections have been made. In frogs, tadpoles and fish, the center is paralyzed (Hepner, 1915).

Iris.—Contradictory results have been reported (consult Pollock, 1920).

Paramecium.—Pituitary extract increases the pulsation-frequency of the contractile vacuole.

Secretions.—Injection of pituitary may produce a temporary increase of *milk secretion*, followed by compensatory decrease, the daily output being practically unchanged. The flow of *cerebro-spinal fluid* is increased; the *salivary and pancreatic secretions* and the gastric acidity are diminished.

Lactal Secretion.—Ott and Scott, 1910 and 1912, discovered a marked galactagogue effect in goats; a number of other gland extracts, especially of the sexual apparatus, had a similar but weaker action. The observations were confirmed by all subsequent workers. The increase occurs within fifteen minutes after the intravenous or hypodermic injection; but there is a corresponding decrease at the next milking, so that the daily output of milk is not changed (Hammond, 1913; Hill and Simpson, 1914). The fat content is increased at the first milking, without decrease at the next. The non-fat solids are not affected (Hill and Simpson, 1914). If the injections are repeated over long periods, the effect is lost (Simpson and Hill, 1915). No increase of milk is said to occur in cows (Gadin, 1913) or human (Schaefer, 1913); but Hill and Simpson, 1914, found that intramuscular injection of 1 c.c. of pituitary solution in the fifth month of human lactation was followed by marked increase of milk and fat.

Mechanism of Action on Milk.—The fact that the response (in goats) is perceptible within half a minute, as also the secondary decrease, suggests that the increase is not due to secretion, but merely to the more complete expression of stored milk by contraction of the smooth muscle of the gland (Simpson and Hill, 1914). The increase of milk-fat would agree with this. Gaines, 1915 (full discussion of the subject), presents manometric evidence of such contraction in lactating glands (non-lactating glands do not respond). Simpson and Hill, 1915, point out that barium does not increase the

milk, although it stimulates the muscle powerfully; but this would be counteracted by the intense vasoconstriction. Rothlin et al, 1922, find that the response is lost in the later months of lactation; but it is conceivable that the properties of the muscle have been altered by that time.

Saliva.—Intravenous injection into dogs diminishes the flow of saliva, partly by decreased blood flow, partly by direct depression of secretion. The response to pilocarpine is also diminished (Solem and Lommen, 1915).

Pancreatic Secretion.—This is decreased (Pemberton and Sweet) through vasoconstriction (Edmunds).

Gastric Hyperacidity.—Pal, 1917, claimed that this is depressed to a variable degree.

Cerebrospinal Fluid.—Pituitary affects the pressure merely through its circulatory changes (Dixon and Halliburton, 1913 and 1914).

Cow, 1915, believed that the pituitary principle occurs sometimes in the cerebrospinal fluid; especially after injection of extracts of the duodenal mucosa, which he considers as a stimulant of pituitary secretion.

Metabolism.—The injection of pituitary produces considerable *glycosuria* (Voegtlin and Thompson, 1925) and thus counteracts insulin hyperglycemia (Dale and Burris). The effect has not been explained. It increases the *basal metabolism* of normal individuals, but is said to lower it in hypothyroid patients (McKinlay, 1921). Pal, 1917 claimed that in *Basedow's disease* it decreased the toxic symptoms and the size of the thyroid. It produces *hyperthermia* in pigeons that were rendered poikilothermic by cerebro-thalamic ablation; it has no effect on the temperature of normal pigeons (Rogers, 1921).

Excessive and long-continued doses are said to produce ataxic and motor symptoms, emaciation and disturbances of carbohydrate metabolism. Weed, Cushing and Jacobson, 1913, believe that this is influenced by the posterior lobe. Injections of pituitary lower the assimilation limits for carbohydrates, and cause glycogenolysis and glycosuria. *Stimulation of the hypophysis* in dogs produces hyperglycemia, even when proper precautions are taken against asphyxia, neighboring structures, etc. No result is obtained after section of the splanchnics (Keeton and Becht, 1915).

Toxic Actions.—Aside from the accidents arising from actions on smooth muscle, such as rupture of the uterus or asphyxiation of the fetus, toxic effects are rare and generally unimportant. Seifert (Nebenwirk., 1915, page 206) cites the following: Tinnitus; anxiety; albuminuria; unconsciousness; eclamptic attacks; mydriasis; amaurosis; diarrhea.

The Active Constituents of the Posterior Pituitary.—Attempts at complete isolation have so far been unsuccessful, but very potent preparations have been obtained; that of Abel *et al*, 1923, stimulates the excised guinea pig uterus in dilution of 1:20,000,000,000; and is thus over a thousand times as active as the very potent histamine. It also produces the characteristic vaso-pressor, the diuretic, and the anti-polyuric effect, in somewhat the same ratio as the pituitary extracts. It is therefore natural to suppose that all these actions belong to a single substance, but it might be that a number of substances of similar chemical and physical characters are present. This is suggested by the fact that Dudley, 1923, using a different method, obtained extracts in which these properties are not parallel—but this again might be a result of partial decomposition. The depressor reaction and the broncho-constriction are due to another substance, either histamine or a derivative, which can be easily separated quantitatively from the pressor-oxytocic-diuretic principle (Abel and Nagayama, 1920; Roca, 1921).

The partial separation of the active principles has been accomplished by methods analogous to those used for amine-bases and alkaloids. They are precipitated by alkaloidal precipitants, and soluble in alkaloidal solvents; they are very easily adsorbed, and are apparently easily decomposed when it is attempted to separate them from the last trace of the adsorbent. This, and the fact that they are present in very small quantities, as indicated by the high activity of the partially purified products, explains the difficulty of their isolation. Very slight traces impart

activity to the adsorbent, and the investigator is thus easily misled. It is not necessary to review these partial failures.

Fetal Glands.—The active principle appears very early in fetal life (McCord, 1915).

Absence of Iodine.—Iodine is not present in any part of the pituitary gland, even after excision of the thyroid (Simpson and Hunter, 1911; Seaman, 1920).

Stability.—Alkaline, neutral and faintly acid solutions deteriorate fairly rapidly, especially on heating; but when the acidity of the extract corresponds to about $\frac{1}{4}$ per cent. acetic acid, they may be boiled (but not autoclaved) without loss of activity (H. S. Adams, 1917). Digestive ferments tend to destroy the activity of the extracts, although the data are somewhat contradictory (see Rees and Whitehead, 1923); very possibly the decomposition is secondary to cleavage of the protecting colloid.

The commercial extracts keep practically indefinitely unless exposed to temperatures above 40°C. The dried and defatted glands are very stable. The moist gland keeps at -10°C., but deteriorates at 0°C., in a few weeks (M. I. Smith and McClosky, 1924).

Standardization of Pituitary Extracts.—This is highly important because of the serious consequence of overdosage, especially in obstetrics. Since chemical assay is as yet impossible, it is necessary to measure the potency by the effects. The comparison of the response of the excised uterus of guinea pigs, under standardized conditions, with a standard sample of dried pituitary, is accurate and reasonably convenient, and has the advantage that it measures the action that is most likely to become dangerous. The effects on the blood-pressure go fairly parallel. The uterus method (Dale and Laidlaw, 1912; G. B. Roth, 1914) is described in the U.S.P. Further details are discussed in the papers of Burn and Dale, 1922; Nelson, 1923; M. I. Smith and McClosky, 1923; Pittenger and Quici, 1923.

PREPARATIONS

Pituitarium (Pituitar.), U.S.P.; Pituitary (Desiccated Hypophysis).—The cleaned, dried and powdered posterior lobe from the pituitary body of domesticated animals used for food by man. *Dose*, 0.03 Gm., $\frac{1}{2}$ gr., U.S.P.

* *Liquor Pituitarii* (Liq. Pituitar.), U.S.P.—Solution of Pituitary, solution of Hypophysis. The activity (tested on the isolated uterus of guinea pigs) corresponds to 0.5 per cent. of standard powdered pituitary. The solution is slightly acid. *Dose*, 1 c.c., 15 minims, U.S.P.

ANTERIOR PITUITARY GLAND

Injection of Extracts.—These are practically inactive, and lack almost entirely the autonomic stimulation that is so marked with the posterior lobe. The colloid of the pars intermedia is also inactive toward the uterus and blood-pressure (Burn and Dale, 1922).

Continued Feeding on Growth of Mammals.—This has probably no effect, although some discordant results have been reported, due probably to inadequate controls (consult Sisson and Broyles, 1921).

Genital Tract.—F. T. Frank, 1919, failed to obtain any definite effects from feeding the anterior or posterior pituitary lobes.

Egg Production of Chickens.—S. Simpson, 1920, failed to confirm the older claims that this is increased.

Young Salamanders.—Uhlenhuth, 1922, claims that feeding with anterior pituitary produces marked acceleration of growth, and that this continues beyond the normal size; i.e., that it results in gigantism. The growth and metamorphosis of *tadpoles* is not affected (P. E. Smith and Cheney, 1921).

Therapeutic Results.—The dried anterior pituitary gland has been administered (0.05 to 0.25 Gm., by mouth) in the diseases in which the function of this gland is supposed to be deficient (adiposo-genital dystrophy), and also when it is supposed to be excessive (acromegaly and gigantism). The reported results are not convincing (J. L. Miller, 1925).

Tethelin.—T. B. Robertson, 1916, applied this term to a purified unstable alcoholic extract of the anterior pituitary. The following statements regarding its actions have not yet been sufficiently controlled by other investigators.

Growth and Duration of Life.—Robertson and Ray, 1919, report that the addition of tethelin to the food of mice retards growth and prolongs their life. If the administration is confined to the preadolescent period, the retarded growth is succeeded by a marked acceleration, even beyond the normal, and life is shortened.

Carcinoma.—Feeding of tethelin tends to retard the growth of cancer; but its local injection in rat carcinoma increases the growth of the tumor and tends to metastases, analogous to anterior pituitary. Lecithin retards (Robertson and Burnett, 1916). Tethelin also accelerates the growth of infusoria.

Application to Wounds.—Local application appears to hasten the healing of ulcers, fractures, etc. The therapeutic application of this action is still in an experimental stage.

Toxicity; Excised Uterus.—Tethelin is non-toxic. It does not affect excised uterus (C. A. Schmidt, 1917), but Robertson claims that after hydrolysis it produces uterine stimulation.

GLANDULAR THERAPY

The functions of the organism are regulated by nervous and chemical mechanisms. The chemical regulators or hormones are produced in part by the tissues at large, for instance, carbon dioxide; others are centralized in special tissues, the glands of internal secretion. It is quite conceivable that very active substances may be formed in the body, and in these glands, as mere by-products, or even as waste-products; but there is no doubt that products of these glands have very important functions, and they appear to be the chief agencies for regulating metabolism, growth and the sexual functions. The effects of deficient internal secretion by the pancreas, the thyroids, the parathyroids and the sex glands are very striking. With other glands the deficiency phenomena are so indefinite, so slow in their development, so greatly conditioned on circumstances, so much exposed to sources of error, to complicating injury of other parts, etc., that their nature is very much in doubt. It is also quite probable that deficient function of one gland may be compensated more or less by other glands, or that it may produce other changes in these, and it may be difficult to establish the relationship.

Therapeutic Administration in Glandular Deficiencies.—Brilliant success has been attained with thyroid in cretinism, and with insulin in diabetes; parathyroid therapy is also promising. With other glands there have so far been no definite results. It would be rash to prophesy the future from these failures; but permanent advances can only be expected from scientific experimentation. These demand (1) definite criteria of response, by which partial or complete success may be judged; and such criteria must be independent of the imagination: The discovery of insulin and of the parathyroid hormone had to wait for sufficiently accurate methods of blood-analysis; and (2) the preparation of effective extracts in a form suitable for administration. Oral administration has been adequate only in the case of the thyroid gland. The alimentary tract apparently interposes a protective barrier against the absorption of active quantities of other hormones; perhaps because their chemical structure is peculiarly labile.

Gland therapy can be established on a sound basis only in the direction that has been indicated, however difficult and laborious and tedious this may appear. Its development is rather hindered by premature enthusiasm which is inclined to dispense with definite criteria of action, with adequate controls, with effective preparations or efficient channels of administration, and often with critical diagnosis; which interprets psychic manifestations as scientific observations, and which depends on "autistic

judgment," *i.e.* judgment or rather credulity based on desires instead of facts.

The internal secretions with definite actions are discussed in different places in this book, according to their effects. An excellent critical review of the present status of the subject is presented in the little book, "Glandular Therapy," published by the American Medical Association.

SEXUAL GLANDS

Specific internal secretions of these glands are concerned in the production of the "secondary" sexual characters; and in the cycles of menstruation, pregnancy and lactation. However, their administration produces no therapeutic effects that are not more simply explained by suggestion; nor has any decided action been demonstrated by their injection into animals, normal or castrated; with one exception: The injection of the follicular liquid of the *corpus luteum*, and a lipoid extract of this liquid, hastens sex maturation in immature females, and induces oestrus in spayed females (R. T. Frank, 1922; Doisy, Allen *et al.*, 1924).

Ovarian Substance.—This has little effect on normal animals, but when oxidation has been depressed by castration, in bitches and somewhat in male dogs, it is restored to the normal level or above by the administration of ovarian extract.

Corpus Luteum.—The specific effects of the corpus luteum on the sexual cycle are not secured by its administration (L. Loeb, 1910, 1911 and 1918; Corner and Hurni, 1918). Injections are slightly galactagogue in goats (Ott and Scott, 1910; Schaefer and Mackenzie, 1911). They start hypertrophy of the mammary gland and lactation even in virgin rabbit (Ott and Scott, 1914). Intravenous injection lowers the blood pressure (Villemin, 1910).

Action on Excised Smooth Muscle.—Extracts of corpus luteum or ovary have but little effect on the excised bladder and ureters; they stimulate excised uterus about like other gland extracts; and they produce especially strong stimulation of the vas deferens. This has been suggested as bio-assay; *i.e.*, that concentrations corresponding to 0.1 per cent. of the fresh gland should stimulate the vas deferens of rats. This reaction is stronger with the corpus luteum than with the ovarian extracts (Matsumoto and Macht, 1919).

Mammary Gland.—Extracts increase the movements and the tone of the excised uterus (Ott and Scott, 1909) and are somewhat galactagogue, but not in human subjects (Schaefer and Mackenzie, 1910).

Extract of Prostate.—Feeding with prostate hastens the metamorphosis of *tadpoles*; but unlike thyroid, it does not check growth. The effect is not due to iodine, for this is not present. It seems to be specific to this tissue (Macht, 1920).

Excised Smooth Muscle.—This is stimulated, the uterus being especially sensitive (Ott and Scott, 1909; Macht and Matsumoto, 1920).

Metabolism.—This is increased, but not as much as by ovarian extract.

Orchitic Extracts.—Brown-Sequard, 1889, announced that hypodermic injections had remarkable stimulant qualities. Sensational exploitation brought his claims into rapid discredit, and the extract is now scarcely employed. The most marked effect is said to be an increase of 15 to 20 per cent. in the capacity for voluntary muscular work (ergograph).

This action has been attributed by Poehl to the base *spermine* ($C_8H_{14}N_2$). While this is especially abundant in this extract, it also exists in many other tissues. Its actions on the heart and circulation resemble those of *choline*, which is also present in the orchitic extract. Its phosphate forms the "*Charcot-Leyden*" crystals found in sputa, etc. The action of these substances is supported by a nucleoprotein, which causes a slowed heart and fall of blood pressure through stimulation of the vagus center, and dilatation of the splanchnic vessels, also through the center. The orchitic extract applied to the *isolated heart* (Porter and Langendorff method) shows increase in force and frequency. The excised uterus shows slight stimulation.

Extract of Placenta.—The injection stimulates the contractions of the uterus; and when combined with pituitary, induces premature labor (Ludwig and Lenz, 1923).

Kidneys.—There is no good evidence for or against the formation of an internal secretion by the kidney (critical review, Pearce, 1908). Injections of *kidney extracts* produce blood-pressure changes (Pearce) corresponding to the urine in them.

RECAPITULATION OF ECBOLICS (OXYTOCICS) AND EMMENAGOGUES

Ecboics are remedies which stimulate the gravid uterus to the expulsion of the fetus. When used in the non-gravid condition, they often increase the menstrual flow, and are then called *Emmenagogues*.

They may be grouped into the following classes:

1. *Direct Stimulation of the Uterine Muscle or Innervation*.—Pituitary, ergot, histamine are the only reliable oxytocics for therapeutic use. Other members of this class are quinine, hydrastis, pilocarpine, physostigmine, nicotine, muscarine; and parasympathetic stimulants in general.

2. *Intestinal Irritants*.—These include:

All *Drastic Purgatives*.—Aloes, Myrrh, etc.

Irritant Volatile Oils, especially Savin, Thyme, Pennyroyal, and Turpentine.

All other *Intestinal Irritants*: Cantharides, Digitalis, Metals, etc. A similar action is also claimed for Borax, but may be considered doubtful.

It must be remembered that these irritants produce their ecboic effect only secondarily to a gastroenteritis. The latter may be so violent as to be fatal without accomplishing the desired result. They should not be employed for ecboics, but the volatile oils may be useful as emmenagogues.

Application of heat or counterirritants to the pelvic region or feet: hot foot- or hip-baths, mustard plasters, hot irrigations of the vagina, etc. These milder measures are only emmenagogue. When nutrition is low, they may be greatly aided by *tonics*.

OXYTOCICS OF MINOR IMPORTANCE

Gossypii Radicis Cortex, B.P.; Cotton Root-bark.—The dried root-bark of *Gossypium herbaceum* and other species. This also was used as abortifacient by the negroes. It contains resins, but no alkaloids nor tannin (Power and Browning, 1914, Zellner, 1910). Clinical and experimental reports are not favorable; the perfused uterus, however, is stimulated (Scott, 1911).

Dec. Gossyp. Rad. Cort., B.P.—20 per cent. *Dose*, 15 to 60 c.c., $\frac{1}{2}$ to 2 ounces, B.P.

Ext. Gossyp. Rad. Cort. Liq., B.P.—*Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Peony Root.—Holste, 1916, claims that this contains an alkaloid that stimulates uterine contractions, constricts blood-vessels, and increases blood coagulation. This needs confirmation.

"*Shepherd's purse*:" Extracts of *Capsella bursa-pastoris* obtained a brief popularity as ergot substitutes (H. Boruttau, 1920) but promptly relapsed into oblivion.

UTERINE SEDATIVES AND HEMOSTATICS

A number of drugs of ill-defined actions are popularly credited with "quieting the excitability of the uterus," especially the pains of premature labor; with contracting the os uteri; with arresting uterine hemorrhage; with regulating dysmenorrhea, particularly at puberty and the climacteric; and even with correcting uterine malpositions.

It is difficult to conceive a mechanism by which a drug could produce all of these actions, except to simulate them by the imagination. Many of these complaints are so uncertain in their course, and indeed so largely nervous, that it is easy to imagine any results that are desired.

The use of these remedies was mostly taken from uncritical folk medicine and promulgated by obscure and ill-trained practitioners during the most uncritical period of therapeutics. They owe their continuance in the pharmacopeia mainly to their extensive use in proprietary "*female weakness*" remedies. These in turn rely for their sale on the liberal use of alcohol and exaggerated suggestive advertising.

Under these circumstances, there is practically no serious evidence for the clinical usefulness of these drugs. Excepting hydrastis and cotarnine, which belong to a somewhat different class, there is no record of any competent clinical investigation by experienced critical observers under hospital conditions. The clinical cases that are published are generally very superficially recorded; they generally show evidence of prejudice and exaggeration; and are often vitiated by the simultaneous use of other measures of more evident value.

Experimental Investigations.—Pharmacologically, most of the drugs of this class are practically inert, especially as concerns the uterus. Since the excised uterus reacts essentially like the uterus *in vivo*, it may be fairly taken as an index of uterine activity. Pilcher, 1916, has investigated in this way the drugs which are used most commonly in these female remedies, employing the relatively very high concentrations of 1:1,000 to 1:500.

He obtained no definite effects with: *Chamaelirium luteum* (*Helonias dioica*); *Leonurus cardiaca*; *Passiflora dentata*; *Mitchella repens*, *Chestnut* bark.

The following gave more or less pronounced effects (but not sufficient to confirm any therapeutic value):

Slight Depression.—*Valerian*; *Dioscorea villosa*; *Aletris farinosa*; *Ichthyomethia piscipula*; *Pulsatilla pratensis*; *Cypripedium pubescens*; *Scutellaria laterifolia*; *Scrophularia marylandica*; *Senecio aureus*; *Viburnum opulus*.

Inconstant Stimulation.—*Acer spicatum*; *Cnicus benedictus*; *Viburnum prunifolium*.

Constant Marked Increase of Tone.—*Caulophyllum thalictroides*.

These results were obtained chiefly on the excised uterus of guinea pigs. The excised human uterus required higher concentrations, but gave the same reactions (Pilcher, 1917).

Uteri in Situ in Living Animals.—None of the above drugs produced any effect in anything like normal doses (Pilcher and Mauer, 1918).

Excised Intestines.—These are also affected, similarly to the uterus. *Caulophyllum*, however, lowers the amplitude with little effect on the tone. *Valerian* (oil) depresses the contractions. *Viburnum opulus* and *prunifolium* are inactive (Delzell, Burman and Pilcher, 1916).

VIBURNUMS

Viburnum prunifolium and *Viburnum opulus* have the widest reputation amongst these uterine sedatives, and for that reason deserve more detailed discussion, although their usefulness is no more demonstrated. Illustrative of this is the fact that the drug sold as *Viburnum opulus* has, for the last twenty years, consisted of the bark of a maple, *Acer spicatum* (Farwell, 1913, and others).

Viburnum prunifolium or Black Haw, a rather common shrub, was used somewhat in domestic medicine (Lloyd). It was introduced into medical practice mainly by the clinical papers of Phares, 1866, and Jenks, 1876. Both praise it with extravagant enthusiasm. The next ten years were the high tide of its popularity, as judged by an output of 75 articles on the subject. The interest then abated equally suddenly, for the next thirty years have produced only some 15 papers.

The whole early literature is highly typical of the loosest class of clinical "evidence," and does not merit serious discussion. The mechanism of its reputed action is at most a matter of speculation. The only attempts at investigation date from R. L. Payne, 1888, and Sherman, 1896, and these did not include the uterus. They showed at most that very large doses may produce depression of the whole nervous system, without practical significance.

La Torre, 1912, interprets the histologic picture as contraction of the uterus, compressing the uterine vessels.

The first real search for uterine actions was made by Lieb, 1914. He believed that he observed stimulation of the excised uterus. However, more extensive investigations by Pilcher, 1916; by A. P. Matthews and Hager; by Hager and Becht, 1919, and by Hale, gave generally negative results under all conditions (uterus pregnant and non-pregnant; *in situ* or excised). Neither *viburnum* has any effect on excised intestine.

Viburnum, B.P. (Black Haw).—The dried bark of *Viburnum prunifolium* contains resins (*viburnin*), *valeric* and *tannic acids*, etc. *Dose*, 2 Gm., 30 gr.

Ext. Viburn. Liq., B.P.—*Dose*, 4 to 8 c.c., 1 to 2 drachms, B.P.

REACTIONS RESEMBLING HISTAMINE

General Statement.—Phenomena resembling closely those of histamine are produced by the injection of many tissue extracts, by peptones, secretin, and other products of partial protein cleavage, by blood serum, by bacterial products; by the injection of many colloids; and in the course of anaphylaxis and of traumatic shock.

In some cases the phenomena agree closely with those of histamine and may be due to the presence of this substance or a near derivative. In most cases, however, the correspondence of the effects is not complete (Loewit, 1913); and in some it is only superficial.

PROTEOSES ("PEPTONE")

Effects of Albumoses.—Intravenous injections of "Witte's Peptone" (0.5 Gm. per kilogram) produce typical anaphylactoid phenomena (Biedl and Kraus): temporary but considerable fall of blood pressure (Thompson, 1896 and 1899) by peripheral action, in dogs (but not in rabbits, Pissemsky, 1915); stimulation of the isolated uterus (Dale and Laidlaw, 1910); bronchial constriction, peripheral (Baehr and Pick, 1913; no effect, Trendelenburg); increased flow of lymph and secretions (Popielski, 1908 and 1909); of milk (Ott and Scott, 1912); discharge of the gall-bladder (Klee and Knuepfel, 1914); diuresis independently of the blood pressure (Thompson; Gizelt, 1908; Fröehlich and Pick, 1912); fever on hypodermic injection, etc. In most animals (but not in rabbits) appropriate doses render the blood non-coagulable, and produce hyperglycemia and glycosuria (Y. Henderson and Underhill, 1911). McGuigan and Ross, 1915 and 1917, however, state that the usual result is hypoglycemia, which they attribute to circulatory changes in the liver. The secretion of bile is increased (O'Kada, 1915). Application of peptone to the scarified skin produces a wheal (Sollmann and Pilcher, 1916).

Intravenous injection of small doses of pure proteoses increases the urinary nitrogen very greatly for several days (Whipple, 1916).

Resemblance to Histamine.—Dale and Laidlaw, 1911, called attention to the striking similarity of the anaphylactic and peptone effects to those of histamine; and suggested that the active principle may be similar. Certain minor differences exist; *f.i.*, epinephrine removes the bronchial spasm of peptone and not of histamine (Januschke and Pollak, 1911); histamine does not affect the coagulation of the blood (Modrakewski, 1912).

Repeated Dosage.—Dogs that survive "peptone shock" are immune to repeated injections, even of large doses; some 6 per cent. of dogs have a natural immunity to "peptone," whilst neither native nor acquired immunity for histamine exists in dogs (Abel and Geiling, 1924). On the other hand, it is claimed that the intravenous injection of a small dose of peptone into rabbits produces sensitization, so that another injection results in prompt anaphylactic shock. This sensitization occurs within 10 to 20 minutes, reaches its maximum in half an hour, and then decreases slowly, to complete disappearance in 8 days (de Waele, 1923).

Active Constituents.—"Peptone" preparations consist mainly of proteoses, with some peptone and other protein cleavage products, and among these, histamine (Nagayama, 1920). It is suggestive that histamine and similar amines are among the products of the more complete digestion of peptones. The histamine would doubtless contribute to the effect; but typical peptone effects are produced by preparations free from histamine (Hanke and Koessler, 1920) or other foreign toxic admixtures (Underhill, 1903). The actions therefore seem to be due to the proteose.

Circulation.—The mechanism of the fall of blood pressure is identical with that of anaphylaxis (Thompson, 1896 and 1899; Pearce and Eisenbrey, 1910; Fröehlich and Pick, 1912).

Injection of albumose or histamine into non-anesthetized animals produces flushing of the skin and mucous membranes (Abel and Geiling, 1924).

With rabbits, the vessels of the legs and ears are constricted, whilst the splanchnic vessels are dilated (Kondo, 1919). The excised mammalian heart is weakened by concentrations of 1:1,000 to 1:10,000; stimulated by 1:200 (Pissemsky). *Excised vessels* are generally constricted (Dale and Laidlaw, 1911); the ear vessels are constricted by all concentrations; those of the perfused lung are somewhat dilated (Baehr and Pick, 1913); also the liver-veins (Berezin, 1914); the intestinal, renal and coronary vessels are unaffected by dilute solutions, constricted by strong solutions (Pissemsky, 1915;

Mautner and Pick, 1915). The effects on blood pressure and respiration have also been investigated by Zuntz, 1911.

Notwithstanding these similarities, there are sufficient differences to indicate that anaphylaxis is not due to the formation of ordinary albumoses (Manwaring, 1910; Loewit, 1911 and 1912).

The peptone shock is said to be much less marked in animals whose parasympathetic mechanism has been depressed by *atropine*, and to be greater in those with natural or induced hypersusceptibility of the *parasympathetic* (Garreton *et al.*, 1922; Arloing and Langeron, 1922).

"Hemoclastic Crises."—This term has been applied by Widál to a clinical syndrome that is produced by the injection of peptone, by other active colloids, and by anaphylactic reactions. It comprises leucopenia followed by leucocytosis, diminished coagulability, fall of arterial pressure, and lowered refractive index of the blood.

Blood Coagulation.—The direct addition of peptone to blood does not affect coagulation; but intravenous injection generally renders the blood non-coagulable. This is due to an antithrombin; the blood containing all the necessary elements for coagulation, so that it clots, *e.g.*, on simple dilution with water. This antithrombin seems to be nucleoprotein formed in the liver (Doyon, Morel and Policard, 1911; Denny and Minot, 1915; its production is not increased by bile, bile salts, secretin or electric stimulation). R. J. Lee and Vincent, 1915, attribute the non-coagulability of the anaphylactic blood mainly to an anomalous behavior of the blood-platelets.

Effect on Hemorrhage.—Bleeding from superficial vessels is rather increased by the local application of peptone. Intravenous injection may diminish hemorrhage, parallel to the fall of blood pressure (Hanzlik, 1918). Peptone does not agglutinate red corpuscles *in vitro* (Karsner and Hanzlik, 1920).

Injections of Witte's peptone have been proposed for the treatment of hemophilia, but have caused fatal hemorrhage (Leceboulet and Vaucher, 1914).

Lymphagogue Action and Blood Concentration.—Peptone, and other shock-producing poisons, alter the capillaries so as to produce loss of blood-plasma and consequently increase of the blood-concentration and increase of lymph-flow.

Toxemia.—Whipple, 1916, attributes to a primary proteose the toxic effects of intestinal obstruction, peritonitis, and acute pancreatitis.

Lesions.—Broughton, 1919, after intraperitoneal injections of Witte's peptone into guinea pigs, describes inflammatory lesions in the liver, heart and kidneys, similar to those produced by other foreign proteins.

Febrile Reaction and Leucocytes.—The intravenous injection of vaccines or foreign proteins is followed by a chill, fever, muscular and joint pains, sweating, and a characteristic leucopenia (about the 2nd hour), followed by leucocytosis (4th hour to several days), sometimes of very marked degree (De Aric, 1913; Gow, 1919).

The *leucocytosis* is probably associated with the pyrogenic reaction, but is not proportional to it. It is chiefly polymorphonuclear; but there are also atypical lymph cells, nucleated reds, and myelocytes. In distinction from anaphylaxis, there is no eosinophilia.

Cowic and Calhous, 1919 (Arch. Int. Med., 23:69), believe that the *leucopenia* is due to the emigration of the leucocytes from the blood into the tissue; and that the leucocytosis is due to increased production of these cells.

Modified Response to Autonomic Poisons.—The injection of peptones and other proteins, such as milk and sera, and also cholesterin, and other colloids, *f.i.*, colloidal metals, modify the sensitivity to autonomic poisons. For instance, the direct addition of peptone to a pilocarpine solution diminishes the augmentor action of the latter on excised intestine (perhaps by adsorbing the pilocarpine), but if the intestine is treated first with doses of peptone that are inactive in themselves, they respond more strongly than normal to the subsequent application of pilocarpine (van Leeuwen and van den Broeke, 1920). In intact animals, also, the peptone injections are followed by increased responsiveness to the peripheral autonomic system, for instance to epinephrine and pilocarpine, and this "allergy" persists for a considerable time. This may furnish a key to the understanding of "idiosyncrasies" (Freund and Gottlieb, 1922). Doelken and Herzger, 1922, claim that milk and serum injections modify also the response to strychnine, nicotine, morphine, etc. Gautrelet reports that the injection of peptone (or colloidal silver and other colloids, to a smaller degree), prevents the synergistic hypo-tensor effect of nigrosine and thionine.

Peptone Injections against Infective Fevers.—Intravenous injection of peptone, in proper dosage, tends to bring on a prompt crisis in various infective fevers, and may thus shorten their natural duration. The same

result is secured by the intravenous injection of other agents that produce similar reactions—non-specific bacterial vaccines (for instance, typhoid) or filtered cultures; colloidal metals, etc. This treatment has been employed most extensively in acute rheumatic fever. The clinical relief is generally prompt and considerable. Occasionally, however, the reaction is dangerous. The method is not sufficiently safe for general use.

Reaction for Therapeutic Dosage.—By proper dosage and slow injection, it should be aimed to produce only a slight degree of reaction: slight transitory tachycardia; some deep breathing or dyspnea; transitory headache. These symptoms pass off in 5 minutes; but are followed after $\frac{1}{2}$ –2 hours by more or less prolonged rigor; and then by defervescence with profuse sweating. The fall of temperature lasts till next day, and is accompanied by subjective and objective amelioration.

The injections are repeated on alternate days, until the curé is completed. Nolf, 1919, has used this therapy in typhoid, septicemias, rheumatic fever, and other arthritides, and others have used it against migraine (Miller and Raulston, 1923); against anemias; hemorrhagic processes etc. (Casson, Thèse de Paris, 1919).

Mechanism of Action.—This has been attributed somewhat vaguely to "stimulation of the defensive mechanism," particularly to the leucocytosis and to the change in the colloidal equilibrium of the blood (Widal). The blood flow is probably also altered. Clearer conceptions must probably await a better understanding of the factors that constitute the "defensive mechanism."

Dosage of Peptone.—This is administered as 10 per cent. sterilized watery solution. This is injected intravenously, taking 3 to 5 minutes to inject 10 c.c. and observing at the same time the pulse and face of the patient. The same dose may be injected subcutaneously. If the first injection is well borne, 10 c.c. of 10 per cent. solution are again injected on the next day.

If the peptone solution enters the tissue around the vein, painful inflammation is likely to result. Intramuscular injections are also followed by considerable pain. Cardiac diseases contraindicate all foreign protein therapy (Nolf and Depage; Jobling).

Excessive Reactions.—These occur if the injection is too rapid or the peptone too active. They resemble anaphylactic shock and consist in marked tachycardia (increase of 30 to 40 per minute), cyanosis, with air-hunger, violent headache, nausea, vomiting. They are usually of short duration. Should they occur, epinephrine, 0.5 mg. to 1 mg., may be injected and repeated as needed (Nolf).

Smooth Muscle.—This is generally stimulated, similarly to histamine. In the excised intestine, the stimulation is relatively slight, and inhibition tends to predominate (Olivecrona, 1921). The bronchial spasm in guinea pigs is less intense than in anaphylaxis (Loewit, 1913).

COW'S MILK AS FOREIGN PROTEIN

Sterilized milk has been used for foreign protein therapy; 5 to 20 c.c. being injected intramuscularly, every day or every second day, generally for three doses. The reactions are similar to those of peptone or other colloidal injections: fever (maximum temperature in 6 to 8 hours); sweating; headache; marked local pain, often lasting many hours, but no abscess formation. This "milk-disease" differs from "serum-disease" by its prompt onset, and by the usual absence of arthralgia and of rashes. Repeated injections of the milk at unsuitable intervals may result in true anaphylaxis (Schmidt; Casson, 1919).

SPLIT PROTEIN POISON

V. C. Vaughan, 1907, 1913, 1916, found that the alkaline cleavage of proteins results in toxic products that appear to be identical for all proteins, at least so far as the effects are concerned (Edmunds, 1913; Vaughan, 1916). These agree very closely with the albumoses, although they differ in detail. Rabbits, e.g., are refractory to proteoses, but sensitive to the split proteins (Underhill and Hendrix, 1915). The chemical identity of these poisons has not been established.

Protamines, histones and some other cleavage products also produce peptone-like effects (Thompson, 1900).

TISSUE EXTRACTS WITH HISTAMINE-LIKE ACTIONS

Extracts of practically all tissues, but especially of glands and smooth muscle, produce histamine or peptone-like effects: stimulation of smooth muscle and glands, and fall or rise of blood pressure. Intravenous injection or direct contact are usually required to produce a response.

The pressor principles predominate in saline extracts made at ordinary temperature, but are often destroyed by boiling. The depressor substances are soluble in saline solutions and in alcohol or ether. They are not identical with choline (Swale, Vincent and Sheen, 1903; Fawcett, Beebe, *et al.*, 1915; Vincent, 1918) and are probably more nearly allied to the "peptone" and similar effects. Inorganic constituents may also play a part: expressed heart-juice, *f.i.*, depresses cardiac activity, simply by its potassium content (Macleod, 1907).

Popielski, 1913, named these principles "*vasodilatin*." This implies a chemical identity that has not been established.

SPLEEN EXTRACT

This stimulates smooth and cardiac muscle ("*Lienin*," L. Stern and Rothlin, 1920, Rothlin, 1920). Zuelzer, 1908, 1912, introduced an acid extract, "*Hormonal*," to be injected against intestinal paresis; but its effects were uncertain and sometimes dangerous, even fatal (Seifert, Nebenwirk., 1915, p. 138; Burianek, 1913; Hesse, 1913).

SECRETIN

Pawlow showed that the presence of acid chyme in the duodenum is the normal stimulus to the secretion of pancreatic juice. It was later shown that this is not due to a nervous reflex, but to the production of a peculiar substance "secretin," which may be prepared artificially by macerating the duodenal or jejunal mucosa with dilute acids, soaps, etc. (Bayliss and Starling, 1902); or by contact of these or of irritants with the living mucosa. Secretin does not exist as such in the mucosa, but is formed from an insoluble "prosecretin." Secretin is identified by causing a marked flow of normal pancreatic juice, when the neutralized and boiled filtrate is injected intravenously. (An extensive review of secretin is given by Carlson, Lebensohn and Pearlman, 1916).

Nature and Properties.—Secretin is soluble in water and dilute alcohol (70 per cent.); insoluble in absolute alcohol, ether, etc. It is fairly readily destroyed by acids, alkalies or oxidation; and by the digestive ferments (Carlson *et al.*, 1916). It has not been isolated pure; none of the known constituents of the extracts produce the characteristic effect. Barger believes that it is probably an organic base.

Actions.—Intravenous injection of secretin stimulates the flow of pancreatic juice, bile (Downs and Eddy, 1919) and succus entericus, but not of the other digestive secretions; nor do extracts of other portions than the small intestines produce the secretory effect. The secretion is accompanied by, but not caused by, vasodilation. The pancreas is not readily fatigued, the flow being undiminished after eight hours of continuous injection. Similarly, repeated injections of equal doses give an identical response. The flow is not affected by anesthesia.

Clinical Inefficiency.—Secretin was tried in diabetes and in digestive disorders, but without convincing results. This failure would be expected from the scientific data. In the first place, it has not been shown that prosecretin is deficient in any clinical condition; secondly, the oral administration, even of enormous doses, is quite ineffective, since secretin is rapidly destroyed by the digestive juices (Carlson). Even the hypodermic administration is inactive (Matuso, 1913; Hallion, 1912). Finally, the commercial preparations do not contain secretin, presumably because it is too unstable (Carlson).

Gastrin.—Extracts of the gastric mucosa also contain a substance that stimulates gastric and other secretion. The chemical behavior of purified extracts resembles histamine, although there are differences that indicate that they contain some other basic imidazol derivative (Keeton *et al.*, 1920; F. C. Wood *et al.*, 1920).

Choroid Extract.—This produces a specific increase in the flow of cerebrospinal fluid (Dixon and Halliburton, 1914).

LIVER EXTRACT

The intravenous injection of saline extracts of liver produces a fairly persistent fall in blood pressure (James, Laughton and Macallum, 1925), presumably analogous to that

produced by extracts of other tissues. The liver-extract has been tried clinically in hypertension, and lowered the systolic and diastolic pressure; but about a fourth of the patients showed "reactions" of varying degree, and of the usual anaphylactoid type (MacDonald, 1923). A purified extract which does not give chemical protein reactions has been prepared by James, Laughton and Macallum, 1925; but it must be remembered that anaphylactoid phenomena are produced by non-protein colloids, and it seems rather improbable that the fall in pressure could be secured without some danger of other concomitants. R. H. Major, 1925, found liver extract effective, intravenously, against experimental guanidine hypertension.

Heparin.—This name was applied by Howell and Holt, 1918, to another purified liver extractive, which prevents the coagulation of blood, when added in the proportion of 1 mg. per 40 c.c. or injected into a vein: 200 mg. rendered the blood of an 11 kg. dog non-coagulable during 24 hours; in man, 100 mg. prolonged the coagulation time to three times the original, returning gradually to normal in about 2 hours (Hartman and Mason, 1924). The diminished coagulability of the blood does not materially prolong the duration of hemorrhage (Hartman and Mason, 1924); presumably because the thromboplastic action of the tissues is stronger. The intravenous injection has no effect on the blood-pressure and respiration, provided the heparin is adequately purified, otherwise there may be violent reactions.

The anticoagulant action is attributed to the formation of antithrombin in the blood. This is present in normal circulating blood, but in the shed blood it is overcome by the addition of coagulant phosphatide material from the corpuscles or tissues. The antithrombin concentration of the blood is greatly increased by the injection of peptone, and this is probably the mechanism of the anticoagulant action of peptone injection (Howell, 1925).

HIRUDIN

The cervical glands of the common leech (*Hirudo*) secrete a substance (hirudin, hemophilin) which delays or hinders the coagulation of blood inside and outside of the body. This substance is not destroyed by boiling or by alcohol. It appears to be a deuteroalbumose.

Therapeutic Use.—Leeches were at one time used extensively for the abstraction of blood in local inflammations. Dry or wet cupping is now usually substituted, but they are still employed occasionally; two to four of the animals are applied. The skin should be well cleansed, and, if necessary, a little milk should be rubbed on to tempt the animals to bite. They should not be removed, but allowed to fall off. They can not, of course, be used again. Each leech draws from 5 to 7 c.c. of blood. The quantity may be somewhat increased by applying hot fomentations after removing the animals. It is sometimes difficult to stop the bleeding.

For experimental use, an extract may be prepared, when needed, by crushing the leech-heads with sand, macerating with saline for two hours, and centrifugalizing. Each kilogram of animal requires the heads of three leeches, extracted with 3 c.c. of normal saline. The solution loses activity on standing, more slowly in the cold.

Immunization.—Daily intravenous injection of hirudin into mice creates an anticoagulant substance, effective *in vivo* and *in vitro*, destroyed at 65°C. It also inactivates fluorides, but not the calcium-precipitants. The mechanism of its action has not yet been explained (Vera and Leo Loeb, 1914).

Vessels.—Hirudin dilates these, in frogs, and renders them less sensitive to epinephrine (Kahn, 1912; Trendelenburg, 1915).

Toxic Effects.—Fresh preparations may be injected intravenously in sufficient quantity to render the blood non-coagulable, without damage to the animal. Some commercial samples of hirudin, however, are highly toxic, especially to dogs, probably through the presence of putrefactive bases. The symptoms from 20 to 25 mg. per kilogram in dogs consisted in severe bloody diarrhea and continued vomiting, with hemorrhagic lesions of the viscera (Marshall, 1915).

Engelmann, 1911, injected 0.3 Gm. into a number of eclamptic patients intravenously with and without toxic symptoms. Small quantities were also used in the transfusion method of Satterlee and Hooker, 1914.

KEPHALIN AND THROMBOPLASTIC TISSUE EXTRACTS

Mechanism of Action.—The addition of the phosphatide lipid kephalin to shed blood materially hastens its coagulation. Howell attributes this to the neutralization of a hypothetical "antithrombin" which is supposed to prevent the activation of prothrombin by calcium, *i.e.*, the formation of the fibrin-ferment or "thrombin," which

transforms the soluble fibrinogen of the blood into insoluble fibrin. In normal coagulation the kephalin is supplied to the blood in the form of "thromboplastin" by the disintegration of blood cells, blood platelets and the injured tissue cells over which the blood has flown. According to this view, thromboplastin (or thrombokinase, or zymoplastic substance) consists essentially of an impure kephalin or kephalin-protein compounds (Howell, 1912). There are several other explanations of the phenomena, but Howell's is at least one of the simplest and most useful of the working hypotheses.

Occurrence.—Kephalin is closely related to lecithin, differing only by a methyl group (Koch and Woods, 1905); but lecithin does not hasten coagulation. Kephalin is widely distributed in the body, so that coagulant extracts can be prepared from all tissues. It is especially abundant in the brain, and "thromboplastins" are generally prepared from that source. Mills believes that the kephalin of other organs is combined with protein into more active "tissue-fibrinogen." Such extracts, for instance from fresh lungs, produce intravascular coagulation when injected into the blood stream (Fischl, 1916; Mills, 1919), while kephalin does not produce this effect.

Therapeutic Uses.—Kephalin and brain extracts have been tried as local hemostatics, but are useless, since traumatized tissues evidently furnish more than enough thromboplastin. Hemophilia might be a more promising field, but so far the results have been doubtful (Hurwitz and Lucas, 1916); the same applies to purpura; Hanzlik, 1918, found lung extract unreliable as a hemostatic.

Properties.—The preparation of kephalin is based on its solubility in ether, and its insolubility in alcohol and in acetone. It gradually deteriorates and becomes inactive. Extracts from dried tissues are also inactive. Kephalin is easily prepared in impure form from fresh brain by the use of these solvents, by the method of Hirschfelder, 1915. It may be emulsified by adding the ethereal solution to normal saline; or it may be extracted directly by saline ("Thromboplastin-solution"), Hess, 1916. The preparation of these extracts is described with a sufficient detail in "New and Non-official Remedies," as also the method of testing their activity.

Systemic Phenomena.—Brain extracts produce anaphylactoid phenomena on injection, and agglutination of red corpuscles *in vitro*; but pure kephalin lacks these effects (Karsner and Hanzlik, 1920).

Extracts from fresh lung kill promptly by intravascular coagulation (P. Morse, 1920). Kakinuma, 1919, claimed that the toxicity is destroyed by the addition of glucose. Extracts of dried lung are not coagulant, and produce the usual tissue-extract reactions, a fall of blood pressure and bronchial constriction (Mills, Reap and Jackson, 1921).

NORMAL SERUM

In the process of clotting and by changes in the formed elements, serum acquires the property of stimulating smooth muscle. It also provokes other anaphylactoid reactions, and may cause true anaphylaxis.

Blood-serum contains the elements required in the clotting of blood. Its injection sometimes appears to be effective in controlling persistent bleeding, for instance, in hemophilia, severe anemias, purpura, etc. (Bienwald, 1897; Weil, 1907). The results, however, are inconstant. There are the same after-effects and dangers as with antitoxic sera; and these dangers must be taken more seriously, since the benefits are more problematical.

Administration as Hemostatic.—Normal horse serum is injected hypodermically, 10 to 20 c.c.; the results are said to appear in twelve to twenty-four hours and last one to three months (Richardson, 1908). The intravenous injection of *human serum* or still better, of human blood, is often more effective (vide, Ottenberg and Libman, 1915). In hemophilia, it increases the prothrombin (Addis, 1916). Trember, 1910, attributes the effects to leucocytosis.

Smooth Muscle.—This is stimulated (Schultz, 1912), similar to peptone or histamine, but there are specific differences (Dale, 1913). The proteins of the serum constrict the blood-vessels, but do not act on the stomach, intestines and uterus: alcohol-extracts of serum dilate the vessels and tend to increase the activity of the intestines and uterus (Clark, 1921).

A specific *constrictor substance* is formed in shed blood, probably by changes in the formed elements rather than by clotting (G. N. Stewart and Zucker, 1913). Janeway, Richardson and Park, 1918, find that the vasoconstrictor principle is derived from the breaking up of the blood-platelets. It is not a protein, but a water-soluble crystalloid. This liberation is favored by heat or standing of the blood (Baraden, 1916). The vasoconstriction may play a part in hemostasis.

The principle which stimulates the *intestine* and *uterus* preëxists.

With *perfused hearts* (rabbits), Cushny and Gunn, 1913, find that the addition of serum produces a preliminary stimulation, with stronger and usually faster contractions; and subsequent depression with weakened and slowed contractions, sometimes heart-block, and eventually arrest. The coronary vessels are constricted. Similar effects are produced by the plasma of the operated animal, by starch solution, etc. The authors attribute them to an alteration in the heart produced by excision, and not to the formation of any poison.

The coronary vasoconstriction has been confirmed by Yanagawa, 1916. Of a considerable series of colloids tried, this effect was produced only by serum and by egg-white. It resides in the proteins.

Manwaring, Meinhard and Denhart, 1916, find that the addition of 7 to 10 per cent. of goat serum in perfusion of rabbit's heart produces tachycardia, followed by depression and irregularity. The tachycardia is due exclusively to diffusible substances in the serum; the depression to non-diffusible.

Antagonism to Muscarine.—Serum enhances the antagonistic action of atropine to muscarine, on the frog's heart. This is due to the alcohol-soluble extractives (Kirste, 1921). According to Straub, 1922, this atropine-synergism is absent from the normal circulating human blood, but may appear in pregnancy, or with a high protein metabolism. Confirmation must be awaited.

ALLERGIC PHENOMENA

Although allergy is usually assigned to the subject of immunology, its reactions are distinctly pharmacologic; and they may be better grasped if they are envisaged also from the latter point of view.

The allergic phenomena present a complex of effects essentially identical with those of histamine and peptone, *i.e.*, stimulation of smooth muscle, and especially bronchial constriction; paralysis of the capillaries with fall of blood pressure and edematous infiltration; hemagglutination; and their secondary consequences. The resemblance is so strong, that it points to the fundamental identity of these processes, the differences consisting essentially in the conditions that evoke the effects, rather than in the effects themselves.

The allergic phenomena may be grouped as true anaphylaxis; serum disease; spontaneous hypersusceptibility (food proteins, pollen and bacterial proteins, drug idiosyncrasies); traumatic shock, burns, neurotic edemas; and the anaphylactoid reactions to intravenous injections of colloids, colloidal precipitants, and probably every kind of solution. It is very evident that these agencies differ very widely in their chemical properties and reactions; and that the allergic effects are quite different from the ordinary actions which these same substances produce by other methods of administration, or in the absence of hypersusceptibility. The allergic reactions therefore seem to depend on something more widespread and less specialized and more fundamental than the distinctive chemical properties. They appear analogous rather to the phenomena of coagulation of protein, which also can be produced by a variety of chemical, physical and mechanical agencies. It is not improbable that the analogy extends further; and that the allergic phenomena result from a disturbance of the equilibrium of the colloids, presumably in the direction of a partial

condensation, which would tend to alter the surface tensions, and to diminish the permeability of cell-surfaces, and thus lead to changes in the distribution of water, solutes, and energy. The degree, the rapidity, even the distribution of these changes, and their secondary consequences, would necessarily vary somewhat, and would therefore account for the differences that relieve the basic uniformity of the allergic reactions.

This attractive theory can furnish a plausible explanation for practically all the allergic phenomena; but it has not yet been established by adequate evidence. On the other hand, the differences that exist, according to the conditions that bring about the reactions, are of so much practical importance, that it appears advisable to arrange the details under these conditions. An extensive bibliography of allergic phenomena of pharmacologic importance is given by Hanzlik, 1924.

TRUE ANAPHYLAXIS

Parenteral injection of native proteins sensitizes animals specifically, after an incubation period, so that they react violently to a further injection of the same protein; and the excised tissues of such animals are also specifically hypersensitive to the sensitizing protein. If the animal recovers from the attack, it is desensitized, *i.e.*, it ceases to respond to further injections. This protection (antianaphylaxis or anergy) is lost in time; as is also the susceptibility of the sensitized animals.

The characteristics of true anaphylaxis consist in its dependence on specific sensitization, with an incubation period; in the sensitization of excised tissues; and in the relative violence of the reactions.

Historical.—Anaphylactic phenomena were described by Magendie as early as 1839, and rediscovered by Behring, 1892; Richet (who coined the name); Theobald Smith, 1903; and Pirquet, 1905 ("allergy"). Their modern investigation dates from Otto, 1905; and Rosenau and Anderson, 1906. Anderson and Rosenau, 1908, give an extensive summary of the earlier literature. More recent compilations are those of Hektoen, 1912; Dixon, 1913; H.G. Wells, 1921; Doerr, 1922.

Production of Anaphylaxis.—This results from the parenteral introduction of all "antigens"; *i.e.*, all true proteins; but not from their cleavage products, proteoses, leucine, etc. (Gay, 1913); nor from gelatin; nor from lipoids, etc.

Artificial polypeptids (to, heptaglycylglycin) do not produce anaphylaxis (Abderhalden and Weil, 1920).

It is necessary to distinguish between the first or "sensitizing" and the later or "provocative" injections. Sensitization occurs with very small doses (as little as 0.000,05 mg. of egg-white) intravenously or hypodermically, and exceptionally even by stomach or large intestine; or through the nose (Sewall, 1914). A minimum interval of six to ten days elapses before the sensitiveness is acquired; but then it persists for a long time, weeks or years. Repeated injections during the incubation period may produce immunity.

The maximum degree of sensitization is practically independent of the dose of the sensitizing injection; but curiously, the maximum is reached more rapidly with small than with large injections; for instance, for guinea pigs with 0.004 c.c. than with 0.1 c.c. of horse serum (O. Thomsen, 1917). Injection of the serum of sensitized animals confers *passive sensitization* on the recipient (Otto); immediately, with proper dosage (Doerr and Russ).

There is the same specificity as with other antigens. Specific sensitization may thus be secured simultaneously to several proteins. Wells and Osborne, 1911 and 1913, have studied particularly the specificity for pure proteins. They believe that the specificity is due to certain constituent groups within the protein molecule; but that the whole molecule is involved in the reaction.

Chemically similar proteins from the seeds of different genera react anaphylactically with others, while chemically dissimilar proteins from the same seed often fail to do so (H. G. Wells, and Osborne, 1916).

The **provocative injection** must be considerably larger than the sensitizing injection. It is much more effective by vein. The response is immediate. If an animal recovers from the toxic effects, it becomes immediately refractory or immune to further injection, because the anaphylactic antibodies are saturated or exhausted (Weil and Coca, 1913). This *antianaphylaxis* (anergy) persists for a time, but is eventually lost. The animal again becomes hypersensitive, and this hypersusceptibility may last for years.

Desensitization consists in inducing antianaphylaxis by the injection of doses so small that they do not provoke shock. Insusceptibility also occurs if the injections are repeated at intervals of two or three days before the sensitization has developed. This so-called *refractory state* may persist for long periods.

Symptoms of Anaphylactic Reaction.—These are mainly as follows: Great restlessness; severe fall of blood pressure and consequent shock; fall of temperature (Pfeiffer and Mita, 1910), etc.; rigidity of the lungs by violent contraction of the bronchial muscles, resulting in respiratory distress and asphyxial convulsions; stimulation of other smooth muscle (uterus, stomach and intestines); diminished coagulability of the blood (Weil, 1917; Bulger, 1918); increased concentration of the blood, appearance of nucleated reds, and changes in the leucocyte ratio (Richet *et al.*, 1919); leucopenia; eosinophilia; loss of complement; increased lymph flow (Calvary, 1911); local inflammatory reaction.

Repeated anaphylactic shock results in cell destruction in several organs, with subsequent chronic inflammatory changes. In the liver, the results resemble portal cirrhosis (Longcope, 1913).

Analogous but less severe *parenchymatous degenerations* of the myocardium, liver and kidneys may occur in rabbits, after a *single injection* of a large dose of horse serum or egg-albumen. They develop in ten to twenty-one days, about the time when the antibodies are produced (Longcope, 1915, 1921).

Susceptibility.—*Guinea pigs* are especially susceptible, and in them the lung rigidity is most prominent, arresting respiration and producing asphyxial death in a few minutes (Auer and Lewis, 1909).

In *dogs* and *rabbits* this phenomenon is much less marked, the severe and prolonged fall of blood pressure being the most prominent feature. However, death may occur by bronchial constriction (Pelz and Jackson, 1918). *Cats* are intermediate (Edmunds, 1914).

Man seems to be relatively insusceptible. The rare acute accidents in the injection of antitoxic sera, serum-disease, and some varieties of asthma and hay fever (Meltzer, 1910) are probably anaphylactic manifestations.

Lung Rigidity.—Auer and Lewis, 1909, showed that in guinea pigs dying acutely of anaphylaxis the lungs are rigidly distended and incollapsible even after death, by tetanic contraction of the bronchial muscles. The effect occurs after destruction of the central nervous system and even after degeneration of the vagi, so that it must be exerted directly on the muscle fiber or myoneural junction (Auer, 1910). It is abolished by atrophine (Auer). Chloral is uncertain (Rosenau and Anderson, 1909). Schultz and Jordan, 1911, showed that the severity of the bronchial phenomena in guinea pigs is explained by their relatively thick mucosa; so that the contraction occludes absolutely even the larger bronchi.

In dogs, the fatal broncho-constriction is not prevented by atropine. Epinephrine is effective and may save the animal if it has time to act before the asphyxia has gone too far (Pelz and Jackson, 1918).

The isolated perfused lung of guinea pigs may react to anaphylaxis by bronchial spasm, or sometimes by vascular spasm. The condition may also be simulated by plugging of the pulmonary vessels by thrombi or agglutinated corpuscles (Manwaring and Crowe, 1917).

Coca, 1910, finds the pulmonary circulation unobstructed in guinea pigs; but with rabbits dying acutely from anaphylaxis the pulmonary circulation is almost impermeable to saline, even under pressure several times greater than exists in the pulmonary

artery during life. The arrest of the pulmonary circulation would be the immediate cause of death.

Coca considers that the obstruction is due to vascular spasm, more probably than to thrombosis; but the evidence is not conclusive.

Blood Pressure.—In guinea pigs, the circulatory changes are mainly asphyxial (Auer and Lewis, 1910). In other animals, there is a characteristic fall of blood pressure, often to 20 to 30 mm. Hg. The mechanism of this "anaphylactic shock" has not been conclusively demonstrated but is presumably the same as with the analogous histamine fall, *i.e.*, direct relaxation of the capillaries. The blood accumulates mainly in the large veins, especially of the liver and portal system; so that the smaller vessels of the kidneys, intestines, and other parts of the body are mechanically drained (Pearce and Eisenbrey, 1910 and 1912; Edmunds, 1913); indeed, the fall does not occur if the liver has been excluded from the circulation. The liver therefore has a predominant share, directly or indirectly, in the fall, the blood pressure being lowered because a greater part of the blood stagnates in the portal system.

The vasomotor center is not directly involved in the fall; nor is there any good evidence of a peripheral action on the arterioles or veins. These continue to contract to epinephrine or barium; they do not contract to splanchnic stimulation, but this could be explained simply by the altered distribution of the blood.

The older views as to the mechanism of the fall are unsatisfactory. Biedl and Kraus, 1909, assumed vasomotor paralysis; Mautner and Pick, 1915, 1922, suggested contraction of the smaller portal vessels, interfering with the return of blood to the heart. R. Weil, 1916, attributed the fall to portal obstruction by acute injury to the hepatic cells, similar to phosphorus poisoning. Airila, 1914, attributed the fall in rabbits to increased resistance of the pulmonary vessels; but Edmunds, 1914, found no evidence of deficient blood supply of the left heart in cats; to the contrary, the pressure in the pulmonary veins often rose. v. Behring, 1914, attributes the shock to clumping of the platelets and thrombosis of the cerebral vessels.

It seems evident that the acute blood-pressure "shock" may involve different mechanisms to a varying degree, according to conditions. In the acute shock produced by intravenous injection of foreign antisera, the splanchnic organs and liver appear to play an insignificant role (J. Forssman, 1920).

Cardiac Disturbances.—The heart suffers by the low blood pressure, and is also affected directly, although this usually plays a minor part in the "shock." The changes are peripheral. As shown by electrocardiograms, on rabbits and dogs, they consist in disturbances of conduction and abnormalities of ventricular contraction, affecting especially the right heart. These may progress to final rigor (Robinson and Auer, 1913; Auer and Robinson, 1913). The heart-muscle and diaphragm show histologic changes; also with other anaphylactoid agents (Kundratitz, 1913). The isolated heart of sensitized animals is directly poisoned by the antigen (Cesaris-Demel, 1910-1912). Acute heart failure is also sometimes seen in intact cats (Edmunds, 1914).

Physical Changes in Plasma.—The following have been described: flocculation of the plasma colloids; lowering of surface tension of serum; increase of refractometric index of plasma. Flocculation has also been demonstrated *in vitro* by incubation of the serum of a sensitized animal with an antigen (Opie, 1923).

Local Hypersensitivity.—The anaphylactic state appears to increase the susceptibility to non-specific irritants. When xylene (1 c.c.) is rubbed on the ear of normal rabbits, it is merely rubefacient; but when the animals have been injected with sub-symptomatic doses of an antigen (sensitizing and provocative), xylene produces vesication and eschar (Auer, 1920). Auer suggests that the xylene produces an exudation that contains free antigen from the provocative injection; and that this reacts with the tissues sensitized by the first injection.

Share of Tissues in Anaphylaxis.—Anaphylactic sensitization is manifested mainly in the tissues, rather than in the circulating blood. This is shown by the transfusion experiments of Pearce and Eisenbrey, 1910, who found that a sensitized dog transfused with normal blood exhibits immediate anaphylactic shock when the antigen is injected; whereas a non-sensitized dog transfused with sensitized blood shows no immediate effect when the antigen is injected. It is also proven by the fact that excised and blood-free organs of sensitized animals exhibit a high specific response to the sensitizing protein.

Response of Excised Sensitized Tissue.—Schultz, 1910, first showed that washed smooth muscle of sensitized animals reacts specifically to the sensitizing protein. Foreign serums generally stimulate the smooth muscle of normal (non-sensitized) animals; but the muscles of sensitized animals respond to very much smaller doses of the sensitizing serum, whilst their reaction to other serums remains unchanged.

The further experiments of Dale, 1913, showed that the excised uterus of sensitized guinea pigs is contracted by extreme dilutions of the specific antigen; the production of the hypothetical toxic substance must therefore occur directly in the sensitized tissue. The response is almost immediate, so that the hypothetical cleavage, if such occurs, must be immediate, and not by ordinary ferment action.

In guinea pigs, which have been rendered immune (desensitized) by repeated injections, the excised uterus is still sensitive to the antigen. This form of antianaphylaxis must therefore be due to an inhibiting substance in the blood of the immune animal.

However, in the excised uterus, one dose of the antigen desensitizes the uterus to further doses (but not to normal serum). The antigen therefore destroys the hypersusceptibility of the sensitized muscles (perhaps by saturating the receptors). The persistence of the normal reaction to normal serum is a further proof that this is quite distinct from the anaphylactic response.

Prolonged contact with serum of a sensitive animal again renders the uterus sensitive (passive sensitization); but a normal uterus can not be passively sensitized.

Weil, 1914 and 1916, confirmed the results of Schultz and Dale.

W. H. Moore, 1915, found that the susceptibility of the sensitized uterus is increased if all blood has been removed by transfusion with Locke's solution; indicating that the blood has an inhibiting influence.

If the muscle is further freed from tissue lymph and other diffusible elements by repeated centrifugation in Locke's solution, the sensitiveness is greatly decreased; the sensitiveness being quantitatively restored if these muscles are treated with normal guinea-pig serum. This indicates that some constituent of normal serum is essential to anaphylactic stimulation.

Manwaring, Meinhard and Denhart, 1916, observed that the isolated rabbit heart is poisoned by goat serum. If the rabbit had previously been sensitized to the serum, the heart is more resistant. On the other hand, the addition of the serum of a sensitized rabbit to the goat serum increases the toxicity.

Direct reactions of the tissue with the antigen have also been observed in the liver (Weil, 1917) and lungs (Manwaring and Crowe, 1917).

Relation of Anaphylaxis and Immunity Reactions.—The relation of anaphylaxis to other "immunity" reactions indicates identity of the underlying process; anaphylaxis being merely a special manifestation of the defensive mechanism against foreign proteins. It refers simply to those phenomena of the "immunity reactions" which happen to be injurious to the animal. As with the other immunity reactions, it involves the reaction of the antigen with its antibody, under proper conditions; so that the antigen is rendered amenable to the action of the complement (alexin), leucocytes, etc.

Anaphylatoxin.—In the case of anaphylaxis the product of this reaction is poisonous, and is therefore called "anaphylatoxin." This need not necessarily represent a special chemical substance; for the toxic properties may be merely physical ("flocculation"). The term anaphylatoxin will be used in this wider sense.

An "antigen" is any substance that induces the formation of a specific antibody. "Antibodies" are the specific substances produced by the organisms under the influence of antigens. They are supposed to act as amboceptors; *i.e.*, by linking the antigen to the complement. The "complement" is an unknown substance (or substances), normally present in the blood, and which acts on the antigen-antibody combination.

R. Weil, 1916, proposes the term "sensitizin" in place of "anaphylactic antibody." Ordinarily, the sensitizin is identical with the precipitin; but heat may deprive it of part of its precipitating power without loss of sensitizing value.

Production of Anaphylatoxin.—Since a sensitizing injection and a following incubation period are necessary to anaphylaxis, it is evident that a definite change must occur in the body before the anaphylatoxin is formed or can become effective. Several possible explanations of this are tenable.

Nature of Anaphylatoxin. The similarity of the anaphylactic phenomena indicates that whatever the nature of the antigen, the resulting poison (the "anaphylatoxin")

of Friedberger, 1910; "proteotoxin" of Zinsser; "serotoxin" of Jobling and Peterson, 1914), is probably identical or closely related. The process has been conceived as a production of toxic protein cleavage products, through "defensive ferments." No such products, however, have been isolated. It is more probable that the phenomena depend on altered physical properties (surface tension) of the ordinary plasma protein; and it is also conceivable that the change is in the reactivity of the tissues themselves to the antigen.

Protein Cleavage Theory.—This has been generally abandoned. It was based partly on the similar symptomatology of anaphylactic and peptone shock (Biedl and Kraus); partly on the presence of specific proteolytic "defensive ferments" in the blood (Zuntz, 1912). Neither evidence is conclusive. General stimulation of smooth muscle is produced by many dissimilar poisons, so that the symptomatology is not a safe criterion of identity. On the other hand, the defensive ferments do not seem to be concerned, for they are present in the blood on the second and third day after the sensitizing injection, when the provocative injection is still quite ineffective (Abderhalden, 1912).

Furthermore, no increase of cleavage products has been actually demonstrated, *f.i.*, in the anaphylactic lung (Auer and Van Slyke). Again, the reaction of excised tissues of sensitized animals to antigen are more rapid than is customary in ferment processes (Dale, 1913). Neither of these facts actually disproves the cleavage theory; for the increase of the products might be too small to be demonstrable; and the conditions for ferment action in the tissues are probably much more favorable than in the test-tube (Dixon, 1913).

However, the toxification of proteins without cleavage, as described in the next paragraph, and the production of analogous phenomena by non-protein colloids, made the unproven assumption of protein-cleavage superfluous.

Toxification of Serum Proteins.—It has been observed that serum protein may be rendered toxic *in vitro*, either by antigen (Friedberger, 1910); or by non-specific means, especially by contact with certain colloids, especially agar (Keysser and Wassermann, 1911; Bordet, 1914; Novy and De Kruij, 1917). Novy assumed that the plasma contains a thermolabile protein matrix ("Taraxigen") which is liable to be modified by a variety of agents, non-specific as well as specific, into a toxic phase "Taraxin," probably without cleavage. He conceived this change to occur as a by-product of the interaction of antigen and antibody, and that it can also be produced by direct action of other colloids on the "Taraxigen." All these assumptions are hypothetical.

Non-specific Sensitization.—Thienes and Hanzlik, 1926, have found that the reactions of smooth muscle are greatly modified by previous treatment with a great variety of colloid or colloid-precipitants.

Site of Production of Anaphylatoxin.—Further considerations show that the direct formation of anaphylatoxin in the blood has really a minor share. In passive anaphylaxis, namely, the degree of reaction is usually quite small or even absent if the antigen and antibody are injected simultaneously, and when they would therefore seem to have the best chance of interacting in the blood; and that the severest reactions occur if the antigen is injected twelve to twenty-four hours after the antibodies—when, in fact, the antibodies have largely disappeared from the blood, and are presumably fixed in the tissues. This makes it probable that the reaction occurs more effectively in the tissues than in the blood. This is further supported by the observation, that blood-free organs of sensitized animals react with the specific antigen. It leads to the view that both in active and passive anaphylaxis, the antibodies are localized mainly in the cells (as "sessile receptors"); and that it is here that the interaction of antibody and antigen, and the formulation of anaphylatoxin mainly occurs (Friedberger). A part of the antibody, however, is given off to the blood, and some anaphylatoxin may therefore be liberated in the blood stream (Friedemann, 1909; Biedl and Kraus, 1910). Manwaring, 1910, and Voegtlin and Bernheim, 1911, and Weil, 1917, believe that the anaphylatoxin is produced mainly in the liver.

There is also direct evidence that the union of antibody and antigen is relatively slow in the blood stream; for they may exist there simultaneously and ununited, for days, combining slowly *in vitro* if the blood is removed. This suggests the presence in the blood stream of some inhibiting substance or conditions, such as are common in colloid reactions. For instance, it is known that antireactions are inhibited by excess of either antibody or antigen.

Working Hypothesis of Allergic Phenomena.—The schema adapted from the theories of Dale and of Lumière, arranges the salient phenomena into a logical concept. Although it has not been proven, it accounts in a

plausible and simple manner for numerous phenomena which are otherwise very confusing. It may thus serve a very useful purpose, so long as it is not in contradiction with well established facts; and provided that it does not stifle further inquiry. The essence of the hypothesis is, that all allergic phenomena depend on the formation of relatively impermeable colloidal precipitates in the cell surface. This occurs especially (a) if the cell-membrane contains precipitins; (b) if the colloidal equilibrium of the plasma is abnormally unstable; or (c) if the cell surface is similarly unstable.

The phenomena may be conceived in the following sequence:

(1) Sensitization produces precipitins which are present in the plasma and in the cell-walls.

(2) The precipitin in the cell-wall reacts with the antigen, producing a "floculation," *i.e.* a colloidal precipitation membrane on the surface or in the pores of the cell membrane. A similar membrane may be formed by the adsorption of an antigen-precipitin floculate from the plasma.

(3) This changes the surface tension and the permeability of the cell, and therefore its osmotic pressure, electric potential, etc.

(4) This results in stimulation.

(5) In accordance with the general tendency of colloidal precipitates, this floculation changes rapidly into a coarser-grained, discontinuous precipitate, which does not affect permeability, and consequently the cell rapidly recovers (if it was not killed during the impermeability).

(6) Similar floculation-precipitates and analogous effects may be produced by other substances that precipitate proteins (metallic salts, acid, colloids, tannin), that are precipitated by the plasma (barium, arsphenamine), or that are strongly adsorbed (peptone, bile, acids). Foculates that are produced in the plasma, or that are injected into the blood stream may also be adsorbed on the cell-surface.

(7) Serum, agar and other colloids which do not ordinarily floculate with the blood, may be rendered precipitable on the cell-surface, *i.e.* "toxified," by previous treatment with chemical or physical agents that render their colloidal state more labile, *i.e.* by "pre-floculation."

(8) A similar instability (the "colloido-clasis" of Widal) may be produced in the blood plasma or in the cells of the body. Quinine and most other specific drug-idiosyncrasies probably come under this heading.

(9) Cells may become hypersusceptible to all kinds of colloids, if either their membrane-proteins, or their surface potential, is altered so as to precipitate these colloids.

(10) If the precipitating agent is introduced more slowly, than the rate of concretion into the non-disturbing discrete precipitate, all the precipitable substance in the cell wall is used up without material change in the permeability, and therefore without noticeable effect. This explains desensitization, the refractory phase, and antianaphylaxis.

Treatment of Allergic Intoxications.—The hypodermic injection of epinephrine (1 mg., for man) tends to relieve the bronchial spasm and the edemic phenomena. If it fails, little else can be done, especially if the blood pressure has fallen to shock-level. The chief treatment should be prophylactic: the recognition of hyper-susceptibility by skin-tests; and if necessary and feasible, desensitization (see Serum-disease).

Treatment of Anaphylactic Shock.—The continued low blood pressure furnishes an opportunity for investigating the treatment; this is of practical importance because the phenomena are very similar to those of surgical shock. The indications are evidently to relieve the splanchnic congestion and to increase the volume of blood to the heart and medulla. Pearce and Eisenbrey, 1910, found that venous transfusion with blood or saline only increases the splanchnic congestion without aiding the heart or medulla. Arterial transfusion is more successful; but the best results are obtained by combining transfusion into an artery with bleeding from a vein. Cardiac or vascular stimulants alone did not produce permanent improvement; but the combination of slow epinephrine infusion with digitoxin gave good results.

J. P. Simonds, 1916, found but little pressor response to epinephrine in anaphylactic or peptone shock. Ephedrine also has only a limited success (Chen and Schmidt); pituitary is practically useless. Mautner and Pick, 1915, obtained good results from the vasodilator action of nitrites or caffeine.

ANAPHYLACTOID HYPERSENSITIVITY

This title covers a group of conditions formerly classed as "idiosyncrasies" or "dyscrasias;" the subjects of which respond to small quantities of special substances by more or less violent symptoms of the anaphylactic type, but occurring without antigen-sensitization. Accidental sensitization cannot be excluded in every case of protein-reactions; but the spontaneous reactions are generally distinctive, and many are produced by substances that are not antigens. The following conditions may be counted in this group: Asthma, hay-fever, serum disease, serum collapse, food idiosyncrasies, urticaria, erythema, eczema, angioneurotic edema, drug idiosyncrasies, "nitritoid" crises.

The subjects can be desensitized, locally or systemically, by graduated injections; but the desensitization is of short duration.

Reviews of these conditions are given by Longcope, 1920 (Nelson Loose Leaf Medicine).

Differences from Anaphylaxis.—The sensitivity is apparently largely *hereditary*; *i.e.*, there is generally a family history; but it may not become manifest until later in life. It is often not so narrowly circumscribed as true anaphylaxis, *i.e.* the patient is often hypersensitive to several factors; and one susceptibility may give way to another, from time to time. The serum does not contain specific antisubstances; nor can the susceptibility be transferred by injection of the serum.

Skin-tests of Hypersensitivity.—The human skin is highly sensitive to the capillary poisons and therefore furnishes a very useful index of allergic hypersensitivity. Its diagnostic importance in the eruptive fever rests on a similar basis. It is not improbable that this extensive sheet of epithelial cells and the related mucous membranes, play an important part in defense-reactions.

The specific responses of the skin to local inoculation are of two types; but the difference between them is probably mainly one of degree (Strickler, 1922). (a) The urticarial reactions produced by histamine, peptone, etc.; and by the substances to which the subject is hypersusceptible. They consist mainly in edema, with a little erythema and itching, all of short duration. (b) Those indicating the presence of an infective agent in the body; for instance the tuberculin tests. These are accompanied by cellular reactions and are therefore more or less persistent.

The skin-reactions are a reliable qualitative, but not quantitative, index of hypersusceptibility; *i.e.* the degree of the systemic reaction is not always proportional to the degree of the skin reaction (Caulfield, 1921). However, in the same individual, changes in susceptibility, for instance, by desensitization, are fairly paralleled by the skin-test. The skin may also be desensitized locally (Mackenzie and Baldwin, 1921); but not in the case of the non-specific urticarias of histamine, etc. (Sollmann).

SERUM REACTIONS

Allergic reactions are of very common occurrence in the therapeutic use of serums. They vary widely in type, in severity, in time of onset, and in frequency, depending on the susceptibility of the patients, the dose, the channel of administration, and the repetition of the injections. They fall in three distinct, although related groups, according to the mechanism of their production: (1) spontaneous hypersusceptibility with immediate reaction; (2) responses to repeated injections; and (3) serum-sickness, the normal delayed reaction to a single injection (*vide* Longcope, 1920, Nelson Loose Leaf Medicine).

Spontaneous Hypersusceptibility to Serum; Acute Serum Shock.—

Occasionally the first injection of serum produces a violent, generally fatal allergic reaction. The phenomena start very promptly, shortly after or even during the injection, with edema of the respiratory mucosae and presumably bronchial spasm, intense dyspnea, cyanosis, failure of the respiration, collapse, and asphyxial death within 10 to 20 minutes. This may occur with relatively small doses of any of the serums, crude or refined. Serious symptoms are recorded in something like 1:10,000 injections of antitoxic serums, death in 1:100,000 (Park, 1913). A history of previous allergic tendencies (asthma, hay-fever) can generally be elicited (for instance in two thirds of the thirty histories of serum death collected by Gillette, 1909). The spontaneous nature of the hypersusceptibility is also indicated by the fact that the reactions are much more violent than the usual responses of normal subjects to repeated injections.

Treatment.—Epinephrine, 1 mg. hypodermically, should be injected on the first appearance of the symptoms. The addition of atropine, 2 mg., is advisable. The prognosis is bad, and safety consists in the use of proper precautions *before* the serum is injected: inquiry for a history of allergic hypersensitivity (asthma, hay fever, food idiosyncrasies). An endermic test should be made if possible. If positive, desensitization should be attempted. In the absence of a skin test, it is advisable as a routine to inject 0.5 c.c. of the serum half an hour before the full dose. Atropine may be injected in advance, and epinephrine should always be ready.

Endermic Test.—This consists in the endermic injection of 0.02 to 0.1 c.c. of a 1:10 saline dilution of the serum, with a control injection of the same quantity of normal saline solution. Hypersusceptibility is shown by a definitely larger wheal, generally with pseudopodial spurs, and an erythematous areola. If these phenomena do not appear within half an hour, there need be no fear of dangerous reaction.

Desensitization.—The following scheme is adapted from MacKenzie, 1921: If hypodermic administration is contemplated, 0.025 c.c. of the serum (diluted if more convenient) is injected hypodermically; the injection is repeated every half hour, doubling the dose progressively at each injection (*i.e.* 0.05; 0.1, 0.2, c.c. etc.), until the full therapeutic dosage is reached.

For intravenous administration, the desensitization is begun hypodermically to the sixth dose (0.8 c.c.), then changed to the intravenous injection of 0.1 c.c., and this is doubled progressively every twenty minutes up to the full dosage.

If a reaction develops at any stage of the desensitization, it is necessary to start again with the next lower dose.

Very slow intravenous injection of diluted serum might perhaps avoid the occurrence of acute anaphylactic shock. Sensitized animals, at least, tolerate more than the ordinary fatal dose of the antigen when it is injected in that manner. (J. H. Lewis, 1919).

Reactions to Repeated Injections of Serum.—These correspond to true anaphylaxis. They vary according to the interval between the injections. If the second injection is given before the antibodies are present in the blood (generally about 10 days, but varying in the individual), the "refractory state" of anaphylaxis results; *i.e.* the outbreak of "serum disease" is postponed for about a week; and so on with repeated injections; although in the end the serum disease may develop, sometimes with apparently increased severity.

If the second injection is made after antibodies have been developed, *i.e.* after some ten days, it provokes a more prompt and more violent reaction than that of normal serum sickness, the degree depending doubtless on the quantity of antibodies present, and on the amount of antigen introduced at the second injection. The phenomena range from the accelerated development (2 to 4 days) of mild serum-sickness, to alarming, but rarely

fatal asthma and collapse immediately, or within 12 to 24 hours, (Pirquet and Schick, 1905). The anaphylactic hypersensitivity and the violence of the reaction decrease with time: severe immediate reactions occur in $\frac{2}{3}$ of large injections made within two months; after three months, there is generally only accelerated serum sickness; after a year, generally only normal serum sickness. The endermic test is apt to be positive for years.

Serum Sickness. *Phenomena.*—This constitutes the “normal serum reaction.” It sets in after incubation of usually 6 to 8 days, with swelling of the lymph-glands and moderate leucocytosis (later leucopenia); skin rashes, generally urticarial or erythematous, and local edemas, rise of temperature, malaise, gastrointestinal disturbance, headache and arthralgia, water and chloride retention (Rackemann et al., 1916), but without albuminuria; delayed blood coagulation (Shattuck, 1917). It is sometimes preceded by prodromal sensitiveness and slight redness of the skin at the site of the injection. The condition lasts from one to twenty days.

Mechanism.—The serum reaction appears to be due to the interaction of the antibody (precipitin) with the antigen that is still present in the organism; for the time of onset coincides with the appearance of the precipitin in the blood, and with the outbreak the remaining antigen suddenly disappears the blood (MacKenzie and Leake, 1921), after which the antibodies continue to increase (Longcope and Rackemann, 1916).

The occurrence and the intensity of the reaction would be proportional to the amount of undestroyed antigen available when the antibodies appear, and therefore to the quantity of serum originally injected; accordingly serum-sickness occurs in only 10 per cent. of the patients injected with 1 to 10 c.c. of serum; but with 75 per cent. to 100 per cent. of those injected with 90 c.c. or more. It is relatively less common with purified than with crude serums, and is more severe with the serums of animals other than the horse.

Treatment.—The urticaria can probably be diminished by epinephrine (1 mg., hypodermically).

Netter, 1906, claimed that the rashes are less frequent if calcium chloride is administered: 1 Gm. daily by mouth, on the day of injection and on the two following days; but this appears to have been abandoned as unsuccessful.

DRUG IDIOSYNCRASIES

A number of drug idiosyncrasies show such striking correspondence with the most distinctive characteristics of the protein idiosyncrasies (food poisoning) and with allergic reactions in general, as to suggest an intimate connection. The most distinctive relations are, *First*, the possibility of desensitization, which has been described for several of the reactions, but not for all. *Second*, the idiosyncrasy phenomena do not resemble the ordinary effects of the drug, but belong to the allergic type: urticaria and acute edema of the mucous membranes, asthma, skin eruptions and catarrh, collapse. *Third*, very small doses are effective. *Fourth*, the hypersusceptibility does not extend to the ordinary actions; for instance, idiosyncrasy to quinine or acetyl-salicylic acid does not increase their analgesic and antipyretic action.

The idiosyncrasy may be present on the first use of the drug, or it may develop later.

Drug idiosyncrasies may be arranged under the following types; some of these very probably do not belong to the "idiosyncrasy" class; but it seems impossible at present to draw a sharp line.

Type 1. *Urticarial* (skin or mucous membranes): Quinine; acetyl-salicylic acid; morphine, etc. Quinine and acetyl-salicylic acid can be desensitized.

Type 2. *Plant Dermatitis*: Primrose, Ivy etc. Desensitization reported.

Type 3. *Acquired susceptibility to Dermatitis*: Procaine?

Type 4. *Iodism and Bromism*: Variable susceptibility; depending probably on associated irritations.

Type 5. *Nitritoid Reactions*: Arsphenamine, usually after several injections: dyspnea, cyanosis, suffusion of face.

Type 6. *Sympathetic Collapse*: Cocaine group; epinephrine.

Type 7. *Retinitis*: Atoxyl; optochine; aspidium.

Type 8. *Hepatitis*: Chloroform; phosphorus, arsenic; aspidium.

"REACTIONS" TO INTRAVENOUS INJECTIONS

The physical conditions, and especially the colloid-equilibrium of the blood are disturbed by any sudden alterations in its composition, and consequently the intravenous injection of a considerable variety of substances produce anaphylactoid phenomena. Indeed it would be difficult to devise an intravenous injection that would be absolutely devoid of such effects. Even normal saline solution and transfused blood may produce some "reaction." The degree of disturbance and the violence of the symptoms varies greatly according to the nature of the substance, the speed of the injection and the susceptibility of the individual. Generally there is only a brief fall of blood pressure or "nitritoid reaction" or chill; but there may be violent asthma and asphyxial death. As it is not possible to predict the degree of reactions, all intravenous injections imply a risk, which should not be undertaken unless it is necessary. Even the milder reactions are undesirable side-effects that complicate the therapeutic actions, except in the relatively few instances when they are evoked intentionally.

Phenomena of Intravenous Reactions.—These have the common character of the histamine phenomena and differ from the ordinary pharmacologic actions of the substances, if these are otherwise active. They generally have little or no action on excised organs, which consorts with the view that the primary disturbance is in the colloidal condition of the blood. They occur without incubation and are not transferable. Hypersusceptibility plays a large part in some, a small part in others. The details of the effects vary with the agents and with conditions, but the difference is in degree more than in kind. The phenomena are described by Hanzlik, de Eds and Tainter, 1925; and the literature is reviewed by Hanzlik, 1924.

Symptoms in Man.—Those of the milder type bear a superficial resemblance to the response to nitrites, and have therefore been called "nitritoid crises;" although their mechanism is probably quite different. They consist in excitement and anxiety, flushing of the skin, sweating, precordial distress, tremors, cough and dyspnea; vertigo, headache, nausea, vomiting; chill and fever; joint pains. The serious cases rapidly develop intense asthma, cyanosis, fall of blood pressure, collapse and asphyxial death. The sudden deaths are more commonly caused by colloids and toxins, injected by vein, and sometimes even hypodermically. They are reviewed by Lamson, 1924. The phenomena in animals are essentially similar (Hanzlik, 1924).

Pulmonary Distention.—This is generally present in the fatal cases, at least in animals. Bronchial spasm, however, plays a minor share. More commonly the bronchial stenosis is the result of pressure from pulmonary or peribronchial edema, or from obstruction of the vessels by agglutinated corpuscles or platelets; and in the case of agar, by the coagulated colloid. The type of the bronchial obstruction is rather characteristic of each agent (Hanzlik and Karsner, 1920; Loewit, 1913).

Fall of Blood-pressure.—This may be due partly to capillary injury, as with histamine; but as edema is generally not very marked, it is probable that other factors are more important; especially the obstruction of the pulmonary circulation by the agglutination. It is conceivable, but not proven, that the heart muscle is also disturbed directly.

Blood Changes.—Agglutination of the corpuscles and especially of the platelets is a frequent condition; the carbohydrate colloids produce it even in vitro (Karsner and Hanzlik, 1920). The coagulability of the blood is generally diminished, and the surface tension is altered.

Causative Agents.—In principle the flocculation of colloids in the blood may result from any agent that tends either to precipitate the blood, or to be precipitated by the blood. The substances that have been reported to produce these effects may be grouped according to their physical characters;

1. *Colloidal Suspensions.*—Bacteria and other micro-organisms and vaccines, (including faulty distilled water), barium sulphate, camphors, carbon (india ink), fullers' earth, kaolin, oils, resins etc.

2. *Suspensoid Colloids.*—Colloidal metals and metal oxides, arsenic sulphide, dialyzed iron, gold, silver etc.

3. *Carbohydrate Emulsoid Colloids.*—Acacia, agar (gelose), pectin, starch, tragacanth etc.

4. *Proteins.*—All kinds more or less.

5. *Toxins.*

6. *Dyes of More or Less Colloidal Character.*—Congo red, gentian violet, mercurochrome etc.

7. *Precipitant Agents.*—Acids, formaldehyde, metallic salts, tannin etc.

8. *Precipitable Substances.*—Arsphenamine, especially acid; barium salts etc.

9. *Crystalloids.*—Bromides, iodides, and especially hypertonic solutions; Hexamethenamine, glucose, sodium chloride, sucrose etc.

NITRITES, NITROGLYCERIN, AND OTHER ALKYL NITRATES

The nitrites, the nitrous esters and the organic nitrates, which are reduced to nitrites in the body, lessen the tone of arterial muscle, thus producing a prompt fall of blood pressure. Their other effects are unimportant. They are used for relief of arterial spasm and other conditions of high blood pressure.

Members.—This group comprises the inorganic nitrites (NaNO_2); the nitrous esters (amyl nitrite, ethyl nitrite, "Sweet Spirits of Niter"); and substances which liberate the nitrite ion within the body. Most important amongst the latter is glycerin tri-nitrate (nitroglycerin or glonoin), which is easily broken up by alkalis into a mixture of nitrates and nitrites; a similar change occurs in the body. Erythrol tetranitrate and mannitol hexanitrate undergo analogous decompositions, but much more slowly. Even inorganic nitrates are reduced to a slight extent (Binz, 1901), especially by the putrefractive bacteria of the colon, and may then give rise to the phenomena of nitrite poisoning; but this requires very large doses such as the quantities of Bismuth Subnitrate used in Roentgen diagnosis.

Hydroxylamine (NH_2OH) is decomposed in the body into nitrite and ammonium. It produces the effects of both these substances (methemoglobin formation, convulsions, central paralysis, Lewin, 1889).

Differences in Activity.—It is generally assumed that the organic nitrates act only after being reduced to nitrites; but this is not proven. The fact that excised vessels react promptly to these nitrates suggests that they may perhaps act directly. It is also remarkable that the effective dose of nitroglycerin is but a hundredth of that of sodium nitrite. Presumably the organic esters penetrate more readily into the cells, and perhaps the reduction occurs only after their penetration or there may be certain peculiarities in the reduction. These may also explain individual differences of suscep-

tibility. C. R. Marshall, 1912, finds that the introduction of OH and CO₂H groups into organic nitrates diminishes their vasodilator action.

The nitrates of monohydric alcohols are less effective than the polyhydric, probably because of slower decomposition. Nitroglycerin and erythrol-tetranitrate act quantitatively alike when equimolecular doses are injected into a vein; by mouth the action of the erythrol ester is weaker and more prolonged, because it is much less soluble, and therefore more slowly absorbed (Marshall, 1913).

Reducing Properties of Tissue.—Many other substances are reduced in the tissues; such as methylene blue, arsenic acid; the oxides of tellurium and selenium; nitrobenzol into aniline; sulphur into hydrogen sulphide, etc. The change is not due to ferments (Heffter, 1907, 1908). The reducing power of different organs varies greatly. Many other substances are, of course, oxidized in the tissues, the processes of oxidation and reduction going hand in hand.

Actions on the Circulation.—The most important effect of the nitrites is a prompt fall of blood pressure, due to vasodilation by direct action on the blood vessels.

Course of the Vasodilation.—This is first noticed in the skin of the face, in an area similar to that involved in blushing, but which may extend over the entire trunk to the ilium. The *meningeal vessels* undergo dilation at the same time. There is consequently redness of the face, heat and throbbing in the head, and headache. The flushing of the skin is brief, but

FIG. 11.—Amyl nitrite on carotid pressure, dog. The nitrite is inhaled between the two vertical lines. The upper tracing is taken from a normal dog, the lower after atropine. The heart was quickened by the nitrite in the upper tracing, but not in the lower.

headache is apt to persist, especially with erythrol tetranitrate. The retinal vessels are also dilated.

When amyl nitrite is inhaled, there is generally at first some reflex (vagal) slowing of the heart. Very soon, however, the *heart is greatly quickened*, so much so that a rise of blood pressure is frequently observed at the start (Hewlett, 1906), the dilatation being more than overcome by the quickened beat.

The dilatation does not, however, remain confined to the skin, but spreads to other vessels, and relaxation of the splanchnic area in particular causes a *speedy fall of blood pressure* (Fig. 11) and a dicrotic pulse (Fig. 12). The fall of blood pressure is due entirely to the extensive vasodilation, produced by the direct action of the nitrite on the arterioles. The vasomotor center is not inhibited, but rather stimulated by the cerebral anemia (Pilcher and Sollmann, 1914). It is possible, however, that the preliminary blushing is a central effect.

Evidences of Vasodilation.—The fall of pressure occurs equally well when the cardiac changes are excluded by atropine. The vasodilation can be demonstrated directly by inspection (the blushing); by plethysmo-

graphic measurements (Dossin, 1911) and by the increased rate of vein flow.

Effects on Vein Flow and Vein Pressure.—Burton-Opitz and Wolf, 1910, on injecting nitrite into the femoral artery, found the vein flow and vein pressure increased in the corresponding leg, whilst the general arterial pressure was practically unchanged. If amyl nitrite was inhaled, the vein flow in the leg decreased with the blood pressure, because of the withdrawal of the blood into the more powerfully dilated splanchnic vessels. Capps, 1911-1913, also found a fall of vein pressure.

In man, Hewlett, 1913, found increase of the volume, but scarcely of the blood flow, of the arm. Stewart, 1915, showed a quite definite increase of the blood flow of the hand.

There are also definite changes in the "pulse-flow" (the flow during the cardiac cycle). These occur when therapeutic doses are given in arterial tension, even when the blood-pressure readings are not reduced (Hewlett, 1917).

Systolic and Diastolic Blood Pressure.—The relative preponderance of these indicates the mechanism of blood-pressure changes: If the greater change is in the *diastolic pressure*, the cause is in the vasomotor-tone or heart-rate. If the change is greater in the *systolic pressure*, the cause is in the cardiac force or blood-volume (Pilcher). With nitrite, therefore, the diastolic fall should be greater than the systolic, unless there is very marked increase of the heart-rate.

FIG. 12.—Amyl nitrite on sphygmogram: *a*, normal; *b*, after inhalation of four drops.

Site of the Dilator Action.—Vasodilation occurs after ligation of the blood vessels of the brain (Mayer and Friedrich, 1875); after destruction of the spinal cord (Lauder Brunton, 1869); in excised organs (Atkinson, 1888; Marshall, 1898, etc.); and even in excised arterial segments (Cow, 1911). The perfusion method shows that the vasomotor center is more commonly stimulated (see below). The dilator action must therefore be peripheral. Nitrites also relax other smooth muscle, without reference to their innervation. The action is therefore presumably directly on the contractile substance.

Antagonisms.—Nitrites are mutually antagonistic with most vascular constrictors; thus, splanchnic stimulation (Bernheim, 1874), epinephrine, strophanthin, etc., raise the blood pressure during the nitrite fall; and conversely, nitrites lessen the rise of these constrictor agencies. The result is essentially an algebraic addition of the two opposed actions.

The antagonism is quantitative; *f.i.*, sciatic stimulation gives the same millimeter rise during as before the nitrites; and nitrites give the same millimeter fall during as before strophanthin, hydrastinine, pituitary, strychnine or ergot. This suggests that the point of attack of the nitrites is different from that of the pressor agencies (Pilcher and Sollmann, 1915).

Cameron, 1906, proposed to utilize the antagonism for the bio-assay of epinephrine. He states that 0.6 mg. of nitroglycerin exactly neutralizes the pressor effect of 0.0075 mg. of epinephrine.

Capillaries.—These are dilated (microscopic observation) by the direct injection of undiluted amyl nitrite into the human skin (Carrier, 1922); but this may have been due to local irritation.

The Vasomotor Center.—This is not depressed, but rather stimulated by its anemia; the stimulation, however, can not overcome the peripheral depression. This is shown by the perfusion experiments of Pilcher and Sollmann, 1915. Similarly the blood pressure does not fall if a nitrite is introduced into the cerebral circulation, but prevented from reaching the systemic vessels. (Filehne, 1874, had concluded that the vasomotor center is depressed.)

The Pulmonary Circulation.—The pulmonary vessels are not so markedly dilated; indeed, Macht, 1914, found constriction in excised pulmonary arteries. The pressure in the pulmonary artery is generally slightly increased (Bradford and Dean, 1894; recent literature in Wiggers, 1911). The rise is probably due partly to the engorgement of the large veins.

Brain-volume.—In man (trephined), this is dilated by the inhalation of amyl nitrite (Raphael and Stanton, 1919).

The Coronary Vessels.—The outflow from the coronary veins is increased in intact animals (F. Meyer, 1912; Schloss, 1913) and in excised mammalian hearts (O. Loeb, 1903). The coronary vessels are therefore dilated (also excised arterial rings; Voegtlin and Macht, 1913); and the coronary circulation is improved. This explains the beneficial action in angina pectoris.

Intraocular Tension.—This is raised by amyl nitrite, even when the general blood pressure is lowered (Wessely, 1915). This enjoins caution when using nitrites in *glaucoma*. The *retinal vessels* are also dilated (Hirschfelder, 1915).

The Tachycardia.—This is due mainly to depression of the vagus center, for after section of the vagi, or after atropine, nitrites cause but little further acceleration (Mayer and Friedrich, 1875). The slight remaining quickening is abolished by dividing the accelerators (Dossin, 1911). The rate of the excised heart is not changed by nitrites (Plumier, 1905). The excitability of the vagus trunk to direct electric stimulation persists.

The depression of the vagus center is due to the fall of blood pressure, and not to a direct action of the nitrite, for no quickening occurs if the pressure is kept level by partial compression of the aorta (Filehne, 1879; Sollmann). The vagus center may still respond to strong reflex stimulation (Mayer and Friedrich).

In man, the acceleration on inhaling amyl nitrite is considerable, often to double. No acceleration occurs in complete *heart-block*. This has a diagnostic value, similar to atropine (Belloir and DuBos, 1913).

In experimental partial heart-block, the rate is still quickened by amyl nitrite (Fredericq, 1916).

Electrocardiograms.—When amyl nitrite is inhaled by intact dogs, there is at first a marked reflex increase of vagus tone, shown by slowing of the sinus-rate, exaggerated sinus arrhythmia, lengthened A-V time or A-V block, and a negative tendency of the P and T waves.

As the blood pressure falls, these changes are reversed. The vagus tone becomes depressed, the sinus-rate is quickened, the arrhythmia and block disappear, and A V time is shortened; the P and T waves become more positive.

These phenomena are not affected by previous digitalization; however, large doses of nitrite abolish the ectopic beats due to digitalis (Halsey, 1917).

Character of Pulse.—As the result of the quickening, *the excursions of the heart are smaller*. The blood-pressure waves appear particularly low, because the pressure wave is more readily dissipated, on account of the dilatation. The pulse, on the other hand, may be bounding and dicrotic, because the arteries are emptied more completely during diastole.

The heart-muscle shows no important direct change; however, the better coronary circulation and the lowered peripheral resistance may improve and relieve a weakened heart (MacNider, 1908).

The excised mammalian heart is scarcely affected by moderate doses, perhaps slightly stimulated, then depressed (Loeb, 1903; Plumier, 1905; Dossin, 1911).

The excised frog's heart may be quickened by low concentrations (1:10,000); higher concentrations weaken (1:5,000), or stop (1:1,000) the contraction.

Methemoglobinemia.—Excessive doses of nitrites form methemoglobin (Gamgee, 1868) and this causes cyanosis and asphyxia. However, since the blood corpuscles are not destroyed, the animals generally recover.

The methemoglobin formation by sodium nitrite, *in vitro*, is proportional to the hydrogen-ion concentration (C. R. Marshall).

Penetration of Red Blood Corpuscles.—These absorb nitrite ions, with removal of chloride ions. The entrance of the nitrite ions is retarded by certain anions (Rohonyi, 1916).

Respiration.—This is accelerated (Mayer and Friedrich), probably by the changes in the blood and circulation.

The Bronchial Muscles.—These are relaxed by nitrites (Doyon, 1906; excised, Titone, 1913; surviving lungs, Baehr and Pick, 1913). This may explain their *use in asthma*. The smoke of the "Charta Potassii Nitratis" (paper impregnated with salt-peter) probably owes a part of its effect to nitrite compounds.

Gall-bladder.—This is relaxed by nitrites (Lieb and McWhorter, 1915).

Intestinal Muscle.—Hirschfelder, 1915, finds that the systemic administration of nitrites relaxes the intestinal constriction produced by lead salts. It has been used clinically in lead colic, but with limited success.

Excised Ureter.—This is rapidly paralyzed (Macht, 1917).

Digestion.—Nitrites cause some slight interference with the digestive ferments (Hale, 1910); but probably not enough to be important. Sodium nitrite is supposed to produce some gastric irritation, by the liberation of nitrous acid—this is not sufficient to interfere with its therapeutic use.

Urine.—The variations produced in the secretion of urine appear to be purely secondary, and will depend upon whether the renal arterioles or those of the general circulation are relatively more dilated; the former causing an increase, the latter a diminution, of urine.

In patients with excessively high blood pressure, the nitrites generally increase, sometimes quite considerably, the excretion of urine, nitrogen, total solids and phenol-sulphonephthalein (Lawrence, 1912).

Pressure of the Cerebrospinal Fluid.—This is increased by amyl nitrites, presumably through the methemoglobin asphyxia (Dixon and Halliburton, 1913 and 1914).

Metabolism.—The effects have been studied by Surveyor, 1906.

Temperature.—The dilation of the skin vessels considerably increases the surface-temperature (as much as 3°C. in the blush-area, Lahnstein). There is a corresponding increase of heat loss, but this is easily compensated in normal individuals, at least for small doses, so that the normal temperature is not affected. In fever, however, there is a distinct antipyretic effect (Jacobj, 1913; Krauss, 1913). Ethyl Nitrite, as "Sweet Spirits of Niter," has been used popularly as a diaphoretic and diuretic. Its action is not very energetic. Large doses of nitrites also lower the normal temperature by depressing the circulation.

Fate.—Some 60 to 70 per cent. of the nitrites disappear in the body, their fate being unknown.

Rapidity and Duration of Action.—This constitutes the principal difference between the members of the group. Amyl nitrite; when inhaled, acts in ten to fifteen seconds, the action disappearing again within seven minutes. Glyceryl trinitrate, ethyl nitrite, and sodium nitrite act in two to ten minutes, the action persisting a half to two hours. With erythrol nitrate, the effects appear only after half an hour, and last five hours (Wallace and Ringer, 1909; E. Matthew, 1909; Rzenkowski, 1909; J. L. Miller, 1910).

The following table from Matthew shows in detail the average relation for oral administration in man. (The fall in diastolic pressure is about half of that in the systolic pressure; Lawrence, 1912.)

Drug	Dosage	Fall begins, minutes	Maximal fall reached	Maximum maintained	Return to normal	Extent ¹ of fall (mm. Hg.)
Spir. glyceryl nitratis.....	2-3 minims	1	5 minutes	2 minutes	½ hour	25-30
Sodium nitrite.....	2-3 grains	5	15 minutes	20 to 60 minutes	1-2 hours	32
Erythrol tetranitrate.....	½ to 1 grain	5	22 minutes	2 hours	5-6 hours	35
Mannitol hexanitrate.....	1 grain	15	2½-3 hours	3 hours	6 hours	35
Amyl nitrite by inhalation (Wallace and Ringer).....	3 minims	1	3 minutes		7 minutes	15

¹ Systolic blood pressure.

Influence of Dosage.—The extent of the fall increases with the dosage, the increase becoming progressively smaller. The duration of the action is not so much influenced by the dosage.

Influence of Pathologic Conditions; Individual Susceptibility; Untoward Effects.—The average effect is about the same in disease as in health. In cases of abnormally high blood pressure, the absolute fall may be greater, but the percentile fall and the duration are the same (Wallace and Ringer). In advanced cases, there may be very little fall, perhaps because the dilator action is automatically compensated by increased central tone. Arterial sclerosis also decreases the fall. Nervous and anxious patients may react with rise of pressure and tachycardia (O'Hare 1920; G. Richard, 1921), presumably due mainly to excitement. Others may react by marked cardiac slowing and alarming syncope, even after small doses. The severity of the headache is also variable. Other side actions which may occur are localized edema, excessive sweating, and visual disturbances (Cornwall, 1913). On the other hand, tolerance is sometimes quite marked.

Habituation.—This usually occurs more or less if the administration of nitroglycerin is continued, often in two or three days. The dosage must then be increased or the response disappears. Suspension of the administration for a few days may restore the susceptibility. Matthew claims that the tolerance is not acquired with sodium nitrite or erythrol tetranitrate.

Therapeutic Use in Arterial Hypertonus.—The nitrites are employed mainly for reducing the blood pressure in conditions of arterial hypertonus. The effect is not curative, but the symptomatic relief of the headache, etc., is usually marked, outlasting the blood-pressure effect of the single doses. However, they usually lose their efficiency after a short time. Increasing the dose generally produces unpleasant symptoms—headache, restlessness, sometimes dyspnea. They must therefore generally be alternated with venesection, sweating, nauseants, etc. The effect of these is usually less marked but more lasting (J. L. Miller, 1910; C. H. Lawrence, 1912). Nitroglycerin and sodium nitrite appear to be the most useful; the action of amyl nitrite being too brief, whilst erythrol tetranitrate often causes intense headache. Sodium nitrite is said to give least headache (Hewlett, 1912).

Administration and Dosage.—The dosage of the nitrites should be kept as low as possible, to prevent the rapid development of tolerance. It is best to give just enough to cause a slight quickening of the pulse, and feel-

ing of fulness in the head; or a fall of systolic pressure of about 30 mm. This dose may be given four times a day. The initial dose may be 0.5 mg. ($\frac{1}{100}$ gr.) of nitroglycerin, increasing gradually. The equivalent doses of the other nitrites are shown on the preceding page. The treatment may be intermitted for a few days in every two or three weeks, starting again with a smaller dose. Hypodermic injections are rarely needed, the drugs being readily absorbed.

Cardiac Insufficiency.—The relief of the heart from excessive resistance may render nitrites useful in these conditions. Nitroglycerin (1 mg.) is used, generally in combination with digitalis.

Angina Pectoris.—The inhalation of amyl nitrite was introduced by Lauder Brunton in 1867. In some cases (presumably with spasm of the coronary arteries) the relief is complete; in others, probably of different pathology, it is ineffective. One to 3 drops of the promptly acting amyl nitrite are inhaled. It may be carried in thin glass capsules, "pearls," one of which is crushed in a handkerchief, as needed.

Ingalls and Meeker, 1918, prefer a nitroglycerin tablet of $\frac{1}{100}$ gr. dissolved under the tongue. This generally acts in 1 to 3 minutes. If it fails, they repeat the dose every few minutes until relieved.

They found that sodium nitrite often disturbs the stomach after a few doses.

They believe that death in angina is generally due to vagus arrest of the heart; and that the nitrite fall of pressure saves life by inhibiting the vagus center. There is no definite evidence for this suggestion.

Migraine sometimes yields to nitrites, presumably in those cases attributed to spasm of the cerebral arteries. *Epilepsy* is also said to be sometimes benefited. Relief of *lead colic* (Riegel, 1878) has been claimed, but the efficiency is at best unreliable.

Internal Hemorrhage.—The lowered blood pressure would tend to arrest hemorrhage, but the bleeding would be favored by the direct dilator action. The resultant of these opposite tendencies is difficult to foresee, and probably varies with different conditions. Nitrites would therefore be unreliable remedies. Experimentally, Frey, 1909, found a slight increase of pulmonary hemorrhage; Lisin, 1907, claims diminution of intestinal hemorrhage.

Capillary hemorrhage from superficial wounds is increased by the systematic administration of nitrites, notwithstanding the fall of pressure (Hanzlik, 1918).

Toxic Effects.—Nitroglycerin has a toxicologic importance from its use as an explosive. Overdoses produce nausea, vomiting, colic, and sometimes bloody diarrhea. The skin is flushed and perspiring. There is vertigo and persistent throbbing headache; rarely blindness and delirium. The respiration is first hyperpneic, then dyspneic and slowed. The surface becomes cold and cyanotic; the pulse is gradually slowed, dicrotic and intermittent. Paralysis sets in, and is followed by clonic convulsions. The reflexes are lost. Death occurs by failure of respiration, after four to seven hours. The *fatal dose* varies greatly. D. D. Stewart, 1905, reports a patient in whom 20 gr. of absolute nitroglycerin produced only slight effects.

Nitrite poisoning may be caused by large doses of bismuth subnitrate (see Index).

Absorption.—Nitroglycerin is readily absorbed. Even the application of it to the skin causes some effect, and persons engaged in its manufacture suffer severely from headache during the first few days. After this, however, they appear to be quite unaffected, unless they leave work for several weeks and then resume the occupation. The work is said to be not unhealthful. The *local action* on the hands may result in skin eruptions and ulcerations.

Smokeless gunpowders, (nitroglycerin, nitrocellulose, etc.), when exploded, liberate gases which produce the combined effects of nitrites and asphyxia. The principal products are NO_2 (nitrogen peroxide) and CO (Kiefer, 1905). The vasodilation and tachycardia are followed by persistent headache ("powder-headache"), which does not yield to acetanilid, etc., but is best treated by strong coffee, and poultices applied to the back of the neck.

Sodium nitrite produces, in animals, symptoms similar to those of nitroglycerin (Dossin, 1911).

Amyl nitrite also has similar effects (Rosen, 1888).

PREPARATIONS

* *Amylis Nitris* (Amyl. Nitris), U.S.P.; *Amyl Nitris*, B.P.; Amyl Nitrite.—A liquid containing not less than 80 per cent. of $C_5H_{11}NO_2$ (chiefly iso-amyl nitrite). A clear, yellowish liquid; peculiar, ethereal fruity odor; pungent aromatic taste. Almost insol. in water, miscible with alc. or eth. Amyl Nitrite is very volatile even at a low temperature, and is inflammable. *Dose*, by inhalation, 0.2 c.c., 3 minims, U.S.P.; 0.12 to 0.3 c.c., 2 to 5 minims, B.P. It may be carried in thin glass capsules, "pearls," one of which is crushed in the handkerchief as needed.

Erythrol Tetranitrate, N.N.R.; (Tetranitrol), $C_4H_6(NO_3)_4$.—Colorless and tasteless crystals sol. in alc., insol. in water. Dangerously explosive. *Dose*, 0.03 to 0.06 Gm., $\frac{1}{2}$ to 1 gr., N.N.R., in tablets of 0.03 Gm.

* *Spiritus Aethylis Nitritus* (Sp. Aeth. Nitrit.), U.S.P.; *Liq. Ethyl. Nitrit.*, and *Spir. Aetheris Nitrosi*, B.P.; Spirit (Solution) of Ethyl Nitrite; Spirit of Nitrous Ether (Sweet Spirit of Niter). An alcoholic solution of ethyl nitrite, $C_2H_5NO_2$, containing about 4 per cent., U.S.P.; 2 per cent., B.P. (It also contains aldehyde, paraldehyde and ethyl nitrate; but these do not contribute materially to its action; Marshall and Gilchrist, 1915). A pale yellowish liquid; of ethereal odor and sharp taste. Deteriorates readily, unless stored in filled amber colored bottles. Partly filled bottles should be kept in the ice-box (Roberts, 1921). *Incompatible* with antipyrine, morphine and iodides. Brownish color with salicylates; slight effervescence with uva ursi, buchu, and acetates. The addition of water throws ethyl nitrite out of solution, which then evaporates rapidly, lowering the strength (E. R. Squibb, 1889). Dilution should therefore be made shortly before administration (Marshall and Gilchrist, 1915). *Dose*, 2 c.c., 30 minims, U.S.P.; 1 to 4 c.c., 15 to 60 minims, B.P.

* *Spiritus Glycerylis Nitratis* (Sp. Glyceryl. Nitrat.), U.S.P.; *Liq. Trinitrini*, B.P.; Spirit of Glyceryl Nitrate; Solution of Trinitrin (Spirit or Solution of Nitroglycerin or Glonoin).—An alcoholic solution of about 1 per cent. of $C_3H_5(NO_3)_3$. A clear colorless liquid, with odor and taste of alcohol. Miscible with water and alcohol. *Dose*, 0.06 c.c., 1 minim, U.S.P.; 0.03 to 0.12 c.c., $\frac{1}{2}$ to 2 minims, B.P.

Tabellæ Trinitrini (Tab. Trinitrin.), B.P.—0.5 mg., $\frac{1}{4}$ 30 gr. *Dose*, 1 or 2 tablets. The commercial tablets are fairly, although not quite uniformly, active. Nitroglycerin is not volatile and the tablets do not deteriorate rapidly (Edmunds and Roth, 1908; Rippetoe and Smith, 1914).

* *Sod. Nitris*, U.S.P., B.P.; Sodium Nitrite, $NaNO_2$.—Freely sol. in water (1:1.5). *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.03 to 0.12 Gm., $\frac{1}{2}$ to 2 gr., B.P. Maximum dose, 0.3 Gm. 5 gr.

THE DIGITALIS GROUP

Digitalis, *Strophanthus*, *Squill*, *Apocynum*, *Barium*, and a number of other drugs increase the tone, excitability and contractility and the refractory phase of the cardiac muscle, stimulate the vagus center and slow the conduction through the His bundle. With therapeutic doses, these actions result in slower but more powerful beats of the heart, which bring about compensation in valvular cardiac lesions and thus relieve the symptoms—the irregularities, edemas, congestions, dyspnea, etc. Under these conditions, there is often marked diuresis. The blood pressure is generally unchanged in man, usually increased in animals. The vagus center may also be stimulated, especially by toxic doses, partly directly, partly through the rise of blood-pressure. The tone of the arterial muscle is increased.

The effects set in slowly on oral administration; almost immediately on intravenous injection. They tend to be cumulative, and to outlast the administration for a considerable time.

Toxic doses produce vomiting, cardiac irregularity, and sudden heart failure. The recognition of these toxic effects is important since they often arise from the cumulative action.

The members of the group are local irritants. Their hypodermic injection is painful. Their absorption from the gastro-intestinal canal is slow and often uncertain.

The active principles are generally neutral glucosides, and therefore rather unstable, especially in acid, aqueous solutions. Digitalis contains several distinct glucosides with similar actions, of which the crystalline Digitoxin is the most definite. The various "strophanthins" are derived from several plants. They are chemically related, but differ in activity and toxicity according to their origin.

All the characteristic digitalis effects are produced by all the members of the group, so that a single description will suffice. The differences between them are only quantitative. So far as they are known, they will be pointed out as occasion arises.

Drugs Producing Digitalis Effects.—A considerable number of drugs containing glucosides with "digitalis" action are used in medical practice; such as Digitalis, Strophanthus, Squill, and Apocynum. Of less practical importance are Helleborus, Adonis, Convallaria, Oleander, Cheiranthus, etc. Digitaloid glucosides are important constituents of arrow-poisons; viz., strophanthin, ouabain, antiarin, acocantherin, etc. (Trendelenburg, 1909). The toxic principles found in the skin and blood of the common toad (Bufo and Bufo) produce typical digitalis effects. They appear to be non-nitrogenous derivatives of cholesterol (review, Faust, 1910). A very similar principle (Bufo) is contained in the "parotid" glands of the tropical toad, Bufo (Abel and Macht, 1911). Frogs' skin also has a similar but much weaker action (Fuehner, 1910).

Handovsky, 1920, describes an alkaloid "Bufo," from the skin of the common toad. It stimulates the vagus center, but paralyzes the respiration, brain and cord. Peripherally it produces direct stimulation of all smooth muscle.

Erythrophleine, a glucosidal alkaloid, can be counted in the group. Other alkaloids—veratrine, caffeine, urine, epinephrine—remind somewhat of digitalis, but are not typical. Barium salts, alkaline hydrates, and even normal saline solutions produce cardiac actions which resemble digitalis, but the resemblance may only be superficial.

Active Constituents of Digitalis.—These consist of glucosides, allied to saponin in composition and actions (foaming, heart, etc.), but more specialized in the location of their effects, and also more absorbable. It is doubtful whether any of these have been isolated in pure form, so that they are characterized mainly by their solubility, stability, and absorbability. These vary, however, with conditions, with the methods of extraction and with different specimens of the drug (E. Meyer, 1917), so that almost every investigator arrives at different results.

The active principles are classified on the basis of the contrast of their solubility in water and alcohol (Schmiedeberg and Kiliani) or in water and chloroform (Kraft), as shown in the following table. Kraft's classification is now the most commonly followed.

It should be remembered that the names do not refer to chemical individuals, but to groups of constituents with similar solubility characters in cold water and chloroform; and then only if the extraction is carried out in a definite manner.

The dried leaves contain about 1 per cent. of active principles, distributed more or less equally among the three groups of Kraft (Straub).

CLASSIFICATION OF KRAFT

	SOLUBILITY IN COLD WATER	SOLUBILITY IN CHLOROFORM
Digitoxin group.....	o	+
Digitalein group.....	+	o
Gitalin group.....	+	+
Digitonin (Saponin).....	+	sparingly

CLASSIFICATION OF SCHMIEDEBERG AND KILIANI

	SOLUBILITY IN COLD WATER	SOLUBILITY IN ALCOHOL
Digitoxin cryst.....	o	+
Digitalin Ver. Amorph.....	slightly	+
Digitalein.....	+	+
Digitonin (Saponin).....	+	sparsingly

Historical.—Schmiedeberg, 1875, first isolated active principles from digitalis seeds, which have, however, somewhat different constituents than the leaves. His results were generally confirmed and extended by Kiliani, 1890 to 1899; Kraft, 1912; and Kiliani, 1913 and 1914. The nomenclature introduced by the different investigators, and by the promoters of commercial varieties of these impure "principles" is hopelessly confusing; only a few of the more important are discussed here.

Cleavage-products.—Splitting off the sugar from the glucosides leaves the "genins" (digitoxigenin etc.), which are $\frac{1}{3}$ to $\frac{1}{2}$ as active as the glucosides (Straub, 1916).

Digitoxin Group. Schmiedeberg; Kiliani.—These crystalline, alcohol soluble principles are probably the most important constituents of the leaves, in activity and in quantity (0.22 to 0.4 per cent.); but do not occur in the seeds. They form crystals, but are never the less variable (Cloetta). They are readily soluble in alcohol or chloroform, difficultly soluble in water or ether. They produce all the characteristic digitalis effects, but some of the undesirable side actions are too prominent.

Cloetta found that the best commercial products are impure; and the medicinal may only contain $\frac{1}{2}$ of digitoxin.

In the presence of other substances, even of water, the solubility characters of Digitoxin are considerably modified, perhaps by converting it into colloidal forms. It is quite conceivable that some of the principles of the other groups may be physical modifications or compounds of digitoxin.

Digitoxin can be split into a hexose (digitoxose) and the crystalline digitoxigenin, Kil.

Digitophyllin, Kil., is a similar crystalline principle of the leaves. *Anhydrogitalin*, Kraft, is also a closely related constituent of digitalis infusions.

Gitalin Group.—These are amorphous principles, soluble in water, and more soluble in chloroform; *i.e.* they are the constituents that are extracted from the cold aqueous solutions by chloroform. Kiliani, 1914, found that the gitalin of Kraft is a mixture. Hatcher 1919, 1920 and Weiss and Hatcher, 1923, found that the ether-soluble portion of gitalin contains a fraction which gives the reactions of *digitoxin*, and which is so rapidly absorbed that the clinical effect occurs promptly on oral administration (Eggleston, 1920); but which is also excreted so rapidly (S. Weiss and Hatcher, 1923), that the effective dosage is relatively high.

Digitalein Group.—These are especially easily soluble in water, and relatively insoluble in chloroform. The digitalein of Schmiedeberg and of Kiliani are the type. Most of the commercial products intended for intravenous injection are mixtures of digitaleins and gitalins (E. Meyer); for instance, *Digalen*, *Digipan*, *Digipuratum*, *Digitalysatum*, *Verogen* (Straub; Krehl, 1919).

Digitonin Group (Digitalis Saponins).—They comprise the more typical water-soluble saponins; *Digitonin*, *Digitsaponin* or *Gitonin*. These do not have the typical digitalis effect on the heart, but probably modify the solubility of the other principles.

They occur in crystalline and amorphous form. The crystalline is less readily soluble in water. Both are only slightly soluble in alcohol and lipid solvents. The crystalline Digitonin Kil. was considered a definite substance, which can be split into a hexose and digitogenin; but Windaus and Schneckenberger, 1913, consider it a mixture, from which they have isolated *Gitonin*. The amorphous Digitonin Schm. (Digitsapo-

nin, Kraft) is probably a mixture of the crystalline with several amorphous saponins (Kraft). The digitonins are precipitated by tannin; they combine with many alcohols and phenols to crystalline compounds. Digitonin does not produce the digitalis effects but has the irritant and hemolytic properties of the saponin group. The digitsaponins of the leaves are not hemolytic (Kobert, 1912). Digitonin and its decomposition products are further discussed by Windaus and Weil, 1922.

Inactive Principles.—A number of these have been isolated, such as the crystalline glucoside *gitin* and *digin*, Kraft, 1912, from the leaves.

The name *Digitalin* has been applied to a number of quite dissimilar products. The resulting confusion is so dangerous, that the term is not employed by modern workers; it must never be used without designating the kind of digitalin that is meant.

The original *Digitalinum Verum* of Schmiedeberg and Kiliani consisted of those amorphous glucosides of the leaves and seeds that are soluble in alcohol, but little soluble in water, chloroform and ether. It splits into dextrose digitaligenin and digitalose Kil. It produces typical digitalis effects, being about half as active as digitoxin.

Commercial Digitalins.—These are impure, often variable, mixtures of digitalis principles. The following are the most important varieties:

Digitalin "Amorphous," generally means French or Belgian digitalin (digitalin chloroformique); uncertain composition; insoluble in water (perhaps mainly Digitalin, Schm.).

Digitalin "Crystallized," objectionable synonym for Digitonin; for Nativelle (French); and for Digitoxin.

Digitalin "Homolle," mixture of glucosides; mainly true Digitalin; practically insoluble in water.

Digitalin "Nativelle," crystalline, probably mainly Digitoxin or Digitophyllin.

Digitalin "German," amorphous mixture from seed; contains principally Digitonin (50 to 60 per cent.) and some Digitalin verum (5 to 6 per cent.), and Digitalein. Soluble in water or alcohol.

Galenic Digitalis Preparations.—The marked differences in the solubility of the pure principles is much less important in the galenic preparations. Even digitoxin is largely extracted from the leaves by water, presumably by the solvent action of the digitonin; so that the infusion represents practically the full activity of the leaf. The effects of infusion and tincture are therefore nearly equivalent. The infusion is practically inferior because of its more rapid deterioration.

Variations in the alcoholic strength of the menstruum between 35 and 95 per cent. make little difference. The fluidextract is unreliable, being sometimes only three times as active as the tincture, instead of ten times, as it should be theoretically (Hale, 1911). Glycerin extracts are inferior (Rippetoe, 1910). Acidified extracts are weak and unreliable (Pearson, 1913).

Powdered digitalis is often used, but is rather more irritant. All things considered, a good standardized Tincture is still the best and most reliable preparation.

Deterioration of Digitalis.—The principles are stable when dry or in alcoholic solutions; but like all glucosides, they are subject to decomposition in the presence of water especially by bacteria, moulds or acids. This results in loss of activity; there is little evidence for the statement that the toxicity is increased. J. Loewy, 1906, claimed that an infusion lost nearly 25 per cent. of its activity by standing twenty-four hours at room temperature; but Hatcher and Eggleston, 1915, found it practically unchanged a week or longer under ordinary conditions. The addition of alcohol is not necessary. *Acids are incompatible with the digitaloid glucosides*, although they have been employed in some of the preparations, *f.i.*, of Squills.

W. Straub, 1916, finds that the splitting of the sugar from the digitaloid glucosides lowers their toxicity (for frogs) relatively little; but this does not necessarily prove that they retain the cardiac actions unimpaired.

Tinctures and other preparations containing at least 50 per cent. of alcohol generally keep satisfactorily, their deterioration averaging perhaps 10 per cent. per year (Hamil-

ton, 1918). However, there are marked discrepancies. (Sharp and Lankaster, 1910; Hale, 1911; Symes, 1913; Pittenger and Mulford, 1918; Hamilton, 1918. Haskell, Daniel and Terry, 1923, found that a tincture kept five years under store-conditions, had not lost any activity. The storage temperature is a material factor (Newcomb, 1918; Joachimoglu, 1921).

The *dry leaves*, so long as they are not mouldy, keep indefinitely (Sharp and Lankaster; Hatcher and Eggleston, 1913), without the necessity of the elaborate precautions advocated by Fock, 1906. They are not injured by heat of 120°C. but suffer above 140° (Hale, 1911).

Chemistry of Strophanthins.—The strophanthins are glucosides, differing quantitatively in their actions (even the similarly named commercial specimens, Heffter, 1909). Confusion exists as to the identity and relations of the several kinds found on the market and isolated by different investigators. This is due partly to incomplete knowledge of the plants, partly to ignorance of the constitution of the substances; and largely also to careless nomenclature. They are sometimes denoted by prefixing the first letter of the species from which they are obtained, *f.i.*, *g*-strophanthin from *S. gratus*, etc.

The numerous species of *Strophanthus* (Apocynaceæ) and other plants were used by the natives of Africa for the manufacture of *arrow-poisons*. The *official varieties* are the seeds of *Strophanthus Kombé* (U.S.P., B.P.), and *S. hispidus* (U.S.P.). The strophanthin originally isolated by Fraser, 1870, was the amorphous Kombé variety (Gilg, 1904). The following outline is based mainly on the paper of Heffter and Sachs, 1912.

Strophanthin amorphous (*Strophanthin-Boehringer*) is the official strophanthin. It occurs in the Kombé and hispidus. The two are very similar, probably identical. Kombé further yields a crystalline strophanthin (Houghton, 1911; Brauns and Closson, 1913, 1914) which is very similar. The amorphous is slightly more toxic for rabbits than the crystalline Kombé. All three are hydrolyzed by acids with the production of the crystalline **Strophanthidin**, $C_{27}H_{38}O_7$. This is several times more toxic than strophanthin, and produces similar cardiac action, but with greater tendency to respiratory paralysis (Groeber, 1913).

Dresbach and Wadell, 1924, found that the most characteristic effect of strophanthidin consists in emesis, which is also produced by intravenous injection. It is also diuretic; and its peritoneal injection provoked defecation. It is not irritant when applied to the conjunctiva. The *crude drugs* Kombé and hispidus are about equally active.

Ouabain, *gratus Strophanthin-Thoms*; crystallized strophanthin-Merck, $C_{30}H_{46}O_{12} \cdot 9H_2O$.—This is the only "crystalline strophanthin" on the market. It is the best characterized of the principles. It does not yield strophanthidin. It was first isolated by Arnaud, 1888, from the wood of *Acocanthera Ouabaio*; and by the same investigator, 1898, from *S. glaber*. Later, 1910, Thoms obtained it from *S. gratus*, which was found to be identical with *glaber*. This is more readily obtained genuine than the other *Strophanthus* species. Strophanthin has been described as methyl-ouabain; and acocantherin as dimethyl-ouabain; but the evidence for these views is not convincing (Brauns and Closson). Ouabain is about twice as toxic as strophanthin; and this is twice as strong as acocantherin. *S. gratus* also contains a second amorphous strophanthin (Thoms). The "**pseudo-strophanthins**" of Feist were probably ouabain, but their identity is now obscure.

DIGITALIS ACTIONS ON THE CIRCULATION

Digitalis produces the following important reactions:

(1) Increased contractility of the cardiac muscle, *i.e.* lowered threshold of irritability, and more powerful and more prolonged contraction with corresponding lengthening of the refractory period. This entails corresponding changes in the conduction, which is a function of the contractility *i.e.* the conduction is stronger but slower, also with prolongation and intensification of its refractory phase. This lengthening of refractoriness is the more marked, the shorter the normal refractoriness of the structures.

It is therefore most marked in the His bundle, and tends to produce auriculo-ventricular block.

Pharmacology of the Isolated Purkinje Fibers.—The excised His-bundle, when placed in oxygenated Ringer's solution, makes rhythmic contractions like other cardiac muscle, and reacts similarly to pharmacologic agents: it is stimulated by strophanthin, barium, epinephrine, caffeine, calcium and camphor, depressed by quinine, chloroform, potassium and oxalate (Pick, 1923).

(2) The *tone of the heart-muscle* is increased so that the *systolic shortening* becomes greater and more prolonged. Under suitable conditions this culminates gradually in systolic arrest; namely in the ventricle of the cold-blooded heart and in the perfused mammalian heart. In living mammals systolic arrest would be impossible because the heart would be asphyxiated by impairment of the coronary circulation.

The *diastolic tone* would also tend to be increased, and the diastolic relaxation would be less complete. This plays a part in the systolic arrest. In the intact animal, however, the prolonged refractory condition may lead to a passive distention in diastole, due to the prolonged inflow of blood. This is seen most strikingly in the distended auricles of the digitalized heart of intact frogs.

(3) *Digitalis stimulates the vagus-center* (along with other medullary centers). This is perhaps due to a reflex from the direct cardiac action, since it would be difficult to conceive as merely accidental the universal co-existence, apparently in all the digitaloid drugs, of the peripheral muscular and central vagus action. Moreover, the vagus action generally appears only after the muscle effects have reached a certain height.

Vagus-stimulation diminishes the cardiac tone and excitability; it weakens the cardiac contractions and therefore shortens the refractory period; the conduction is correspondingly weakened, although it is quickened. All these effects are exactly the opposite of the muscular action of digitalis, and as has been suggested, they may represent an attempt at a central compensation against the peripheral action. Nevertheless both actions coincide in interfering with conduction and therefore in tending to produce block, although by opposite mechanisms; the direct muscular action by prolonging the refractory phase, the vagus action by raising the threshold of excitability. Both actions participate in the therapeutic effect on auricular fibrillation. The muscular action plays probably a rather larger share, for the greater part of the therapeutic effect persists if the vagus action is eliminated by atropine. As the dosage is increased, the vagus phenomena come to predominate, but with fatal doses, the muscular action again obtains the upper hand.

(4) Digitalis also acts directly on the *blood-vessels*; but these effects play a relatively unimportant part in its ordinary actions.

The details will be presented in the order of the increasing complexity of the phenomena, *i.e.* strips of cardiac muscle, perfused cold-blooded heart, excised mammalian heart, intact mammals, and therapeutic effects. In view of the complicated inter-actions, it need not cause surprise that results obtained on limited experimental material may sometimes appear contradictory.

Strips of Cardiac Tissue.—These should give the least complicated picture of the muscular effects of digitalis, but they have not been studied exhaustively. For *frog-preparations*, S. Loewe, 1918, observed increased systolic excursions and lengthened diastolic pause; Sasaki, 1921, found that helleborein lowered the threshold to stimulation, increased the contractility and rhythmicity and the refractory period (*i.e.*, the

resistance to tetanus by faradization). Increase of tone was shown by lengthened duration of the systolic peak and incomplete diastolic relaxation, the duration of the diastole not being increased. This terminated in systolic standstill.

Isolated Auricle of the Frog.—The toxic dose of digitalis is at least ten times as great as for the ventricle; the phenomena, however, are similar (W. Straub, 1915).

Ventricle Strips of Turtle.—Large doses produce acceleration (even after atropine or ergotoxine), and increase of amplitude and tone (Greene, Boutwell and Peeler, 1915).

Tonus Waves in Turtle Auricles.—These are augmented by vagus stimulation and inhibited by the sympathetic (Rosenzweig); accordingly, they are increased by digitalis (0.3 to 0.5 per cent.) and antagonized by epinephrine (Gruber, 1921).

Entire Frog Heart.—The phenomena are identical in the perfused heart, or with the natural circulation. They are always preceded by a latent period of five to ten minutes, even if strong solutions are applied directly. Small doses of all digitaloids (Benedicenti, 1902; including barium, Poulson, 1910) produce an *apparently depressant effect*, i.e. a gradual slowing and diminished tone (F. Williams, 1880, perfused heart), which may terminate in diastolic arrest (Jacobj, 1900; Wybauer, 1900), especially if the drug is applied to the exterior of the heart (Werschinin, 1910). It is rarely witnessed in intact animals, and is then followed by the usual systolic phase (Boehm, 1872). This depressant effect has been interpreted as vagus-stimulation; but it is not prevented by atropine (Boehm, 1872; Benedicenti, 1902), and is probably due to diminished conductivity and heart block (i.e. increased refractoriness) between sinus and auricle, preventing the transmission of the pace-making impulses (Straub; Clark, 1914). The heart still responds to mechanical stimulation. Submaximal vagus-stimulation increases the block (Haldschinski, 1908).

Therapeutic Stage.—If the digitalis is injected or perfused, instead of being applied to the surface of the heart, the sinus block does not proceed to arrest (Holste, 1912; Clark, 1912), and the other parts of the heart participate in the effects. The typical course was described by Boehm, 1872. The increase of contractility is shown by increased systolic excursions and these prolong the refractory state, so that the rate is slowed. This offers opportunity for greater filling and therefore for greater diastolic distention. F. Williams, 1880, showed in the perfused heart that the output per beat is thus increased. The time output and the blood pressure may alter in either direction, according to the degree of slowing. The earlier effects are mainly on the auricles and the auriculoventricular interval is unchanged (Clark and Mines, 1913). If the heart was weak, the stimulation may also be perceptible on the ventricle (Clark, 1914). Hearts exhausted by perfusion with a saline solution may be revived.

The *toxic irregularities* start soon after. The systolic phase of the ventricle becomes exaggerated, so that at times the apex, at times the base, remains firmly contracted during the diastole. These partial diastoles may alternate so that the blood is merely pumped back and forth from one part of the ventricle to the other. This has been called, rather inappropriately, "*cardiac peristalsis*." Again, a part of the ventricle may remain firmly contracted for a considerable time, and then may resume rhythmic contraction. (The "*peristalsis*" was first described by Vulpian, 1855.)

Eventually, the ventricular diastoles become weaker and weaker, until the ventricle finally goes into permanent *systolic standstill*, and appears as a small white lump, contrasting sharply with the turgid auricles. The apex is often arrested before the base. The auricles continue to pulsate for a time and eventually stop distended.

The ventricular systolic standstill is not paralytic; for if the ventricle is forcibly distended with fluid, it will again start effective beats (Schmiedeberg, 1874). The standstill is due to *excessive tone*, which prevents diastolic relaxation under the ordinary venous pressure. It is not an ordinary but prolonged contraction, for the heart-muscle is not in the refractory phase (Tait and Pringle, 1916). Schmiedeberg considered it as increased "*elasticity*," but it is probably an instance of "*plastic tone*."

Other hearts may not show the "*peristalsis*," but instead the phenomena of *partial auriculo-ventricular "block,"* i.e., the ventricular rate suddenly falls to one-half, then one-third, one-fourth, etc., of the auricular rate (Straub, 1901). The auriculo-ventricular interval is also lengthened (Clark and Mines, 1913). Eventually the auricular rate, and finally the sinus rate, may also be halved. The block is explainable by *prolongation of the refractory period*, for Brandenburg, 1904, showed that the heart is now less easily excitable to extrasystoles. On the other hand, the *spontaneous contractility* is increased, for if the sinus-auricular junction is crushed (I-Stannius experiment) the ventricles are not arrested as in the normal frog, but at once initiate a spontaneous rhythm.

De Noer, 1917, has made detailed studies of the effects on existing irregularities, etc. The oxygen consumption of the excised frog-heart is decreased according to the diminished rate and excursions (Gottschalk, 1913).

Fixation of Digitaloids in Heart.—W. Straub, 1910 to 1913, investigated the quantitative relations of digitalis on excised frogs' hearts, using the response of "test hearts" as a quantitative method. He found the effects roughly proportional to the concentration of the poison, not to the absolute amount used. From this he argued that the reaction must be confined to the surface (envelope) of the muscle cells; the mechanism being similar to that of saponin action. Further investigation, however, showed that the quantity is also important (Clark, 1912; Gruenwald, 1912; Issekutz, 1915), and that the concentration is probably important mainly in determining the rapidity of penetration.

The effects of digitalis outlast its actual application. With small doses, the heart recovers completely on washing; but when immersed anew in digitalis solution, even after a long time, its threshold is found lowered (Gottlieb, 1914; Issekutz, 1915). These facts indicate that *digitalis is absorbed and stored in the heart muscle*, remaining there in active form for a considerable time. The amount of drug used up, however, is very small (Straub; Gruenwald; Clark; Holste, 1912); somewhat greater with digitalin than with strophanthin (Weizsaecker, 1913). Fuchner, 1912, finds that methyl-violet, which has a typical digitalis effect, actually accumulates in the *cardiac muscle of frogs*, the effects corresponding to the quantity of dye so fixed.

There is reason to believe that an actual storage of digitaloids occurs in the heart cells of mammals (Hatcher, 1912), although the evidence is not conclusive. Lhota, 1912, states that the storage occurs particularly in the heart and blood vessels, but also in the liver and other organs.

Concentration Coefficient.—Sollmann, Mendenhall and Stingel, 1915, determined the ratio of concentration and activity. They found that the feebler the actions of ouabain, the more is its activity increased by doubling the concentration. The reasons for this are explained in their paper.

Vigor of the Heart.—Holste, 1912, and Weizsaecker, 1913, find that this influences the response quantitatively. The greater the intensity of the cardiac functions, the prompter the strophanthin effect.

Temperature.—The cardiac effects of the digitaloids on frogs increase with the temperature (Trendelenburg, 1909), the increase being greater for low than for high temperatures. The activity is increased by heat not only directly, but also through the more rapid heart rate (Sollmann, Mendenhall and Stingel, 1915). In the perfused mammalian heart, the effects are also quickened by heat; in this case the more rapid coronary flow is a contributing factor (Gunn, 1914).

Hyperpyrexia (by hot baths) also increases considerably the toxicity of digitalis for intact mammals; the effects, including the reversal of the T wave, being qualitatively as in normal mammals (Hirschfelder *et al.*, 1920).

Influence of Serum.—Werschinn found the systolic action much weaker in Ringer's solution than in serum-solutions of the drugs. Oppenheimer, 1913, observed that serum inhibits the action of the less soluble digitaloids, but not of strophanthin. Cholesterin and egg-albumen did not have equivalent effects.

Oxygen increases the digitalis effect (Gruenwald, 1912).
